The caOS Operating System Manual

Angelo Coppi

October 27, 2026

Contents

1 Introduction: Bare Metal and RTOS **79**
1.1 Chapter 1 - Introduction: Bare Metal and RTOS 79
1.1.1 1.1 What are embedded systems? 79
1.1.2 1.2 “Bare Metal” Programming 79
1.1.3 1.3 What is an RTOS? 80
1.1.4 1.4 When to use Bare Metal or RTOS? 81
1.1.5 1.5 RTOS on ARM Cortex-M microcontrollers 82
1.1.6 1.6 Available RTOS 83

2 The Kernel: Tasks, Scheduler and Stack Management **85**
2.1 Chapter 2 - The Kernel: Tasks, Scheduling, and Memory Management 85
2.1.1 2.1 The Task 85
2.1.2 2.2 The Scheduler 87
2.1.3 2.3 The Context Switch 88
2.1.4 2.4 Working Memory Management (Stack) 89
2.1.5 2.5 The System Timer 90
2.1.6 2.6 System startup 90

3 Resources: Synchronization and Mutexes **93**
3.1 Chapter 3 - Resources: Sharing and Synchronization 93
3.1.1 3.1 The concurrency problem 93
3.1.2 3.2 Safe (Atomic) Operations 95
3.1.3 3.3 Mutex 95
3.1.4 3.4 Semaphore 97
3.1.5 3.5 Condition Variable 97
3.1.6 3.6 Spinlock 98
3.1.7 3.7 Message Queue 98
3.1.8 3.8 Event Groups 99
3.1.9 3.9 Task Notification 99
3.1.10 3.10 Deadlock 99

4 Memory: Partitioning and Protection **101**

5 Embedded I/O: Drivers, Sensors, Timers **103**
5.1 Chapter 5 - Embedded I/O: Drivers, Sensors, and Timers 103
5.1.1 5.1 GPIO (General Purpose Inputs/Outputs) 103
5.1.2 5.2 Driver model: Weak Functions 104
5.1.3 5.3 UART (Universal Asynchronous Receiver/Transmitter) 105
5.1.4 5.4 Communication buses: SPI and I2C 106
5.1.5 5.5 Hardware Timers 106
5.1.6 5.6 Time measurement and performance analysis 107
5.1.7 5.7 Interrupts and I/O: the RTOS challenge 107

6 Reliability: Watchdog, Errors, OTA **109**
6.1 Chapter 6 - Reliability: Watchdog, Error Handling and Updates . . . 109
6.1.1 6.1 Types of errors in embedded systems . . . 109
6.1.2 6.2 Cortex-M errors . . . 109
6.1.3 6.3 Fault handler in an RTOS . . . 110
6.1.4 6.4 Watchdog Timer . . . 111
6.1.5 6.5 Checks and Safety . . . 112
6.1.6 6.6 Protection against corruption . . . 112
6.1.7 6.7 Reset and Recovery . . . 113
6.1.8 6.8 Firmware Update (OTA) . . . 114

I caOS Implementation **117**

7 caOS Overview **119**
7.1 Chapter 7 - Overview of caOS . . . 119
7.1.1 7.1 What is caOS? . . . 119
7.1.2 7.2 Project Structure . . . 120
7.1.3 7.3 Supported Microcontrollers . . . 121
7.1.4 7.4 caOS Modules . . . 122
7.1.5 7.5 Configuration . . . 124
7.1.6 7.6 Build System . . . 124
7.1.7 7.7 Entry point: ca_os_main() . . . 125
7.1.8 7.8 Configurable Tick . . . 125

8 caOS Features **127**
8.1 caOS Features . . . 127
8.1.1 1. Scheduler and Kernel . . . 127
8.1.2 2. Hardware Drivers . . . 129
8.1.3 3. Network Stack . . . 131
8.1.4 4. Cryptography . . . 133

9 caOS Kernel: Scheduler and Tasks **135**
9.1 Chapter 8 - The caOS Kernel: Scheduling and Task Management . . . 135
9.1.1 8.1 The Task in caOS . . . 135
9.1.2 8.2 Task Creation . . . 137
9.1.3 8.3 Stack Allocation . . . 140
9.1.4 8.4 Scheduling Algorithm . . . 141
9.1.5 8.5 Context Switching . . . 145
9.1.6 8.6 Idle task and maintenance . . . 149
9.1.7 8.7 Stack protection . . . 150
9.1.8 8.8 Suspension, Blocking and Wake-up . . . 150
9.1.9 8.9 System Startup . . . 153

10 Synchronization in caOS **157**
10.1 Chapter 9 - Synchronization in caOS . . . 157
10.1.1 9.1 Synchronization Architecture . . . 157
10.1.2 9.2 Mutex . . . 157
10.1.3 9.3 Recursive Mutex . . . 159
10.1.4 9.4 Semaphore . . . 159
10.1.5 9.5 Condition variable . . . 161
10.1.6 9.6 Critical Sections . . . 161

10.1.7 9.7 Code . . . 162
10.1.8 9.8 Event Groups . . . 163
10.1.9 9.9 Task Notification . . . 164
10.1.10 9.10 Stream Buffer . . . 165
10.1.11 9.11 Message Buffer . . . 165
10.1.12 9.12 Read-Write Lock (`ca_rwlock_t`) . . . 166
10.1.13 9.13 Barrier (`ca_barrier_t`) . . . 167
10.1.14 9.14 Block Pool (`ca_block_pool_t`) . . . 168

11 Memory Management in caOS **171**
11.1 Chapter 10 - Memory Management in caOS . . . 171
11.1.1 10.1 Memory Layout . . . 171
11.1.2 10.2 Heap Allocator . . . 173
11.1.3 10.3 MPU Protection . . . 174
11.1.4 10.4 MemAux: newlib replacement . . . 177
11.1.5 10.5 Summary: who allocates what and where . . . 177

12 Drivers and I/O in caOS **179**
12.1 Chapter 11 - Drivers and I/O in caOS . . . 179
12.1.1 11.1 The Extern pattern . . . 179
12.1.2 11.2 GPIO Driver . . . 181
12.1.3 11.3 Debug UART . . . 181
12.1.4 11.4 Stdout and repeater . . . 183
12.1.5 11.5 CLI (Command Line Interface) . . . 184
12.1.6 11.6 Hardware timers . . . 189
12.1.7 11.7 Software Timer . . . 191
12.1.8 11.8 Profiling with Measure . . . 192
12.1.9 11.9 ITM (Instrumentation Trace Macrocell) . . . 192
12.1.10 11.10 Hardware Watchdog (wdt) . . . 193
12.1.11 11.11 Backup registers (bkp) . . . 194
12.1.12 11.12 CORDIC Coprocessor (cordic) . . . 195
12.1.13 11.13 FMAC filter accelerator (fmac) . . . 196
12.1.14 11.14 Operational amplifiers (opamp) . . . 197

13 SafeGuard and Fault Recovery in caOS **199**
13.1 Chapter 12 - SafeGuard and Fault Recovery in caOS . . . 199
13.1.1 12.1 SafeGuard: control with recovery . . . 199
13.1.2 12.2 CPU Fault Handling: dedicated handlers and per-task recovery . . . 203
13.1.3 12.3 Stack overflow and corruption detection: defense levels . . . 204
13.1.4 12.4 Kernel protections: overall framework . . . 206
13.1.5 12.5 CRC32 . . . 208
13.1.6 12.6 Keys Store . . . 209
13.1.7 12.7 Diagnostica: dump e statistiche . . . 210

14 Thread Pool in caOS **213**
14.1 Thread Pool in caOS . . . 213
14.1.1 Motivation . . . 213
14.1.2 Pool Architecture . . . 213
14.1.3 Synchronization mechanism . . . 214
14.1.4 Public API . . . 214
14.1.5 Configuration in `os_config.h` . . . 215
14.1.6 Memory Usage . . . 216

14.1.7 Use Cases . . . 216
14.1.8 Limitations . . . 216
14.1.9 Internal Implementation . . . 216

15 Cryptography in caOS **219**
15.1 Chapter 13 - Cryptography in caOS . . . 219
15.1.1 13.1 Hardware driver overview . . . 220
15.1.2 13.2 CRC32 . . . 220
15.1.3 13.3 HASH (SHA-256) . . . 220
15.1.4 13.4 AES . . . 223
15.1.5 13.5 RNG . . . 225
15.1.6 13.6 Initialization in `ca_os_configure()` . . . 226
15.1.7 13.7 Pattern: Key Derivation . . . 226
15.1.8 13.8 Crypto Infrastructure (`caos/crypto/`) . . . 227
15.1.9 13.9 Keys Store (`keys_store.h`) . . . 228
15.1.10 13.10 AES Channel Service (`aes_channel_service.h`) . . . 230
15.1.11 13.11 Crypto levels: architecture summary . . . 236
15.1.12 13.12 Availability by MCU family . . . 236
15.1.13 13.13 Keystore Service (`keystore_service.h`) . . . 236
15.1.14 13.14 ECDSA P-256 (`ecdsa_p256.h`) . . . 241
15.1.15 13.15 Crypto module status summary . . . 242

16 caOS Network Stack: Low Level **245**
16.1 Chapter 14 - caOS Network Stack: Low Level . . . 245
16.1.1 14.0 Zero-copy Architecture . . . 245
16.1.2 14.1 MPU Configuration — NCacheable Regions . . . 246
16.1.3 14.2 Network stack modules . . . 247
16.1.4 14.2.1 Interface abstraction — `ca_net_iface_t` . . . 248
16.1.5 14.3 Initialization Sequence . . . 250
16.1.6 14.4 Configuration — `ca_net_cfg_t` . . . 251
16.1.7 14.5 Link control . . . 251
16.1.8 14.6 Source files . . . 251

17 caOS Network Stack: net_proto **253**
17.1 Chapter 14 - caOS Network Stack: net_proto (pure decoder/builder) . . . 253
17.1.1 14.7 Overview . . . 253
17.1.2 14.8 Decoding pipeline . . . 253
17.1.3 14.9 L2 — Ethernet and VLAN 802.1Q . . . 254
17.1.4 14.10 Proto — ARP . . . 255
17.1.5 14.11 Proto — IPv4 . . . 256
17.1.6 14.12 Proto — UDP . . . 256
17.1.7 14.13 Proto — ICMP . . . 257
17.1.8 14.14 Proto — TCP (wire-format and builder) . . . 257
17.1.9 14.15 Proto — DHCP (pure functions) . . . 258
17.1.10 14.16 Proto — NTP, Syslog, DNS, mDNS (Pure Functions) . . . 259
17.1.11 14.17 Route lookup — `ca_net_resolve_mac` . . . 260

18 caOS Network Stack: Network Services **261**
18.1 ARP Service (`EN_ARP_SERVICE`) . . . 261
18.1.1 Architecture . . . 261
18.1.2 API . . . 261
18.1.3 Parameters `os_config.h` . . . 262

18.1.4 Typical pattern . . . 262
18.2 Route Service (EN_ROUTE_SERVICE) . . . 262
18.2.1 Configuration . . . 263
18.2.2 Public API . . . 263
18.2.3 Integration with DHCP . . . 263
18.2.4 Static configuration (without DHCP) . . . 263
18.2.5 CLI . . . 263
18.3 DHCP Service (EN_DHCP_SERVICE) . . . 264
18.3.1 Configurable parameters . . . 264
18.3.2 State machine . . . 264
18.3.3 Public API . . . 264
18.3.4 Callbacks . . . 265
18.3.5 Adapter dhcp_udp_handler . . . 265
18.3.6 Critical Warnings . . . 265
18.4 NTP Service (EN_NTP_SERVICE) . . . 265
18.4.1 API . . . 265
18.4.2 Parameters os_config.h . . . 266
18.4.3 Typical pattern . . . 266
18.5 Syslog Service (EN_SYSLOG_SERVICE) . . . 266
18.5.1 API . . . 266
18.5.2 Parameters os_config.h . . . 266
18.5.3 Typical pattern . . . 267
18.6 DNS Service (EN_DNS_SERVICE) . . . 267
18.6.1 API . . . 267
18.6.2 os_config.h Parameters . . . 267
18.6.3 Typical Pattern . . . 267
18.7 mDNS Service (EN_MDNS_SERVICE) . . . 267
18.7.1 API . . . 267
18.7.2 Embedded network scenario without router . . . 268
18.8 TCP Service (EN_TCP_SERVICE) . . . 268
18.8.1 Configuration . . . 268
18.8.2 State machine . . . 268
18.8.3 Public API — client . . . 269
18.8.4 Configuration structure — client . . . 269
18.8.5 Public API — server . . . 269
18.8.6 Configuration structure — server . . . 269
18.8.7 CLI . . . 270
18.8.8 Warnings . . . 270
18.9 UDP Server (EN_UDP_SERVER) . . . 270
18.9.1 API . . . 270
18.9.2 Configuration Structure . . . 270
18.10 UDP Client (EN_UDP_CLIENT) . . . 271
18.10.1 API . . . 271
18.11 IP Defrag Service (EN_IP_DEFRAG) . . . 271
18.11.1 Configuration parameters . . . 271
18.11.2 Operational flow . . . 272
18.11.3 Initialization . . . 272
18.11.4 Public API . . . 272
18.12 TFTP Service (EN_TFTP_SERVICE) . . . 272
18.12.1 Configuration parameters . . . 272
18.12.2 Public API . . . 273

18.12.3 `on_block` Callbacks . . . 273
18.12.4 Server side: `ca_tftp_receive` . . . 273
18.12.5 CLI . . . 273
18.13 Packet Tracer Service (`EN_PACKET_TRACER`) . . . 274
18.13.1 Architecture . . . 274
18.13.2 Configuration . . . 274
18.13.3 API . . . 274
18.13.4 CLI . . . 274
18.13.5 Output format . . . 274
18.14 HTTP Service . . . 275
18.14.1 Configuration `os_config.h` . . . 275
18.14.2 Architecture . . . 275
18.14.3 Data structures . . . 276
18.14.4 Public API . . . 277
18.14.5 DHCP Integration . . . 277
18.14.6 Usage patterns . . . 278
18.14.7 CLI Capture Integration . . . 278
18.14.8 Implementation details . . . 278
18.14.9 CLI: `http` command . . . 279
18.14.10 Warnings . . . 279
18.15 MQTT Service . . . 280
18.15.1 Features . . . 280
18.15.2 Configuration `os_config.h` . . . 280
18.15.3 Architecture . . . 280
18.15.4 Public API . . . 281
18.15.5 Initialization . . . 281
18.15.6 Pattern — periodic publish + reconnect . . . 282
18.15.7 CLI: command `mqtt` . . . 283
18.15.8 Warnings . . . 283
18.16 Modbus/TCP Service . . . 283
18.16.1 `os_config.h` Configuration . . . 283
18.16.2 Architecture . . . 283
18.16.3 Initialization . . . 284
18.16.4 Public API . . . 284
18.16.5 Usage patterns . . . 285
18.16.6 CLI: command `modbus` . . . 285
18.16.7 Warnings . . . 286
18.17 iperf Service . . . 286
18.17.1 `os_config.h` Configuration . . . 286
18.17.2 Architettura . . . 286
18.17.3 Initialization . . . 287
18.17.4 Public API . . . 287
18.17.5 CLI: command `iperf` . . . 288
18.17.6 Typical Performance (NUCLEO-H753ZI, 100BASE-TX) . . . 288

19 caOS USB Driver: DWC2 Core **289**
19.1 Low-level USB Driver . . . 289
19.1.1 Overview . . . 289
19.1.2 The Two USB IPs . . . 290
19.1.3 Two transfer modes (DWC2) . . . 290
19.1.4 Per-EP Code (DWC2) . . . 291
19.1.5 Public API . . . 291

19.1.6 Source layout . . . 293
19.1.7 Notes per family . . . 293

20 caOS USB Stack: Management and Classes 295
20.1 USB device stack: management and classes . . . 295
20.1.1 Overview . . . 295
20.1.2 Two-level model (D1) . . . 295
20.1.3 API management (D18 — 5 functions) . . . 295
20.1.4 Class framework — `ca_usb_class_ops_t` . . . 296
20.1.5 Class services . . . 296
20.1.6 Endpoint allocation . . . 297
20.1.7 Composite PID (D14) . . . 298
20.1.8 Device identity (os_config.h) . . . 298
20.1.9 Composite devices . . . 299
20.1.10 Source file . . . 299
20.1.11 Reference Examples . . . 300

21 FatFS on caOS: SDIO Driver 301
21.1 FatFS on caOS: SDIO driver . . . 301
21.1.1 Overview . . . 301
21.1.2 Layer 1 — FatFS and the ffconf.h redirect . . . 301
21.1.3 Layer 2 — glue diskio (`fatfs_diskio.c`) . . . 302
21.1.4 Layer 3 — `ca_sdio` driver . . . 303
21.1.5 Status by family . . . 305
21.1.6 File structure . . . 306

22 Centralized Power Manager 307
22.1 Centralized power manager . . . 307
22.1.1 Overview . . . 307
22.1.2 `pwr info` — power state snapshot . . . 307
22.1.3 Frequency scaling . . . 308
22.1.4 Low-power modes . . . 309
22.1.5 Wake-up sources . . . 310
22.1.6 Status by family . . . 311
22.1.7 Implementation notes . . . 312
22.1.8 Configuration . . . 312
22.1.9 File structure . . . 313

23 Migrating from FreeRTOS, Zephyr and ThreadX to caOS 315
23.1 Migrating from FreeRTOS, Zephyr and ThreadX to caOS . . . 315
23.1.1 Overview . . . 315
23.1.2 1. Application structure . . . 315
23.1.3 2. Tasks . . . 316
23.1.4 3. Time . . . 318
23.1.5 4. Critical sections and scheduler lock . . . 319
23.1.6 5. Synchronization and communication . . . 320
23.1.7 6. Heap . . . 322
23.1.8 7. Semantic differences . . . 323
23.1.9 8. Summary table . . . 323
23.1.10 9. Porting checklist . . . 324
23.1.11 10. From Zephyr to caOS . . . 324
23.1.12 11. From ThreadX to caOS . . . 327

II Practical Examples **331**

24 Hello World: the First Program on caOS **333**
24.1 Example 1 — Hello World: the first program on caOS . . . 333
24.1.1 Introduction . . . 333
24.1.2 The source code . . . 333
24.1.3 Line-by-line analysis . . . 334
24.1.4 What this example teaches us . . . 335
24.1.5 Example output . . . 335

25 Scheduling and Memory Allocation **337**
25.1 Example 2 — Scheduling and memory allocation . . . 337
25.1.1 Introduction . . . 337
25.1.2 What is scheduling? . . . 337
25.1.3 What is dynamic memory allocation? . . . 337
25.1.4 The source code . . . 338
25.1.5 Detailed analysis . . . 338
25.1.6 What this example teaches us . . . 340
25.1.7 Example output . . . 340

26 Mutex and Shared Resource Access **341**
26.1 Example 3 — LED and GPIO CLI . . . 341
26.1.1 Introduction . . . 341
26.1.2 Architecture . . . 342
26.1.3 Source code . . . 342
26.1.4 Detailed analysis . . . 343
26.1.5 Expected output . . . 344
26.1.6 Required configuration in `os_config.h` . . . 344
26.1.7 Summary . . . 344

27 Queues: Inter-Task Communication **345**
27.1 Example 4 — Code Queue: task-to-task communication via queues . . . 345
27.1.1 Introduction . . . 345
27.1.2 What is a queue? . . . 345
27.1.3 The source code . . . 346
27.1.4 Architecture . . . 347
27.1.5 Detailed analysis . . . 348
27.1.6 Typical execution scenario . . . 350
27.1.7 What this example teaches us . . . 351
27.1.8 Example output . . . 351

28 Recursive Mutex: Handling Recursion in Multitasking **353**
28.1 Example 5 — Recursive mutex: managing recursion in multitasking . . . 353
28.1.1 Introduction . . . 353
28.1.2 What is a recursive mutex? . . . 353
28.1.3 The source code . . . 353
28.1.4 Architecture . . . 356
28.1.5 Detailed analysis . . . 356
28.1.6 When to use recursive mutexes . . . 358
28.1.7 Beware of potential issues . . . 358
28.1.8 Important considerations for the embedded world . . . 358
28.1.9 What this example teaches us . . . 359

28.1.10 Example output . . . 359
28.1.11 Verification of waits with timeout (`twait`) . . . 359

29 Semaphore: Controlling Access to Shared Resources 361
29.1 Example 6 — Semaphore: controlling access to shared resources . . . 361
29.1.1 Introduction . . . 361
29.1.2 What is a semaphore? . . . 361
29.1.3 The source code . . . 361
29.1.4 Architecture . . . 366
29.1.5 Detailed analysis . . . 367
29.1.6 When to use semaphores . . . 369
29.1.7 What this example teaches us . . . 369
29.1.8 Example output . . . 369
29.1.9 Verification of waits with timeout (`twait`) . . . 370

30 Condition Variable: Producer-Consumer Coordination 371
30.1 Example 7 — Condition Variable: producer-consumer coordination . . . 371
30.1.1 Introduction . . . 371
30.1.2 What is a condition variable? . . . 371
30.1.3 The source code . . . 372
30.1.4 Architecture . . . 374
30.1.5 Detailed analysis . . . 374
30.1.6 API . . . 377
30.1.7 What this example teaches us . . . 377
30.1.8 Example output . . . 378
30.1.9 Verification of waits with timeout (`twait`) . . . 378

31 Critical Sections: Protecting Data by Disabling Interrupts 381
31.1 Example 8 — Critical sections: data protection with interrupt disabling . . . 381
31.1.1 Introduction . . . 381
31.1.2 What is a critical section? . . . 381
31.1.3 The source code . . . 382
31.1.4 Architecture . . . 383
31.1.5 Detailed analysis . . . 384
31.1.6 API . . . 385
31.1.7 Critical sections vs other primitives . . . 386
31.1.8 Warning: fundamental rules . . . 386
31.1.9 What this example teaches us . . . 386
31.1.10 Example output . . . 386

32 Task Notification: Lightweight Inter-Task Signaling 389
32.1 Example 9 — Task Notification: lightweight signaling between tasks . . . 389
32.1.1 Introduction . . . 389
32.1.2 What is a task notification? . . . 389
32.1.3 The source code . . . 389
32.1.4 Architecture . . . 391
32.1.5 Detailed analysis . . . 392
32.1.6 API . . . 394
32.1.7 Notifications vs other primitives . . . 394
32.1.8 When not to use notifications . . . 394
32.1.9 What this example teaches us . . . 394
32.1.10 Verification of waits with timeout (`twait`) . . . 395

33 Watchdog **397**
33.1 Example 10 — Watchdog Timer (WDT) . . . 397
33.1.1 Introduction . . . 397
33.1.2 What is the Watchdog Timer? . . . 397
33.1.3 Driver API (`wdt.h`) . . . 398
33.1.4 The source code . . . 398
33.1.5 Architecture . . . 399
33.1.6 CLI Commands . . . 399
33.1.7 Expected Output . . . 400
33.1.8 The bench test . . . 401
33.1.9 Differences between Families . . . 401
33.1.10 Best Practices . . . 402
33.1.11 Summary . . . 402

34 CPU Temperature **403**
34.1 Example 11 — Core Temperature Monitor with Watchdog Protection . . . 403
34.1.1 Introduction . . . 403
34.1.2 Thermal Protection Architecture . . . 403
34.1.3 Source Code . . . 404
34.1.4 CLI Commands . . . 406
34.1.5 The digital DTS sensor (H563) . . . 406
34.1.6 Detailed analysis . . . 407
34.1.7 Expected Output . . . 408
34.1.8 Test Variants . . . 409
34.1.9 Threshold Considerations . . . 410
34.1.10 Thermal System Debugging . . . 410
34.1.11 Best Practices . . . 410
34.1.12 Summary . . . 411

35 Extending the System Command Line **413**
35.1 Example 12 — Extending the CLI with user commands . . . 413
35.1.1 Introduction . . . 413
35.1.2 The system CLI . . . 413
35.1.3 Source code . . . 414
35.1.4 Detailed analysis . . . 416
35.1.5 Adding more commands . . . 418
35.1.6 Expected output . . . 418
35.1.7 Required configuration in `os_config.h` . . . 419
35.1.8 Summary . . . 419

36 Execution Time Profiling with DWT CYCCNT **421**
36.1 Example 13 — Profiling and task watchdog . . . 421
36.1.1 Introduction . . . 421
36.1.2 The `measure` module . . . 421
36.1.3 Task watchdog . . . 422
36.1.4 Source code . . . 423
36.1.5 Detailed analysis . . . 424
36.1.6 Expected output . . . 425
36.1.7 Required configuration in `os_config.h` . . . 425
36.1.8 Summary . . . 425

37 Streams **427**
37.1 Example 14 — Stream Buffer with interactive CLI . . . 427
37.1.1 Introduction . . . 427
37.1.2 Example architecture . . . 428
37.1.3 Source code . . . 428
37.1.4 Detailed analysis . . . 432
37.1.5 Expected output . . . 433
37.1.6 Stream vs Message Buffer . . . 434
37.1.7 Required configuration in `os_config.h` . . . 434
37.1.8 Summary . . . 435
37.1.9 Verification of waits with timeout (`twait`) . . . 435

38 Messages **437**
38.1 Example 15 — Message Buffer with heap allocation . . . 437
38.1.1 Introduction . . . 437
38.1.2 Example architecture . . . 438
38.1.3 Source code . . . 438
38.1.4 Detailed analysis . . . 442
38.1.5 Expected output . . . 444
38.1.6 Stream vs Message Buffer . . . 445
38.1.7 Required configuration in `os_config.h` . . . 446
38.1.8 Heap memory management . . . 446
38.1.9 Summary . . . 446
38.1.10 Verification of waits with timeout (`twait`) . . . 447

39 Thread Pool with RNG and SHA-256 **449**
39.1 Example 16 — Thread Pool with RNG and SHA-256 . . . 449
39.1.1 Introduction . . . 449
39.1.2 Example Architecture . . . 452
39.1.3 Source Code . . . 453
39.1.4 Detailed analysis . . . 455
39.1.5 Expected output . . . 457
39.1.6 Required configuration in `os_config.h` . . . 458
39.1.7 Created threads . . . 458
39.1.8 Summary . . . 459

40 Event Group: Synchronization on Bit Patterns **461**
40.1 Example 17 — Event Group: bit pattern synchronization . . . 461
40.1.1 Introduction . . . 461
40.1.2 Example architecture . . . 462
40.1.3 Source code . . . 462
40.1.4 Detailed analysis . . . 464
40.1.5 Expected output . . . 465
40.1.6 Required configuration in `os_config.h` . . . 466
40.1.7 Created threads . . . 466
40.1.8 Summary . . . 466
40.1.9 Verification of waits with timeout (`twait`) . . . 467

41 SW Timer: One-Shot and Periodic **469**
41.1 Example 18 — SW Timer: one-shot and periodic . . . 469
41.1.1 Introduction . . . 469
41.1.2 Example architecture . . . 470
41.1.3 Source code . . . 470
41.1.4 Detailed analysis . . . 472
41.1.5 Expected output . . . 473
41.1.6 Created tasks . . . 475
41.1.7 Configuration required in `os_config.h` . . . 475
41.1.8 Summary . . . 475

42 RW Lock and Barrier **477**
42.1 Example 19 — RW Lock and Barrier . . . 477
42.1.1 Introduction . . . 477
42.1.2 Example Architecture . . . 478
42.1.3 Source Code . . . 478
42.1.4 Detailed analysis . . . 480
42.1.5 Expected output . . . 482
42.1.6 Created threads . . . 482
42.1.7 Summary . . . 483

43 Block Pool, sleep_until and Timed Primitives **485**
43.1 Example 20 — Block Pool, sleep_until and Timed Primitives . . . 485
43.1.1 Introduction . . . 485
43.1.2 Example Architecture . . . 486
43.1.3 Source Code . . . 486
43.1.4 Detailed analysis . . . 488
43.1.5 Expected output . . . 490
43.1.6 Created threads . . . 491
43.1.7 Required configuration in `os_config.h` . . . 491
43.1.8 Summary . . . 491
43.1.9 Verification of waits with timeout (`twait`) . . . 492
43.1.10 Waiter removed while waiting (`twkill`) . . . 492

44 Multi-Instance UART with Binary Protocol **493**
44.1 Example 21 — Multi-instance UART with binary protocol . . . 493
44.1.1 Introduction . . . 493
44.1.2 Required Hardware . . . 494
44.1.3 The binary protocol . . . 494
44.1.4 Example architecture . . . 496
44.1.5 The source code . . . 497
44.1.6 Detailed analysis . . . 499
44.1.7 Expected output . . . 500
44.1.8 Required configuration in `os_config.h` . . . 501
44.1.9 Bridge VCP UART . . . 501
44.1.10 Created Threads . . . 502
44.1.11 Summary . . . 503

45 I2C Master/Slave Intra-MCU **505**
45.1 Example 22 — Intra-MCU I2C master/slave . . . 505
45.1.1 Introduction . . . 505
45.1.2 Required hardware . . . 506
45.1.3 The protocol . . . 507
45.1.4 Example Architecture . . . 508
45.1.5 The source code . . . 509
45.1.6 Detailed analysis . . . 511
45.1.7 Expected output . . . 513
45.1.8 Required configuration in `os_config.h` . . . 514
45.1.9 Created threads . . . 514
45.1.10 Summary . . . 515

46 Internal Flash: Program / Verify / WDT Reset **517**
46.1 Example 23 — Internal Flash: CLI integrated into the driver . . . 517
46.1.1 Introduction . . . 517
46.1.2 Required hardware . . . 518
46.1.3 Sector map by family . . . 518
46.1.4 Flash alignment constraints . . . 518
46.1.5 Example architecture . . . 519
46.1.6 Flash IRQ driver architecture . . . 520
46.1.7 Source code . . . 520
46.1.8 Command analysis . . . 521
46.1.9 Expected output . . . 522
46.1.10 Required configuration in `os_config.h` . . . 523
46.1.11 Created threads . . . 523
46.1.12 Summary . . . 523

47 Timer: Periodic + Counter **525**
47.1 Example 24 — Timer IRQ: 10 kHz generator + external countdown counter . . . 525
47.1.1 Introduction . . . 525
47.1.2 Required Hardware . . . 526
47.1.3 Timer configuration . . . 526
47.1.4 System architecture . . . 528
47.1.5 Source code . . . 529
47.1.6 Detailed analysis . . . 530
47.1.7 Expected output . . . 531
47.1.8 Required configuration in `os_config.h` . . . 532
47.1.9 Created threads . . . 532
47.1.10 Possible extensions . . . 532
47.1.11 Summary . . . 533

48 Timer: Periodic + Encoder Counter **535**
48.1 Example 25 — Quadrature Signal Generator + Timer Encoder . . . 535
48.1.1 Introduction . . . 535
48.1.2 System Architecture . . . 537
48.1.3 Source Code . . . 537
48.1.4 Detailed Analysis . . . 543
48.1.5 Expected output . . . 544
48.1.6 Required Configuration in `os_config.h` . . . 544
48.1.7 Important Notes . . . 544
48.1.8 Summary . . . 545

49 Cryptography: CRC32, HASH, AES, RNG and Key Derivation 547
49.1 Example 26 — Cryptography: CRC32, HASH, AES, RNG and Key Derivation . 547
49.1.1 Introduction . . . 547
49.1.2 System architecture . . . 549
49.1.3 Source code . . . 549
49.1.4 Detailed analysis . . . 550
49.1.5 Expected output . . . 558
49.1.6 Required configuration in `os_config.h` . . . 559
49.1.7 Important notes . . . 559
49.1.8 Summary . . . 561

50 DAC Output and ADC Readback (Polling and ISR) 563
50.1 Example 27 — DAC output and ADC readback (polling and ISR) . . . 563
50.1.1 Introduction . . . 563
50.1.2 System architecture . . . 565
50.1.3 Source code . . . 565
50.1.4 Detailed analysis . . . 566
50.1.5 Expected output . . . 568
50.1.6 ADC driver architecture — ISR mode . . . 568
50.1.7 Required configuration in `os_config.h` . . . 570
50.1.8 Technical notes . . . 570
50.1.9 Summary . . . 572

51 Real-Time Clock (Polling and ISR) 573
51.1 Example 28 — RTC: setting, reading, and alarms with callbacks . . . 573
51.1.1 Introduction . . . 573
51.1.2 System architecture . . . 575
51.1.3 Source code . . . 575
51.1.4 Detailed analysis . . . 576
51.1.5 Tasks and priorities . . . 580
51.1.6 Expected output . . . 580
51.1.7 RTC driver architecture . . . 581
51.1.8 Technical notes . . . 583
51.1.9 Required configuration in `os_config.h` . . . 584
51.1.10 Summary . . . 585

52 SPI Master and Slave (Polling and ISR) 587
52.1 Example 29 — SPI master-slave on the same MCU . . . 587
52.1.1 Introduction . . . 587
52.1.2 Source configuration . . . 587
52.1.3 System architecture . . . 588
52.1.4 Source code . . . 588
52.1.5 Technical notes — MODF on STM32H7 SPI v3 . . . 591
52.1.6 Expected output . . . 592
52.1.7 CLI Commands . . . 592
52.1.8 Tasks and priorities . . . 593
52.1.9 SPI APIs used . . . 593
52.1.10 Required configuration in `os_config.h` . . . 593
52.1.11 Summary . . . 593

53 EXTI: Interrupt from the User Button **595**
53.1 Example 30 — EXTI: interrupt from user button . . . 595
53.1.1 Introduction . . . 595
53.1.2 Required configuration in `os_config.h` . . . 595
53.1.3 System architecture . . . 596
53.1.4 Software debounce . . . 596
53.1.5 Source code . . . 597
53.1.6 Technical notes . . . 600
53.1.7 Expected output . . . 601
53.1.8 Tamper on the same button (`EN_TAMP`) . . . 602
53.1.9 Tasks and priorities . . . 602
53.1.10 EXTI API used . . . 602
53.1.11 Summary . . . 603

54 DMA: Memory-to-Memory and Memory-to-Peripheral (DAC1) **605**
54.1 Example 31 — DMA: memory-to-memory and memory-to-peripheral (DAC1) . . . 605
54.1.1 Introduction . . . 605
54.1.2 Configuration required in `os_config.h` . . . 605
54.1.3 CLI Commands . . . 606
54.1.4 System architecture . . . 606
54.1.5 Source code . . . 607
54.1.6 Technical notes . . . 609
54.1.7 Expected output . . . 610
54.1.8 Tasks and priorities . . . 610
54.1.9 DMA APIs used . . . 610
54.1.10 DAC APIs used . . . 611
54.1.11 Summary . . . 611

55 ETH: Link UP / Link DOWN Detection **613**
55.1 Example 32 — ETH: link UP/DOWN, packet reception and transmission . . . 613
55.1.1 Introduction . . . 613
55.1.2 Required configuration in `os_config.h` . . . 614
55.1.3 System architecture . . . 614
55.1.4 The source code . . . 619
55.1.5 Technical notes . . . 623
55.1.6 Expected output . . . 625
55.1.7 Tasks and priorities . . . 627
55.1.8 ETH APIs used . . . 627
55.1.9 MCU family support . . . 628
55.1.10 Summary . . . 628

56 caOS Net Stack: Buffer Pool, ARP Reply, ICMP Echo **629**
56.1 Example 33 — caOS Net Stack: buffer pool, ARP reply, ICMP echo, UDP . . . 629
56.1.1 Introduction . . . 629
56.1.2 System architecture . . . 630
56.1.3 Source code . . . 633
56.1.4 Expected output . . . 636
56.1.5 Technical notes . . . 638

57 Multi-Client UDP Server on Port 7961 **641**
57.1 Example 34 — Multi-client UDP Server on port 7961 . . . 641
57.1.1 Introduction . . . 641
57.1.2 System architecture . . . 642
57.1.3 Source code . . . 644
57.1.4 Multi-client model — UDP Server API . . . 647
57.1.5 Expected output . . . 647
57.1.6 Technical notes . . . 648

58 DHCP Client + ARP + ICMP Ping + UDP Server with 2 Clients **651**
58.1 Example 35 — DHCP client + ARP + ICMP ping + UDP server 2 client . . . 651
58.1.1 Introduction . . . 651
58.1.2 System architecture . . . 652
58.1.3 Source code . . . 654
58.1.4 Test procedure from PC . . . 657
58.1.5 Expected output . . . 658
58.1.6 Technical notes . . . 659

59 DHCP + NTP + ARP + ICMP Ping + UDP Server **661**
59.1 Example 36 — DHCP + NTP + ARP + ICMP ping + UDP server . . . 661
59.1.1 Introduction . . . 661
59.1.2 System architecture . . . 662
59.1.3 The source code . . . 663
59.1.4 Test procedure from PC . . . 664
59.1.5 Expected output . . . 665
59.1.6 Technical notes . . . 665

60 DHCP + NTP + DNS + ARP + ICMP Ping + UDP Server **667**
60.1 Example 37 — DHCP + NTP + DNS + ARP + ICMP ping + UDP server . . . 667
60.1.1 Introduction . . . 667
60.1.2 System Architecture . . . 668
60.1.3 Source code . . . 669
60.1.4 Testing procedure from PC . . . 670
60.1.5 Expected Output . . . 671
60.1.6 Technical Notes . . . 671

61 DHCP + mDNS Responder + ARP + ICMP Ping + UDP Server **673**
61.1 Example 38 — DHCP + mDNS responder + ARP + ICMP ping + UDP server 673
61.1.1 Introduction . . . 673
61.1.2 System Architecture . . . 674
61.1.3 Source code . . . 675
61.1.4 PC Test Procedure . . . 676
61.1.5 Expected Output . . . 677
61.1.6 Technical Notes . . . 678

62 UDP Syslog Client (RFC 3164) **679**
62.1 Example 39 — DHCP + Syslog Service . . . 679
62.1.1 Introduction . . . 679
62.1.2 System Architecture . . . 680
62.1.3 The source code . . . 682
62.1.4 Test procedure from PC . . . 684
62.1.5 Expected output (verified on NUCLEO-H753ZI) . . . 685

62.1.6 Technical Notes 686

63 TCP Client HTTP GET **687**
63.1 Example 40 — TCP Client HTTP GET 687
63.1.1 Introduction 687
63.1.2 Hardware 687
63.1.3 os_config.h Configuration 688
63.1.4 Architettura 688
63.1.5 Code — key points 691
63.1.6 Test from PC (verified on NUCLEO-H753ZI) 692
63.1.7 Technical notes 693

64 TCP Server (Echo Server, RFC 862) **695**
64.1 Example 41 — TCP Server (echo server RFC 862) 695
64.1.1 Introduction 695
64.1.2 Hardware 695
64.1.3 Configuration os_config.h 695
64.1.4 Architecture 696
64.1.5 Code — key points 699
64.1.6 Test from PC (verified on NUCLEO-H753ZI) 700
64.1.7 Technical notes 701

65 MQTT Client **703**
65.1 Example 42 — MQTT Client 703
65.1.1 Introduction 703
65.1.2 Hardware 703
65.1.3 os_config.h Configuration 704
65.1.4 Architecture 704
65.1.5 Code — key points 705
65.1.6 Test from PC 707
65.1.7 Technical Notes 708
65.1.8 Fixes implemented during HW testing 709

66 Modbus TCP Client **711**
66.1 Example 43 — Modbus TCP Client 711
66.1.1 Introduction 711
66.1.2 Hardware 711
66.1.3 os_config.h Configuration 712
66.1.4 Architecture 712
66.1.5 task_modbus flow 713
66.1.6 Interactive CLI 713
66.1.7 Test PC — modbus_server.py 714
66.1.8 Expected UART Output 715
66.1.9 Technical Notes 715
66.1.10 TCP CLI command sequence during testing 716

67 iperf TCP Client/Server **717**
67.1 Example 44 — iperf TCP client/server 717
67.1.1 Introduction 717
67.1.2 Hardware 717
67.1.3 os_config.h Configuration 718
67.1.4 Architecture 718

67.1.5 iperf client and server flow . . . 719
67.1.6 Interactive CLI . . . 720
67.1.7 Test PC — iperf_peer.py . . . 720
67.1.8 Expected UART Output . . . 720
67.1.9 Measured Performance . . . 721
67.1.10 Memory . . . 722
67.1.11 Technical Notes . . . 722

68 HTTP Server with CLI over HTTP 723
68.1 Example 45 — HTTP and HTTPS Server with CLI via HTTP . . . 723
68.1.1 Introduction . . . 723
68.1.2 Hardware . . . 723
68.1.3 os_config.h configuration . . . 724
68.1.4 Architecture . . . 725
68.1.5 Route Table . . . 727
68.1.6 PC Tests . . . 727
68.1.7 Parsing HTTP POST — “from the bottom” body . . . 728
68.1.8 `ca_cli_exec_capture` flow . . . 729
68.1.9 Content-Length in the HTTP response . . . 731
68.1.10 Packet Tracer . . . 731
68.1.11 Expected UART output . . . 731
68.1.12 Technical notes . . . 732
68.1.13 Bench verification . . . 732

69 AES Channel Service: Encrypted Ping-Pong 733
69.1 Example 46 — Secure pipe: encrypted ping-pong between two tasks . . . 733
69.1.1 Introduction . . . 733
69.1.2 Hardware . . . 733
69.1.3 os_config.h Configuration . . . 734
69.1.4 Architecture . . . 734
69.1.5 Wire format GCM . . . 734
69.1.6 Keys Store — MPU protection . . . 735
69.1.7 Heap management — mandatory wipe . . . 736
69.1.8 Task_alice flow (100 iterations) . . . 736
69.1.9 Task_bob flow (infinite loop) . . . 736
69.1.10 Output UART . . . 736
69.1.11 Task and priority . . . 736
69.1.12 Tamper detection GCM . . . 737
69.1.13 Implementation notes — CRYP H7 and partial blocks GCM . . . 737

70 Keystore Service: makekey + Encrypted Ping-Pong 739
70.1 Example 47 — Keystore service: makekey + ping-pong encrypted . . . 739
70.1.1 Introduction . . . 739
70.1.2 Hardware . . . 739
70.1.3 os_config.h Configuration . . . 740
70.1.4 Architecture . . . 741
70.1.5 Phase 1 — makekey . . . 742
70.1.6 Phase 2 — start . . . 742
70.1.7 Encrypted ping-pong (same as example 46) . . . 743
70.1.8 CLI — state machine . . . 743
70.1.9 UART Output . . . 743
70.1.10 Security — notes . . . 744

71 IP Defrag Service: DHCP + UDP Server + Fragments 745
71.1 Example 48 — IP defrag service: DHCP + UDP server + fragment reassembly . 745
71.1.1 Introduction . . . 745
71.1.2 Hardware . . . 745
71.1.3 os_config.h Configuration . . . 746
71.1.4 Architecture . . . 746
71.1.5 ip_defrag_service API . . . 746
71.1.6 Internal structure — session . . . 747
71.1.7 Tasks and priorities . . . 747
71.1.8 PC Tests . . . 747
71.1.9 Implementation notes . . . 748

72 TFTP Client: GET and PUT over UDP (RFC 1350) 749
72.1 Example 49 — TFTP Client (RFC 1350) . . . 749
72.1.1 Description . . . 749
72.1.2 TFTP Protocol (RFC 1350) . . . 749
72.1.3 Architecture `tftp_service` . . . 750
72.1.4 API . . . 751
72.1.5 `ca_tftp_cfg_t` Configuration . . . 751
72.1.6 Parameters `os_config.h` . . . 751
72.1.7 CLI Commands . . . 752
72.1.8 PC Testing . . . 752
72.1.9 Application flow (example 49) . . . 754
72.1.10 File Structure . . . 755

73 USB Vendor Class: Multi-EP Bulk Loopback 757
73.1 Example 50 — USB Vendor-Class Bulk Loopback . . . 757
73.1.1 Description . . . 757
73.1.2 Example Architecture . . . 757
73.1.3 Descriptors . . . 758
73.1.4 SETUP handler (EP0) . . . 758
73.1.5 CLI `usb` . . . 759
73.1.6 Parameters (per-MCU, in `ca_os_ex50.c`) . . . 759
73.1.7 Test from PC . . . 759
73.1.8 File structure . . . 760
73.1.9 F407 Notes — slave mode driver . . . 760

74 USB Management Stack: Custom Class 761
74.1 Example 51 — USB Management Stack: custom class . . . 761
74.1.1 Description . . . 761
74.1.2 Hardware . . . 761
74.1.3 os_config.h Configuration . . . 762
74.1.4 Architecture . . . 762
74.1.5 Class config (D20: persistent lifetime) . . . 763
74.1.6 CLI `usb` . . . 764
74.1.7 Mount/unmount state . . . 764
74.1.8 Parameters . . . 764
74.1.9 Expected UART output . . . 764
74.1.10 Test from PC . . . 764
74.1.11 File Structure . . . 765

75 USB CDC-ACM: Virtual Serial Port **767**
75.1 Example 52 — USB CDC-ACM: virtual serial port . . . 767
75.1.1 Description . . . 767
75.1.2 Hardware . . . 767
75.1.3 os_config.h Configuration . . . 768
75.1.4 CDC ACM Structure . . . 768
75.1.5 SETUP class-level . . . 768
75.1.6 Architecture . . . 769
75.1.7 Application API . . . 770
75.1.8 Parameters . . . 770
75.1.9 Expected UART output . . . 770
75.1.10 Test from PC . . . 770
75.1.11 File Structure . . . 771

76 USB MSC: Mass Storage Device (Ramdisk) **773**
76.1 Example 53 — USB MSC: Mass Storage Device (ramdisk) . . . 773
76.1.1 Introduction . . . 773
76.1.2 Hardware . . . 774
76.1.3 os_config.h Configuration . . . 774
76.1.4 Architecture . . . 775
76.1.5 Back-end block device . . . 775
76.1.6 Bulk-Only Transport + SCSI . . . 776
76.1.7 Parameters . . . 776
76.1.8 Expected UART Output . . . 777
76.1.9 Test from PC . . . 777
76.1.10 Technical Notes . . . 778
76.1.11 File structure . . . 778

77 USB NCM: USB Ethernet (L2 Loopback) **781**
77.1 Example 54 — USB NCM: USB Ethernet (L2 loopback) . . . 781
77.1.1 Introduction . . . 781
77.1.2 PC Prerequisite: Remove the interface from NetworkManager . . . 782
77.1.3 Hardware . . . 782
77.1.4 os_config.h Configuration . . . 782
77.1.5 Architecture . . . 783
77.1.6 Loopback L2 with SADA swap . . . 784
77.1.7 Wire NTB (1 datagram per block) . . . 784
77.1.8 Parameters . . . 785
77.1.9 Expected UART Output . . . 785
77.1.10 Test from PC . . . 785
77.1.11 Technical notes . . . 786
77.1.12 File structure . . . 786

78 Net Stack over USB-NCM: Real Ping **787**
78.1 Example 55 — caOS Net Stack on USB-NCM (real ping) . . . 787
78.1.1 Introduction . . . 787
78.1.2 PC Prerequisite: Remove the interface from NetworkManager . . . 787
78.1.3 Hardware . . . 788
78.1.4 os_config.h Configuration . . . 788
78.1.5 Architecture . . . 789
78.1.6 Interface Abstraction: ETH vs NCM . . . 790
78.1.7 Expected UART Output . . . 790

78.1.8 Test from PC . . . 790
78.1.9 Technical notes . . . 791
78.1.10 File structure . . . 791

79 Composite USB: CDC + MSC + NCM 793
79.1 Example 56 — Composite USB CDC + MSC + NCM . . . 793
79.1.1 Introduction . . . 793
79.1.2 PC Prerequisite: Remove the interface from NetworkManager . . . 794
79.1.3 Hardware . . . 794
79.1.4 os_config.h Configuration . . . 795
79.1.5 Endpoint allocation (maximum case) . . . 795
79.1.6 Architecture . . . 796
79.1.7 The three application functions . . . 797
79.1.8 Expected UART Output . . . 797
79.1.9 Test from PC . . . 797
79.1.10 Technical notes . . . 798
79.1.11 File structure . . . 798

80 USB DFU: Runtime Mode 799
80.1 Example 57 — USB Management Stack: DFU runtime . . . 799
80.1.1 Description . . . 799
80.1.2 Hardware . . . 799
80.1.3 os_config.h Configuration . . . 800
80.1.4 Architecture . . . 800
80.1.5 Class configuration (D20: persistent lifetime) . . . 801
80.1.6 Handled DFU Requests (DFU 1.1) . . . 802
80.1.7 CLI `usb` . . . 802
80.1.8 Parameters . . . 802
80.1.9 Expected UART Output . . . 802
80.1.10 Test from PC . . . 803
80.1.11 File structure . . . 803

81 FatFS on SD Card: SDIO Driver with DMA 805
81.1 Example 58 — FatFS on SD card: SDIO driver with DMA . . . 805
81.1.1 Description . . . 805
81.1.2 Hardware . . . 806
81.1.3 os_config.h Configuration . . . 806
81.1.4 Architecture . . . 807
81.1.5 stdout log to file . . . 807
81.1.6 `fat cat` — the trip through the heap . . . 809
81.1.7 Expected output (CLI, HW F4VE) . . . 809
81.1.8 Fault injection: `inject` . . . 810
81.1.9 State per family HW . . . 810
81.1.10 File structure . . . 811

82 Power Manager: Frequency, Stop and Standby 813
82.1 Example 59 — Power manager (pwr) . . . 813
82.1.1 What it demonstrates . . . 813
82.1.2 Requirements . . . 814
82.1.3 Structure . . . 814
82.1.4 Notes . . . 814
82.1.5 HW Status . . . 814

82.1.6 File structure . . . 815

83 PWM: LED Fade with User Button 817
83.1 Example 60 — PWM: LED fade with user button . . . 817
83.1.1 Behavior . . . 817
83.1.2 Thresholds . . . 817
83.1.3 Board mapping . . . 817
83.1.4 Key points of the code . . . 818
83.1.5 Test from CLI . . . 818
83.1.6 Requirements . . . 818

84 LPTIM: Low-Power Blink 819
84.1 Example 61 — LPTIM: blink low-power (periodic + one-shot) . . . 819
84.1.1 Behavior . . . 819
84.1.2 LPTIM Driver . . . 819
84.1.3 Board mapping . . . 820
84.1.4 Key points of the code . . . 820
84.1.5 Test from CLI . . . 820
84.1.6 Requirements . . . 820

85 LPUART: Low-Power Console with Wake from Stop 821
85.1 Example 62 — LPUART: low-power console with wake-up from Stop . . . 821
85.1.1 Configuration (os_config.h) . . . 821
85.1.2 Behavior . . . 821
85.1.3 LPUART Driver . . . 821
85.1.4 Board mapping (external USB-UART adapter, 3.3V) . . . 822
85.1.5 Test without adapter: ST-LINK VCP via jumpers . . . 822
85.1.6 Requirements . . . 822

86 UART DMA: Variable-Length Protocol 823
86.1 Example 63 — UART DMA: variable-length protocol . . . 823
86.1.1 Configuration (os_config.h) . . . 823
86.1.2 The example protocol . . . 823
86.1.3 Header-to-payload flow . . . 823
86.1.4 Driver API (EN_UART_DMA) . . . 824
86.1.5 Host test . . . 824

87 SPI DMA: Full-Duplex Loopback on a Single Board 825
87.1 Example 64 — SPI DMA: loopback full-duplex on single board . . . 825
87.1.1 Configuration (os_config.h) . . . 825
87.1.2 Hardware — 2-wire loopback . . . 825
87.1.3 The synchronous transfer . . . 826
87.1.4 Driver API (EN_SPI_DMA) . . . 826
87.1.5 Behavior . . . 827
87.1.6 DMA Portability by Family . . . 827
87.1.7 SPI v3 Erratum — CRCSIZE (H5/H7/U5) . . . 828
87.1.8 Test Status (Hardware) . . . 828

88 SPI DMA: Master + Slave IRQ on Two Boards 829
88.1 Example 65 — SPI DMA master (with the slave from example 93) . . . 829
88.1.1 Connections: same position on both boards . . . 829
88.1.2 Hardware — reference pair H563 + H753 . . . 829
88.1.3 Hardware — alternative pair U575 + F407 . . . 830

88.1.4 Why two examples (master 65, slave 93) . . . 830
88.1.5 Flow . . . 830
88.1.6 Speed: why the default is DIV256 . . . 831
88.1.7 Why master DMA + slave IRQ . . . 832
88.1.8 Notes per family . . . 832
88.1.9 Test status (hardware) . . . 832

89 Crypto Self-Test: SHA-256, SHA-512, X25519, Ed25519 833
89.1 Example 66 — Cryptographic self-test (SHA-512, X25519, Ed25519, P-256) . . . 833
89.1.1 Purpose . . . 833
89.1.2 Configuration . . . 833
89.1.3 Behavior . . . 834
89.1.4 CLI . . . 835
89.1.5 The tests that matter . . . 836
89.1.6 Note on constant time . . . 836
89.1.7 An instructive bug: `fe25519_sq2` . . . 836
89.1.8 API . . . 836
89.1.9 Implementation notes . . . 837
89.1.10 P-256: MCU timings (10/23/2026) . . . 837
89.1.11 Next step . . . 837

90 SSH Server: Transport, Ed25519 Userauth and Shell 839
90.1 Example 67 — SSH Server: transport, userauth Ed25519 and interactive shell . . . 839
90.1.1 Introduction . . . 839
90.1.2 Hardware and families . . . 840
90.1.3 Handshake flow . . . 841
90.1.4 The shell: channel CLI . . . 842
90.1.5 Keys: volatile host key and authorized key . . . 843
90.1.6 Required configuration in `os_config.h` . . . 843
90.1.7 CLI . . . 843
90.1.8 Linking procedure . . . 844
90.1.9 Expected output . . . 844
90.1.10 Lesson: crypto HW always known-answer . . . 844
90.1.11 Summary . . . 845

91 Fault Test Bench: MPU, Bus, Usage and HardFault 847
91.1 Example 68 — Fault Test Bench: MPU, Bus, Usage and HardFault . . . 847
91.1.1 Introduction . . . 847
91.1.2 Hardware and Families . . . 847
91.1.3 The 19 Cases, by Fault Category . . . 848
91.1.4 How it runs . . . 851
91.1.5 What the dump shows . . . 852
91.1.6 Actual output (STM32H753, Cortex-M7 @ 480 MHz) . . . 852
91.1.7 Comparison: the same bank on STM32H563 (Cortex-M33 @ 250 MHz) . . . 854
91.1.8 Summary . . . 857

92 UDP Server over USB-NCM 859
92.1 Example 69 — UDP Server on USB-NCM . . . 859
92.1.1 Introduction . . . 859
92.1.2 PC Prerequisite: Remove the interface from NetworkManager . . . 860
92.1.3 Hardware . . . 860
92.1.4 os_config.h Configuration . . . 860

92.1.5 Architecture . . . 861
92.1.6 Expected UART output . . . 862
92.1.7 Test from PC . . . 862
92.1.8 Technical Notes . . . 862
92.1.9 File Structure . . . 863

93 DHCP Client over USB-NCM 865
93.1 Example 70 — DHCP Client over USB-NCM . . . 865
93.1.1 Introduction . . . 865
93.1.2 PC Prerequisite: detach the interface from NetworkManager . . . 865
93.1.3 The critical point: there is no DHCP server . . . 866
93.1.4 Hardware . . . 866
93.1.5 os_config.h configuration . . . 866
93.1.6 Startup sequence . . . 867
93.1.7 Expected UART output . . . 868
93.1.8 Technical notes . . . 868
93.1.9 File structure . . . 868

94 DHCP and NTP Client over USB-NCM 869
94.1 Example 71 — DHCP Client + NTP over USB-NCM . . . 869
94.1.1 Introduction . . . 869
94.1.2 PC Prerequisite: Remove the interface from NetworkManager . . . 869
94.1.3 The critical point: the PC must act as a server twice . . . 870
94.1.4 Hardware . . . 870
94.1.5 os_config.h configuration . . . 871
94.1.6 Boot Sequence . . . 871
94.1.7 Expected UART output . . . 872
94.1.8 Technical notes . . . 872
94.1.9 File structure . . . 873

95 DHCP, NTP and DNS Client over USB-NCM 875
95.1 Example 72 — DHCP, NTP and DNS client over USB-NCM . . . 875
95.1.1 Introduction . . . 875
95.1.2 PC Prerequisite: detach the interface from NetworkManager . . . 875
95.1.3 The critical point: the PC must act as a server three times . . . 876
95.1.4 Hardware . . . 876
95.1.5 os_config.h configuration . . . 877
95.1.6 Boot sequence . . . 877
95.1.7 Expected UART output . . . 878
95.1.8 Technical notes . . . 878
95.1.9 File structure . . . 879

96 mDNS Responder over USB-NCM 881
96.1 Example 73 — mDNS Responder over USB-NCM . . . 881
96.1.1 Introduction . . . 881
96.1.2 PC Prerequisite: Remove the interface from NetworkManager . . . 881
96.1.3 mDNS does not need a server . . . 882
96.1.4 Hardware . . . 882
96.1.5 os_config.h Configuration . . . 882
96.1.6 Boot Sequence . . . 883
96.1.7 Note: `task_stats` without `held` . . . 884
96.1.8 Expected UART Output . . . 884

96.1.9 Technical notes . . . 884
96.1.10 File structure . . . 885

97 Syslog Service over USB-NCM 887
97.1 Example 74 — Syslog service over USB-NCM . . . 887
97.1.1 Introduction . . . 887
97.1.2 PC Prerequisite: Remove the interface from NetworkManager . . . 887
97.1.3 The first “link UP” waits in queue, and arrives together with the bound . 888
97.1.4 The PC acts as syslog server and as DHCP server . . . 889
97.1.5 Hardware . . . 889
97.1.6 os_config.h Configuration . . . 889
97.1.7 Boot Sequence . . . 890
97.1.8 Expected output . . . 890
97.1.9 Technical notes . . . 891
97.1.10 File structure . . . 891

98 TCP Client over USB-NCM 893
98.1 Example 75 — TCP Client (HTTP GET) over USB-NCM . . . 893
98.1.1 Introduction . . . 893
98.1.2 PC Prerequisite: detach the interface from NetworkManager . . . 893
98.1.3 What changes compared to UDP clones . . . 894
98.1.4 The PC acts as a DHCP server and a TCP server . . . 894
98.1.5 Hardware . . . 894
98.1.6 os_config.h configuration . . . 895
98.1.7 Startup sequence . . . 895
98.1.8 Expected output . . . 896
98.1.9 Technical notes . . . 896
98.1.10 File structure . . . 897

99 TCP Echo Server over USB-NCM 899
99.1 Example 76 — TCP echo server over USB-NCM . . . 899
99.1.1 Introduction . . . 899
99.1.2 PC prerequisite: remove the interface from NetworkManager . . . 899
99.1.3 The real difference: where `ca_tcp_listen()` is located . . . 900
99.1.4 The PC is the client . . . 901
99.1.5 Hardware . . . 901
99.1.6 os_config.h configuration . . . 901
99.1.7 Boot Sequence . . . 901
99.1.8 Expected output . . . 902
99.1.9 Technical Notes . . . 902
99.1.10 File structure . . . 903

100 MQTT Client over USB-NCM 905
100.1 Example 77 — MQTT Client over USB-NCM . . . 905
100.1.1 Introduction . . . 905
100.1.2 PC Prerequisite: Remove the interface from NetworkManager . . . 905
100.1.3 The broker is the gateway . . . 906
100.1.4 The test that this example carries with it . . . 906
100.1.5 Hardware . . . 906
100.1.6 os_config.h Configuration . . . 907
100.1.7 The PC: MQTT broker + DHCP . . . 908
100.1.8 Boot Sequence . . . 908

100.1.9 Expected output . . . 909
100.1.10 Technical notes . . . 909
100.1.11 File structure . . . 910

101 Modbus TCP Client over USB-NCM 911
101.1 Example 78 — Modbus TCP Client over USB-NCM . . . 911
101.1.1 Introduction . . . 911
101.1.2 PC Prerequisite: Remove the interface from NetworkManager . . . 911
101.1.3 The server is the gateway . . . 912
101.1.4 The confirmation on the first connect . . . 912
101.1.5 Hardware . . . 912
101.1.6 os_config.h Configuration . . . 913
101.1.7 The PC: Modbus server + DHCP . . . 913
101.1.8 Boot Sequence . . . 913
101.1.9 Expected output . . . 914
101.1.10 Technical Notes . . . 915
101.1.11 File structure . . . 915

102 iperf TCP over USB-NCM 917
102.1 Example 79 — iperf TCP over USB-NCM . . . 917
102.1.1 Introduction . . . 917
102.1.2 PC Prerequisite: Remove the interface from NetworkManager . . . 917
102.1.3 The numbers: what to expect and what not to believe . . . 918
102.1.4 Priority: `net` paired with the service . . . 919
102.1.5 Hardware . . . 919
102.1.6 os_config.h Configuration . . . 919
102.1.7 Usage . . . 920
102.1.8 Boot sequence . . . 921
102.1.9 Expected output . . . 921
102.1.10 Technical notes . . . 922
102.1.11 File structure . . . 922

103 HTTP Server with CLI over USB-NCM 923
103.1 Example 80 — HTTP and HTTPS server with CLI via HTTP over USB-NCM . 923
103.1.1 Introduction . . . 923
103.1.2 PC Prerequisite: detach the interface from NetworkManager . . . 923
103.1.3 The three differences compared to ex45 . . . 924
103.1.4 Test on PC . . . 924
103.1.5 Unlimited CLI output: chunked response . . . 925
103.1.6 HTTPS on port 443 . . . 925
103.1.7 Status . . . 926

104 IP Defragmentation and UDP Server over USB-NCM 927
104.1 Example 81 — IP Defragmentation + UDP server on USB-NCM . . . 927
104.1.1 Introduction . . . 927
104.1.2 PC Prerequisite: Remove the interface from NetworkManager . . . 927
104.1.3 Why the test is identical . . . 928
104.1.4 The CRC32 is not a detail . . . 928
104.1.5 The three differences from ex48 . . . 928
104.1.6 Test on PC . . . 928
104.1.7 Status . . . 929

105 TFTP Client over USB-NCM **931**
105.1 Example 82 — TFTP Client over USB-NCM . . . 931
105.1.1 Introduction . . . 931
105.1.2 PC Prerequisite: detach the interface from NetworkManager . . . 931
105.1.3 Why TFTP does not need a gate . . . 932
105.1.4 Test on PC . . . 932
105.1.5 Status . . . 932

106 SSH Server over USB-NCM **935**
106.1 Example 83 — SSH Server over USB-NCM . . . 935
106.1.1 Introduction . . . 935
106.1.2 PC Prerequisite: detach the interface from NetworkManager . . . 935
106.1.3 Static IP: the simplest clone in the series, not the most complex . . . 936
106.1.4 Differences compared to ex67 . . . 936
106.1.5 PC Test . . . 936
106.1.6 Status . . . 937

107 L2 Echo: the Driver Measured Without the Transport **939**
107.1 Example 84 — L2 Echo: the driver measured without the transport . . . 939
107.1.1 Introduction . . . 939
107.1.2 How it works . . . 939
107.1.3 Why static IP . . . 940
107.1.4 The network filter (`EN_NET_FILTER`) . . . 940
107.1.5 The two queues, and why they are short . . . 940
107.1.6 Usage . . . 941
107.1.7 The offered rate (`--mbps`), and why it is needed . . . 941
107.1.8 Searching for the limit (phase `echo_rate_limit`) . . . 942
107.1.9 Reading `eth dump` . . . 942
107.1.10 Configuration . . . 943
107.1.11 Hardware notes . . . 943

108 Several Connections at Once: How the Buffer Pool Is Shared **945**
108.1 Example 85 — Multiple connections together: how the buffer pool is shared . . . 945
108.1.1 Introduction . . . 945
108.1.2 Why it doesn't resolve by shrinking the rings . . . 945
108.1.3 The quota, calculated when needed . . . 946
108.1.4 What this example answers . . . 946
108.1.5 How it works . . . 947
108.1.6 Commands . . . 947
108.1.7 How to read the report . . . 948
108.1.8 Requirements . . . 948

109 callto: Calling an Address from the Console **949**
109.1 Example 86 — `callto`: calling an address from the console . . . 949
109.1.1 Introduction . . . 949
109.1.2 The call runs in a task of its own . . . 949
109.1.3 Syntax . . . 950
109.1.4 The three targets . . . 950
109.1.5 Typical session . . . 950
109.1.6 Portability . . . 951
109.1.7 Automated test . . . 951

110 Lost Wake-up Bench **953**
110.1 Example 87 — Lost wakeup bench . . . 953
110.1.1 Introduction . . . 953
110.1.2 How it works . . . 953
110.1.3 The phases . . . 954
110.1.4 Commands . . . 956
110.1.5 Configuration . . . 956
110.1.6 Test . . . 956

111 CLI Echo on the USB CDC Console **957**
111.1 Example 90 — Echo of CLI on USB CDC console . . . 957
111.1.1 Description . . . 957
111.1.2 Why this example . . . 957
111.1.3 os_config.h configuration . . . 958
111.1.4 Commands . . . 958
111.1.5 How to test . . . 958
111.1.6 Results (10/04, NUCLEO-H753ZI, Debug) . . . 959

112 Kernel Semantics Bench **961**
112.1 Example 91 — Kernel Semantic Testbench . . . 961
112.1.1 Description . . . 961
112.1.2 Why This Example . . . 961
112.1.3 The Mechanism: Actors with a Script . . . 961
112.1.4 Configuration os_config.h . . . 962
112.1.5 Commands . . . 962
112.1.6 How to test . . . 963
112.1.7 Results (05/10, NUCLEO-H753ZI, Debug) . . . 963

113 External SPI NOR Flash on the QSPI **965**
113.1 Example 92 — External SPI NOR Flash on QSPI/OCTOSPI . . . 965
113.1.1 Configuration (os_config.h) . . . 965
113.1.2 Hardware — 6-pin module . . . 965
113.1.3 Commands . . . 966

Chapter 1

Introduction: Bare Metal and RTOS

1.1 Chapter 1 - Introduction: Bare Metal and RTOS

1.1.1 1.1 What are embedded systems?

Imagine you want to control an electronic device such as a smart thermostat, a car, or a robot. An **embedded system** is a specialized computer designed to perform a specific function within a larger device. Unlike a regular computer, an embedded microcontroller (MCU) has very limited resources: a few kilobytes of RAM, relatively low processing speed, and no operating system like Windows or Linux.

When you turn on a microcontroller, it does not happen like when you turn on your computer. There is no operating system that boots up slowly. The microcontroller immediately starts executing your program, directly from the hardware. This is both an advantage (speed) and a challenge (you have to manage everything yourself).

1.1.2 1.2 "Bare Metal" Programming

What is Bare Metal?

Bare Metal means programming directly on the hardware, without any operating system. It is like driving a car without an onboard computer: you have full control but you must manage everything personally.

The typical structure of a bare metal program is an **infinite loop**:

```
int main(void) {
    // Inizializzazione del microcontrollore
    init_clock();     // Imposta la velocit  del processore
    init_gpio();      // Configura i pin di ingresso/uscita
    init_uart();      // Configura la comunicazione seriale

    // Loop che si ripete all'infinito
    while (1) {
        leggi_sensore();
        elabora_dati();
        aggiorna_uscite();
        gestisci_comunicazione();
    }
}
```

Everything happens in sequence, one operation after another. If `leggi_sensore()` takes 10 milliseconds, nothing else is executed during those 10 ms.

Advantages of Bare Metal

- **Simplicity**: the program is linear and easy to understand.

- **Efficiency**: no extra code slowing down the system.
- **Total control**: you know exactly what your program is doing.
- **Low memory consumption**: all space is used for your code.

Limitations of Bare Metal

When your project becomes more complex, the infinite loop shows its limitations:

Problem 1 - Response time: if the loop takes 50 ms to complete a cycle, a critical event might have to wait up to 50 ms before being handled.

Problem 2 - No priority: in the loop, all operations have the same importance. You cannot say "this sensor reading is urgent, the display update can wait".

Problem 3 - System blocking: if a function has to wait for data (for example, a response from a sensor), it blocks the entire system.

Problem 4 - Difficult to expand: adding new features means modifying the main loop, with the risk of breaking what is already working.

Interrupts: a first solution

Interrupts partially solve the response time problem. When something important happens (for example, you press a button or data arrives), the microcontroller temporarily interrupts the main loop to handle it immediately:

```
// Questa funzione viene eseguita immediatamente quando arriva un dato
void USART1_IRQHandler(void) {
    uint8_t byte = USART1->DR;  // Legge il dato ricevuto
    buffer[idx++] = byte;       // Lo salva in un buffer
}

// Il loop principale continua normalmente
while (1) {
    if (idx > 0) {
        elabora_buffer();
    }
    aggiorna_display();
}
```

Interrupts are very useful, but they have limitations: - They must be short, otherwise they block other functions. - They can create data concurrency issues if not handled correctly. - They do not solve the problem of managing different activities with different priorities.

1.1.3 1.3 What is an RTOS?

What is an RTOS?

An **RTOS** (Real-Time Operating System) is a lightweight operating system designed to manage multiple activities simultaneously. Unlike Windows or macOS, an RTOS is:

- **Very small**: it occupies a few kilobytes of memory.
- **Punctual**: it responds to events within guaranteed times.
- **Capable of preempting**: it can stop an activity to perform a more urgent one.

The concept of Task

The heart of an RTOS is the **task** (or process). Instead of a single loop, the work is divided into multiple independent tasks, each with its own job:

```c
// Task 1: lettura sensore (importante)
void task_sensore(void) {
    while (1) {
        leggi_sensore();
        elabora_dati();
        sleep(100);  // Attende 100 ms, permettendo ad altri task di lavorare
    }
}

// Task 2: aggiornamento display (meno importante)
void task_display(void) {
    while (1) {
        aggiorna_schermo();
        sleep(500);  // Aggiorna ogni 500 ms
    }
}

// Task 3: comunicazione (media importanza)
void task_comunicazione(void) {
    while (1) {
        if (dati_disponibili()) {
            invia_dati();
        }
        sleep(50);
    }
}
```

Each task operates as if it had the microcontroller all to itself. It is the RTOS **scheduler** that decides which task should run at any given moment, switching rapidly from one to another.

Advantages of an RTOS

- **Organization**: each task is a separate module, easier to develop and debug.
- **Priority**: important tasks are executed before less important ones.
- **Responsiveness**: an important event immediately interrupts the current task.
- **Efficiency**: when a task is waiting for something, other tasks can work.
- **Safe communication**: specific tools (queues, semaphores) allow tasks to exchange information safely.

Disadvantages of an RTOS

Everything has a cost. An RTOS introduces:

- **Memory consumption**: each task requires its own personal memory area (stack).
- **Context switch**: switching from one task to another takes some CPU time.
- **Complexity**: errors like race conditions are harder to find when there are multiple simultaneous activities.
- **Sizing**: you must accurately decide how much memory to allocate to each task.

1.1.4 1.4 When to use Bare Metal or RTOS?

The choice depends exclusively on the needs of your project:

Use Bare Metal when:

- The system does only one thing (or a few simple things).
- It is not critical to respond instantly to events.
- You have very little memory available on the MCU.
- The project is stable and will not become very complex.

Use an RTOS when:

- There are many independent and different activities to manage.
- You need to respond quickly and deterministically to external events.
- The project will grow and receive many new features.
- You need to communicate in a complex way between different subsystems.
- You want to facilitate porting code to different microcontrollers.

Hybrid approach

In practice, many systems use a mixed approach: a main loop with interrupts for simple cases, and an RTOS when complexity increases. The advantage of a good RTOS is that your code remains linear, while the complexity of simultaneous management is delegated to the operating system.

1.1.5 1.5 RTOS on ARM Cortex-M microcontrollers

ARM Cortex-M microcontrollers are particularly suitable for running an RTOS thanks to dedicated hardware features:

Two separate work areas

The Cortex-M has two separate stack pointers: - **MSP** (Main Stack Pointer): used by the system (kernel) and interrupt service routines (ISR). - **PSP** (Process Stack Pointer): used by individual user tasks.

This separation protects the system: if a task crashes or runs out of stack, it does not damage the kernel's central stack.

Special functions for multitasking

- **SysTick**: a hardware timer integrated into the core that generates the time interrupt (tick) for the scheduler.
- **PendSV**: a low-priority software interrupt used specifically to perform the context switch without interfering with urgent hardware interrupts.
- **SVC** (Supervisor Call): an instruction that allows tasks to call system functions in privileged mode.

Memory protection

In more advanced models (Cortex-M4, M7, M23, M33), there is a **Memory Protection Unit (MPU)** that allows you to: - Isolate a task's memory to prevent it from overwriting that of other tasks. - Protect kernel code from application errors. - Define restricted-access areas (e.g., read-only).

System security

The Cortex-M supports two code execution levels: - **Privileged**: full access to all registers and peripherals (used by the kernel). - **Unprivileged**: limited access, controlled by the system (used by tasks).

This separation makes the entire firmware extremely robust and secure.

1.1.6 1.6 Available RTOS

There are several established RTOS in the microcontroller world:

RTOS	License	Features
FreeRTOS	Free (MIT)	The most widely used, supported by Amazon.
Zephyr	Free	Linux Foundation project, very modular and rich in network stacks.
RTEMS	Free	Highly reliable, used in space and avionics (NASA, ESA).
ChibiOS	Free/commercial	Extremely efficient, natively optimized for STM32.
ThreadX (Azure RTOS)	Free (Eclipse)	Certified for safety-critical environments, now open source.
caOS	Free	The subject of this manual.

Each RTOS has its own strengths. In the following chapters, we will see the fundamental concepts common to all real-time architectures and how caOS implements them specifically.

Chapter 2

The Kernel: Tasks, Scheduler and Stack Management

2.1 Chapter 2 - The Kernel: Tasks, Scheduling, and Memory Management

The kernel is the heart of every RTOS. It is the software component that manages task execution, decides who works and when, and handles saving and restoring the state of each task during context switches. In this chapter, we examine the fundamental concepts that every RTOS must implement.

2.1.1 2.1 The Task

What is a Task

A task (also called a process in some RTOSs) is an independent unit of work. From the programmer's perspective, each task is a function with its own infinite loop:

```
void task_example(void) {
    // Initialization (run only once)
    configure_peripheral();

    // Main loop
    while (1) {
        do_work();
        event_wait();
    }
}
```

From the kernel's perspective, each task is like a small program with its own information:

- **State**: running, waiting, dormant, suspended
- **Workspace**: where the task saves its temporary data
- **Priority**: importance of the task (higher or lower)
- **Name**: identifier to understand which task it is
- **Context**: information about the processor state

Task States

A task can be in different states during its lifetime:

```
                    +----------+
                    |  CREATO  |
                    +----+-----+
```

```
                          |
                          v
   +---------+     +-----------+     +----------+
   | BLOCKED|<--->|   READY   |<--->|  RUNNING  |
   +---------+     +-----------+     +----------+
        |                |                |
        |                v                |
        |          +-----------+          |
        +--------->| SOSPESO   |<---------+
                   +-----------+
                          |
                          v
                   +-----------+
                   |    END    |
                   +-----------+
```

- **Created**: the task has been created but not yet started
- **Ready**: the task is ready to work, waiting for its turn
- **Running**: the task is working (only one at a time)
- **Blocked**: the task is waiting for an event (time, communication, etc.)
- **Suspended**: the task has been manually stopped, it will not work
- **Finished**: the task has finished or has been removed

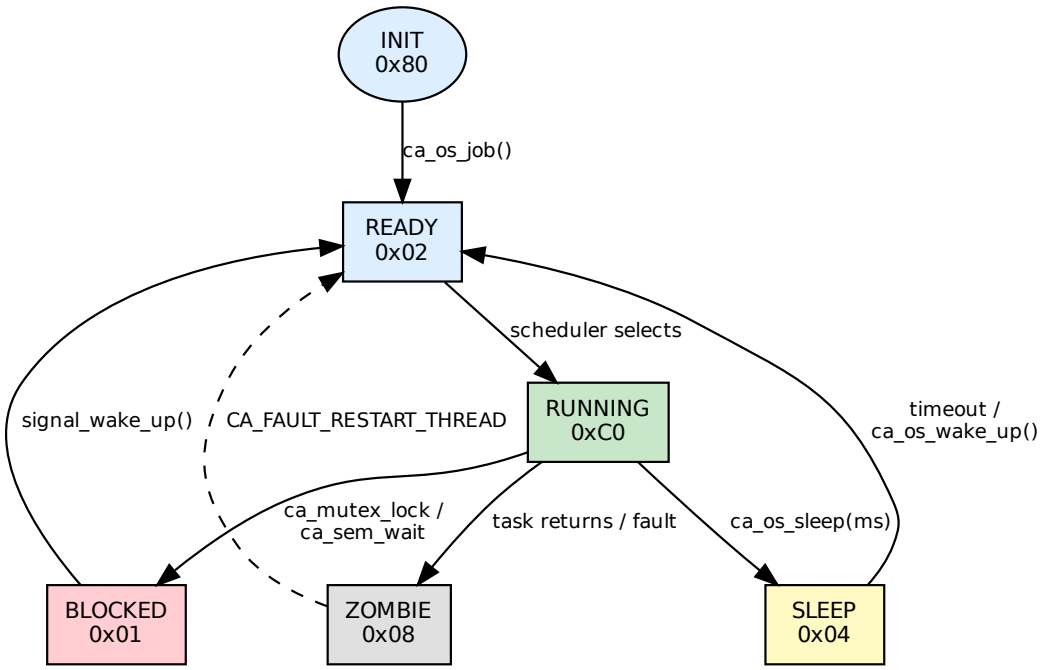

Figure 2.1: caOS task states

Creating a Task

When creating a task, the kernel must:

1. **Create a container** to store the task information
2. **Assign a workspace** (stack) dedicated to the task
3. **Prepare the workspace** so that when the task starts, it executes its function
4. **Add the task to the list** of tasks ready to work

The workspace (stack) is important: when the task starts working, the system prepares the area as if the task had just been interrupted, so when it resumes, it starts exactly from its function.

Idle task

Every RTOS has a special task called the **idle task**: a very low priority task that works only when no other task is ready. The idle task:

- Puts the processor into power-saving mode
- Performs system maintenance operations
- Must never block or stop

2.1.2 2.2 The Scheduler

What is the Scheduler

The scheduler is like an orchestra conductor: it decides which task must work at any given moment. It is called:

- At regular intervals (like a metronome)
- When a task stops voluntarily (to sleep or wait)
- When a new task is ready
- When a task voluntarily yields its place

Scheduling algorithms

Round-Robin The simplest algorithm: each task receives the same amount of working time. When the time expires, the task yields its place to the next one.

```
Time -->
Task A: [====]       [====]       [====]       ...
Task B:       [====]       [====]       [====] ...
Task C:             [====]             [====] ...
         t0   t1    t2    t3    t4    t5
```

Advantages: all tasks receive the same treatment **Disadvantages**: an important task must wait for its turn like all the others

Priority-Based Each task has a priority. The scheduler always runs the most important task among those that are ready. If a very important task arrives while a less important one is running, the former interrupts the latter.

```
Time -->
Task A (high):  [==]   [========]         [===]
Task B (media):     [==]          [======]
Task C (low):                                  [====...]
```

Advantages: important tasks are served immediately **Disadvantages**: less important tasks might never run if the important ones are always active

By priority with sharing A more advanced version: important tasks receive more time, but everyone receives at least some time.

```
CPU time assigned:
  High priority:                                                    (much time)
  Medium priority:                                  (medium time)
  Low priority:                           (little time)
```

Advantages: everyone receives time, but the most important ones receive more **Disadvantages**: more complex to manage

The system heartbeat

The scheduler needs a "heartbeat" to function: a timer that ticks at regular intervals (usually every millisecond).

At each tick, the scheduler: 1. Checks if any task needs to wake up 2. Checks time limits 3. Decides if it is time to switch tasks

Choosing the frequency is a compromise:

Frequency	Advantages	Disadvantages
Fast	Very fast responses	System busy checking
Slow	Little checking work	Less precise responses

2.1.3 2.3 The Context Switch

What is the Context Switch

The context switch is the operation by which the system saves the state of the current task and resumes the state of the next task to be executed. It is the most important operation of the entire RTOS: it must be fast and correct.

What is saved

When switching from one task to another, the system must remember:

- Where the previous task was working
- What data it was processing
- What information it had in memory

How the switch works

The switch does not happen immediately. The system schedules the switch so that it occurs when it is safe to do so, that is, when all important operations are finished.

```
System check:
  1. Checks who must run
  2. If it differs from the current one, schedules the switch
  3. At the end of the important operations:
     - Saves the state of the current task
     - Loads the state of the next task
     - Continues with the new task
```

This two-phase system ensures that the switch does not interfere with critical operations.

Context switch time

On a modern microcontroller, the context switch requires very little time (less than a millisecond). This includes: - Saving and restoring processor information - Updating task lists - Switching to the new task

2.1.4 2.4 Working Memory Management (Stack)

Working memory management (called stack) is very important in an RTOS. Errors here cause problems that are difficult to understand.

A working area for each Task

Each task has its own personal working area. Unlike a normal computer (where memory can grow), on a microcontroller the working area is fixed, assigned when the task is created.

```
Memory

      System area              For the kernel and the important operations
      (4 KB)

      Task 1 area              Where Task 1 works
      (1 KB)

      Task 2 area              Where Task 2 works
      (1 KB)

      Task 3 area              Where Task 3 works
      (512 B)

         ...

      Free memory
      (variabile)

```

How much memory is needed?

How much workspace does a task need? It depends on:

- **How deep the work is**: every function that calls other functions uses memory
- **How much temporary data it uses**: a large array uses a lot of memory
- **If interrupts occur**: when an event arrives, it uses some extra memory
- **Complex functions**: some system functions can use a lot of memory

The risk is **stack overflow**: when a task uses more memory than allocated and starts overwriting other data. The symptoms are unpredictable: other tasks behave strangely, the system crashes at unexpected points.

How to protect memory

Software check A special value is placed at the end of the workspace. At regular intervals, the system checks that the value is still there:

```
Task 1 work area:
                                                  area start
      ... data ...          memory fills from the bottom up

      ... data ...

     SPECIAL VALUE           if found changed, there was an overflow!
                                                  area end
      Other task            the next task's area starts here

```

Advantages: simple to implement **Disadvantages**: discovers the problem after it has happened

Hardware control Some microcontrollers have a special feature that protects memory areas. If a task tries to write outside its area, the system notices immediately.

Advantages: immediate discovery of the problem **Disadvantages**: not all microcontrollers have this feature

Usage monitoring At the beginning, the entire workspace is filled with a special value. During operation, you can see how much of the area has been used by looking at how many special values have been overwritten.

This technique is useful for understanding how much area each task needs.

Memory tips

1. **Do not use large temporary areas**: use fixed or shared areas
2. **Avoid recursive functions**: they can use a lot of memory
3. **Calculate needs carefully**: account for the worst-case scenario
4. **Use hardware protection if available**: it is the safest
5. **Check usage during development**: see how much the tasks use

2.1.5 2.5 The System Timer

How the rhythm works

Most RTOS use a fixed rhythm (e.g., every millisecond). Some advanced systems use a tickless approach: the system wakes up only when it needs to do something, saving energy.

For an RTOS on a microcontroller, the choice of rhythm is a compromise:

- **Fast rhythm**: very precise responses, but the system checks frequently
- **Slow rhythm**: fewer checks, but pauses might be less precise

Converting times

System functions use times in milliseconds because they are easy to understand:

```
os_sleep(100);  // The task wants to sleep 100 milliseconds
```

But inside the system, everything works with the rhythm:

```
// If the tick is every 500 microseconds, then 100ms = 200 ticks
task->pause_counter = ms_to_ticks(100);  // = 200
```

At each tick, the system decrements the counter:

```
// In the periodic check:
for each sleeping task:
    task->pause_counter--;
    if (task->pause_counter == 0)
        wake_up(task);
```

2.1.6 2.6 System startup

The startup sequence of an RTOS follows these steps:

1. **Power-on**: the microcontroller starts from the entry point
2. **Preparation**: copies necessary data, clears memory
3. **main()**: initializes hardware and the system
4. **Task creation**: the program creates all initial tasks
5. **System startup**: the kernel starts running the first task
6. **First boot**: the kernel prepares the first task and starts running

From this moment on, the code in `main()` is no longer executed. The system alternates between tasks, managed entirely by the scheduler.

```
System start

    v
  main()

              prepara hardware (orologio, porte, comunicazioni)
              prepare system
              crea task A
              crea task B
              crea task C
              start system       > Task A (first job)

                                   Ritmo       > Cambio       > Task B

                                                                Ritmo       > ...
```

Previous chapter: Introduction Next chapter: Resources - Sharing and Synchronization

Chapter 3

Resources: Synchronization and Mutexes

3.1 Chapter 3 - Resources: Sharing and Synchronization

When multiple tasks share resources (such as variables, hardware devices, or memory areas), mechanisms are needed to ensure that access occurs in an orderly manner. Without these precautions, **concurrency problems** can occur: bugs that are difficult to reproduce, which corrupt data or cause strange behaviors.

3.1.1 3.1 The concurrency problem

Race Condition

Let's imagine two tasks that need to increment a shared counter:

```
u32 counter = 0;  // Variable shared between the tasks

// Task A                    // Task B
counter++;                  counter++;
```

The `contatore++` operation seems simple, but in reality it requires three steps:

1. Read the current value
2. Increment it by 1
3. Write it back

If the system switches from one task to another at the wrong moment:

```
Task A: reads counter (finds 0)
--- system switches to Task B ---
Task B: reads counter (still finds 0!)
Task B: adds 1 (becomes 1)
Task B: writes the value (counter = 1)
--- system returns to Task A ---
Task A: adds 1 (it started from 0, becomes 1)
Task A: writes the value (counter = 1)
```

We performed two increments, but the counter equals 1 instead of 2. This is a classic concurrency bug.

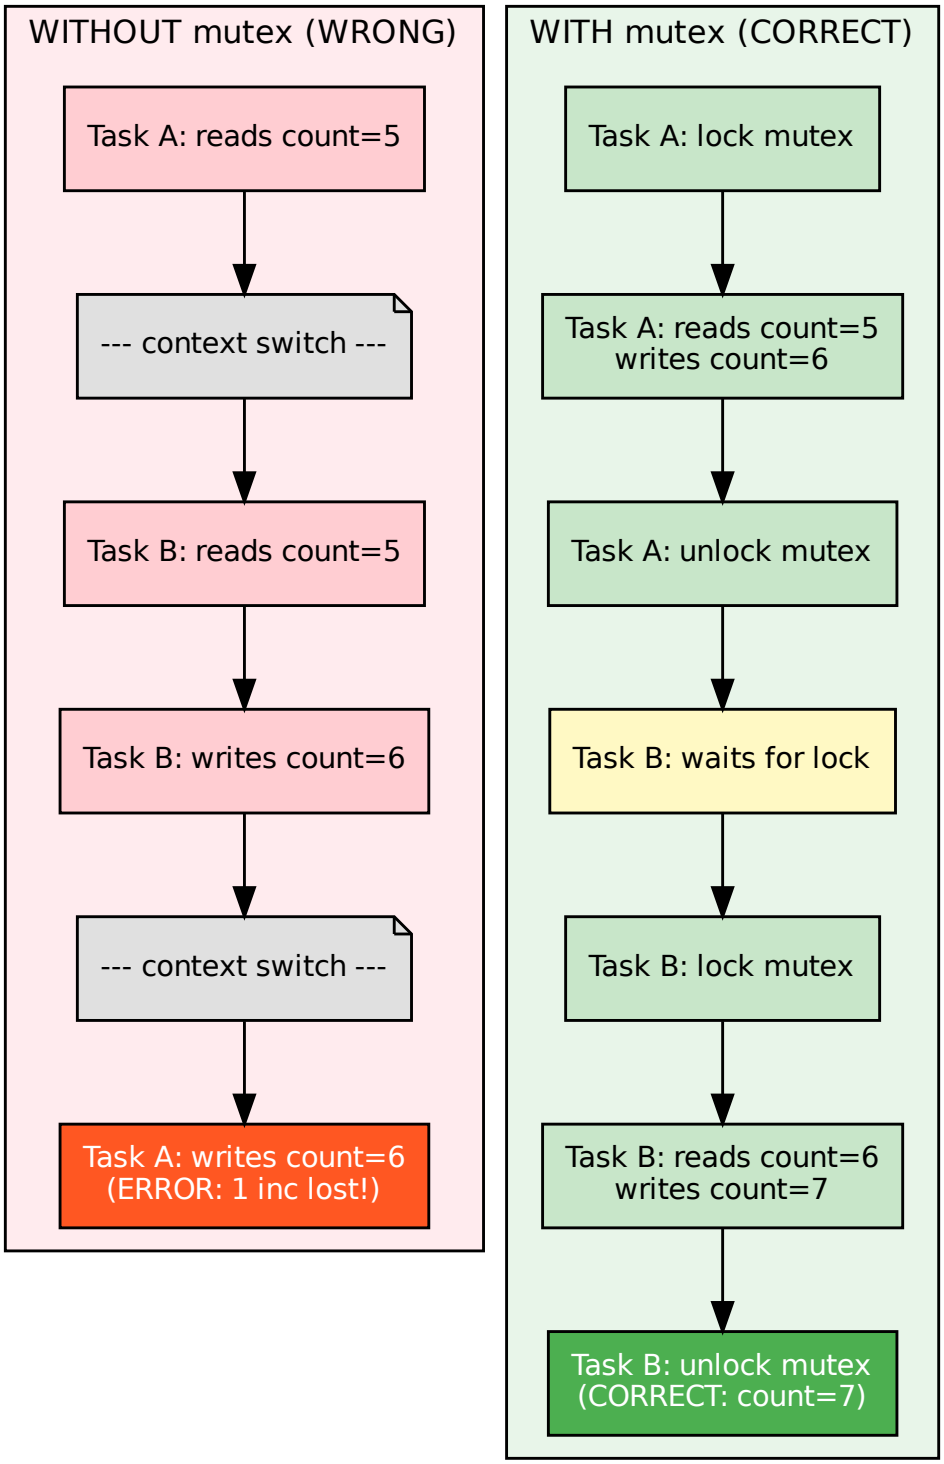

Figure 3.1: Race condition with and without mutex

Critical Section

A **critical section** is a part of code that accesses a shared resource and must be executed without interruptions. The simplest way to protect it is to temporarily disable interrupts:

```
disable_interrupts();   // No task switch possible
counter++;                 // Critical section
enable_interrupts();      // Back to normal
```

It works, but it has a problem: while interrupts are disabled, **no external event** can be handled. If the critical section lasts too long, important information is lost.

Nesting of critical sections

A common problem: if a function disables interrupts and calls another function that does the same thing, when the inner function finishes it might re-enable interrupts too soon:

```
void outer_function(void) {
    disable_interrupts();
    inner_function();       // This one also disables and re-enables
    // HERE interrupts are already re-enabled! Error!
    important_operation();
    enable_interrupts();
}
```

The solution is to keep a **count of how many times** interrupts have been disabled, and re-enable them only when the count returns to zero.

3.1.2 3.2 Safe (Atomic) Operations

Microcontrollers offer special operations that are "atomic" (they cannot be interrupted):

Exclusive Read and Write

There are special operations that allow reading a value, modifying it, and writing it back safely:

```
Riprova:
    Read value (with a "reservation")
    Modify the value
    Write value, but only if nobody else changed it
    If someone interfered, retry
```

If another task modifies the value between the read and the write, the operation fails and is repeated. This is the principle on which many synchronization tools work.

3.1.3 3.3 Mutex

What is a Mutex

The mutex is the most used synchronization tool. It ensures that only one task at a time can access a shared resource:

```
mutex_take(&my_mutex);     // If the mutex is taken, the task waits
// ... use of the resource ...
mutex_release(&my_mutex);   // Release the mutex, wake any waiting tasks
```

The important difference: a task waiting for a mutex **does not consume computing time**. The system switches to other tasks and wakes the first one when the mutex is free.

Properties

A mutex has an **owner**: the task that acquired it. Only that task can release it. This prevents serious errors.

Recursive Mutex

A normal mutex creates problems if the same task tries to acquire it twice:

```
mutex_take(&my_mutex);      // Preso
mutex_take(&my_mutex);      // PROBLEM: the task waits for itself!
```

A **recursive mutex** allows the same task to acquire it multiple times, but it must release it the same number of times:

```
mutex_take(&my_recursive); // counter = 1
mutex_take(&my_recursive); // counter = 2 (same task, OK)
mutex_release(&my_recursive); // counter = 1
mutex_release(&my_recursive); // counter = 0, mutex free
```

Priority Inversion

A common problem in systems with priorities. Imagine three tasks:

- **Task A** (high priority): needs a resource
- **Task B** (medium priority): does not use the resource
- **Task C** (low priority): owns the resource

```
1. Task C takes the resource
2. Task A becomes ready, interrupts Task C
3. Task A looks for the resource     blocked (Task C owns it)
4. Task B becomes ready     runs instead of Task C!
5. Task C cannot free the resource because Task B is running
6. Task A stays blocked     PRIORITY INVERSION
```

Task A (important) is blocked by Task B (less important) which has nothing to do with the resource. This problem has caused serious issues in space missions.

Priority Inheritance

The solution: when an important task is blocked on a resource owned by a less important task, the system **temporarily increases** the priority of the less important task:

```
1. Task C takes the resource (low priority)
2. Task A looks for the resource     blocked
3. System: raises Task C's priority to Task A's level
4. Task B becomes ready, but Task C now has higher priority     Task C goes on
5. Task C frees the resource     priority restored, Task A unblocks
```

Timeout

A task should never wait indefinitely. Mutexes with a timeout allow you to specify the maximum wait time:

```
if (mutex_take_timeout(&my_mutex, 100) == OK) {
    // Mutex taken within 100ms
    mutex_release(&my_mutex);
} else {
    // Time out: handle the error
}
```

3.1.4 3.4 Semaphore

Difference from Mutex

The semaphore is often confused with the mutex, but they have different purposes:

	Mutex	Semaphore
Purpose	Protect a resource	Signal an event or count resources
Ownership	Only the one who takes it releases it	Anyone can signal
Value	0 or 1	From 0 to N
Typical use	Critical section	Inter-task communication

Binary Semaphore (for signaling)

Used to communicate between an interrupt routine and a task:

```
// Interrupt routine: signals that the data are ready
void UART_handler(void) {
    buffer[indice++] = UART->DR;
    sem_signal(&data_ready);      // Wake the task
}

// Task: waits for the data
void task_processing(void) {
    while (1) {
        sem_wait(&data_ready);  // Sleeps until the signal arrives
        process(buffer);
    }
}
```

Counting Semaphore (for multiple resources)

Used to manage a limited set of resources:

```
// 3 buffer disponibili
sem_init(&buffer_free, 3, 3);  // 3 available, maximum 3

// Task: request a buffer
sem_wait(&buffer_free);        // Decreases (if 0, blocks)
buffer = get_DMA_buffer();
// ... use the buffer ...
release_DMA_buffer(buffer);
sem_signal(&buffer_free);        // Aumenta
```

3.1.5 3.5 Condition Variable

The condition variable allows a task to wait for a complex condition to become true:

```
my_mutex mtx;
condition_variable cv;
u32 data_item_available = 0;

// Task produttore
mutex_take(&mtx);
data_item_available = 1;
cond_signal(&cv);       // Wakes ONE waiting task
mutex_release(&mtx);

// Task consumatore
mutex_take(&mtx);
```

```
while (!data_item_available) {    // ALWAYS in a while loop, never an if
    cond_wait(&cv, &mtx);  // Releases mtx, waits, takes mtx back
}
process_item();
data_item_available = 0;
mutex_release(&mtx);
```

The `while` loop is important: a task can be woken up without a reason (spurious wakeup), so it must always check the condition again.

3.1.6 3.6 Spinlock

The spinlock is a mechanism that performs "active waiting": the task that fails to obtain access keeps trying in a loop, using computing time:

```
while (!try_lock(&my_spinlock)) {
    // Busy-wait
}
// Critical section
sblocca(&my_spinlock);
```

When to use Spinlock

- **Very short** critical sections (a few instructions)
- Where waiting is not possible (interrupt routines)
- When a context switch would cost more than the short wait

When NOT to use it

- Long critical sections: it wastes computing time
- In low-priority tasks: priority inversion with no solution
- When the lock is free: a mutex is almost always better

3.1.7 3.7 Message Queue

Queues are the primary method for communication between tasks. Instead of sharing variables (which require protection), tasks exchange messages through a secure queue:

```
// Task produttore
u32 item = read_sensor();
queue_send(&my_queue, &item, timeout);

// Task consumatore
u32 item;
queue_receive(&my_queue, &item, timeout);
process(item);
```

Processing order

- **FIFO** (First In, First Out): messages are processed in the order of arrival. Standard behavior.
- **LIFO** (Last In, First Out): the most recent messages have priority. Useful when only the latest data is relevant.

Queue from Interrupts

Interrupt routines cannot wait. Queues offer special versions for use from interrupts:

```
void UART_handler(void) {
    u8 byte = UART->DR;
    queue_send_from_isr(&rx_queue_isr, &byte);  // Never waits, error if full
}
```

3.1.8 3.8 Event Groups

Event Groups are a set of 32 flags that allow a task to wait for combinations of events:

```
// Task A: signals that the sensor is ready
event_set(&group, BIT_SENSOR_OK);

// Task B: signals that the display is ready
event_set(&group, BIT_DISPLAY_OK);

// Task C: waits until BOTH are ready
event_wait_all(&group, BIT_SENSOR_OK | BIT_DISPLAY_OK, timeout);
// Or: wait until AT LEAST ONE is ready
event_wait_any(&group, BIT_SENSOR_OK | BIT_DISPLAY_OK, timeout);
```

Event Groups are lightweight and allow for complex synchronization without many separate structures.

3.1.9 3.9 Task Notification

Task Notification is a direct method for communicating between tasks, without intermediate data structures. Each task has a built-in notification value:

```
// Task A sends a notification to Task B
notify_send(task_b_id, value, NOTIFY_SET_BITS);

// Task B waits for the notification
u32 val = notify_wait(true, timeout);  // true = clear on wake-up
```

Advantages over semaphore

- **No extra memory consumption**: uses a field already present
- **Faster**: no data structures to manage
- **More flexible**: can carry a value

Limitations

- **Point-to-point**: only one task can wait (no waiting “queue”)
- **Risk of loss**: if the task is not waiting when the notification arrives, it might not see it

3.1.10 3.10 Deadlock

What is Deadlock

Deadlock is a situation in which two or more tasks block each other, each waiting for a resource held by the other:

```
Task A: takes resource_1      OK
Task B: takes resource_2      OK
Task A: looks for resource_2      BLOCKED (Task B owns it)
Task B: looks for resource_1      BLOCKED (Task A owns it)
// Both blocked forever!
```

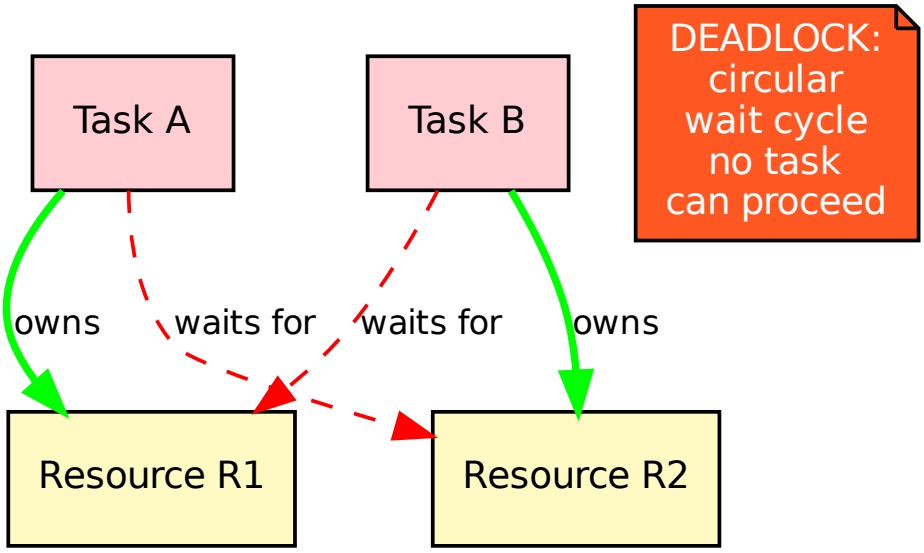

Figure 3.2: Deadlock between two tasks

How to avoid it

- **Fixed order**: always acquire resources in the same order in all tasks
- **Timeout**: use versions with a timeout to avoid infinite waiting
- **Acquire all at once**: acquire all necessary resources at once
- **Minimize sharing**: reduce the number of shared resources

Chapter 5

Embedded I/O: Drivers, Sensors, Timers

5.1 Chapter 5 - Embedded I/O: Drivers, Sensors, and Timers

A microcontroller without peripherals is useless. Its raison d'être is to interact with the outside world: reading sensors, controlling actuators, and communicating with other devices. In this chapter, we see how an RTOS handles I/O and timers.

5.1.1 5.1 GPIO (General Purpose Inputs/Outputs)

What is a GPIO

Every pin of a microcontroller can be configured as a digital input or output. This is the simplest form of I/O:

- **Output**: turning on an LED, controlling a relay, generating a signal
- **Input**: reading a button, a digital sensor, an external signal

GPIO Registers on STM32

Each GPIO port (A, B, C, ...) is controlled by special registers:

Register	Function
MODER	Mode: input, output, alternate function, analog
OTYPER	Output type: push-pull or open-drain
OSPEEDR	Speed: low, medium, high, very high
PUPDR	Internal pull-up/pull-down resistor
IDR	Input data register (read)
ODR	Output data register (write)
BSRR	Bit set/reset register (safe write)
AFR[2]	Alternate function (selects peripheral: UART, SPI, I2C...)

Basic configuration

```
// Example: configure PA5 as a push-pull output, high speed
GPIOA->MODER   &= ~(3 << (5*2));     // Clear the field
GPIOA->MODER   |=  (1 << (5*2));     // Output mode
GPIOA->OTYPER  &= ~(1 << 5);         // Push-pull
GPIOA->OSPEEDR |=  (3 << (5*2));     // Very high speed

```

```
// Safe write (no concurrency problem)
GPIOA->BSRR = (1 << 5);             // Turn PA5 on (LED)
GPIOA->BSRR = (1 << (5 + 16));      // Turn PA5 off (LED)
```

The BSRR register is particularly important: it allows setting or resetting a single pin with a single safe write, without having to perform a read-modify-write operation as with ODR.

The compatibility problem

GPIO registers change from one STM32 model to another: - **F1xx**: uses CRL/CRH with different encoding (4 bits per pin) - **F4xx/F7xx/H5xx/H7xx**: uses MODER/OTYPER-/OSPEEDR (2 bits per pin in MODER) - **Clock enabling**: different RCC registers for each model

A portable GPIO driver must hide these differences behind a common interface.

HAL vs Direct Code

ST provides the HAL (Hardware Abstraction Layer), a library that hides the registers. However:

	HAL	Direct Code
Portability	High (between STM32)	Low (requires abstraction)
Overhead	Significant	Zero
Code size	Large	Minimal
Control	Limited	Total
Debug	Difficult (many layers)	Direct (registers visible)

For a bare-metal RTOS, the natural choice is to write your own drivers with a minimal abstraction layer: a generic interface that calls model-specific functions.

5.1.2 5.2 Driver model: Weak Functions

The problem

A driver must work on different microcontrollers. The general logic (e.g., “configure this pin as output”) is the same, but the hardware details change.

The solution: Weak Functions

The **weak functions** model leverages a feature of the GNU linker:

```
// driver_generico.c - Logica comune
__attribute__((weak))
GPIO_TypeDef* get_port(u8 port_id) {
    return NULL;  // Default: no implementation
}

void gpio_configure(u8 port, u8 pin, u8 mode) {
    GPIO_TypeDef *hw = get_port(port);  // Call the specific version
    if (hw == NULL) return;
    hw->MODER = ...;  // Logic common to all families
}
```

```
// driver_f4xx.c - Replacement for F4xx
GPIO_TypeDef* get_port(u8 port_id) {
    // F4xx-specific table
    GPIO_TypeDef *ports[] = {GPIOA, GPIOB, GPIOC, ...};
    return ports[port_id];
}
```

The linker automatically chooses the "strong" (non-weak) version if present, otherwise it uses the default weak one. When compiling for F4xx, `driver_f4xx.c` is included; when compiling for H7xx, `driver_h7xx.c` is included. The generic code does not change.

Advantages of the model

- **Shared generic code**: common logic is written only once
- **Expandability**: adding a new model only requires a new replacement file
- **No #ifdef**: the code is clean, without complex preprocessor directives
- **Safe default**: if a weak function is not replaced, the default (no action or error) prevents crashes

5.1.3 5.3 UART (Universal Asynchronous Receiver/Transmitter)

What is UART

UART is the simplest and most widespread serial communication peripheral. Two wires (TX, RX), no shared clock, bidirectional communication. Used for:

- Debugging (text on PC terminal)
- Communication with modules (GPS, Bluetooth, WiFi)
- Communication between microcontrollers

Configuration parameters

- **Baudrate**: speed in bits/second (9600, 115200, 921600...)
- **Data bits**: typically 8
- **Parity**: None, Even, Odd
- **Stop bits**: 1 or 2

UART and RTOS

UART presents specific challenges in a multitask environment:

Transmission: if multiple tasks write to the same UART, messages get mixed up. A mutex or a transmission queue is needed:

```
// Approach 1: mutex
mutex_take(&uart_mtx);
uart_send("complete message\r\n");
mutex_release(&uart_mtx);

// Approach 2: message queue
queue_send(&uart_tx_queue, &message, timeout);
// A dedicated task drains the queue and transmits
```

Reception: bytes arrive at any time, regardless of who is waiting for them. Typical handling:

```
// Interrupt routine: saves every byte received
void UART_IRQHandler(void) {
    u8 byte = UART->DR;
    queue_send_from_isr(&rx_queue, &byte);
}

// Task: process the data
void task_rx(void) {
    while (1) {
        u8 byte;
        queue_receive(&rx_queue, &byte, WAIT_FOREVER);
```

```
        process_byte(byte);
    }
}
```

5.1.4 5.4 Communication buses: SPI and I2C

SPI (Serial Peripheral Interface)

Synchronous, bidirectional, master-slave bus. Four wires: - **MOSI**: Master Out, Slave In - **MISO**: Master In, Slave Out - **SCK**: Clock (generated by the master) - **CS**: Chip Select (one wire for each slave)

Fast (up to tens of MHz), but requires many pins. Used for: displays, external flash, fast ADCs.

I2C (Inter-Integrated Circuit)

Synchronous, half-duplex, multi-master bus. Two wires: - **SDA**: Data - **SCL**: Clock

Slow (100KHz-1MHz standard), but requires only 2 pins and supports many devices on the same bus. Used for: sensors (temperature, accelerometer), EEPROM, RTC.

Bus management in an RTOS

A shared bus (SPI or I2C) requires mutual exclusion:

```
// Access to the SPI bus shared by sensor and display
mutex_take(&spi_bus_mtx);
cs_select(SENSORE);
spi_transfer(tx_buf, rx_buf, len);
cs_deselect(SENSORE);
mutex_release(&spi_bus_mtx);
```

Without the mutex, a task switch during the SPI transfer would leave the chip select active and the bus in an inconsistent state.

5.1.5 5.5 Hardware Timers

Timers as time bases

Hardware timers are counters that increment (or decrement) at every clock cycle (or at a divided frequency). When they reach a programmed value, they generate an interrupt.

Main uses: - **SysTick**: the RTOS heartbeat (see Chap. 2) - **Timeout**: measuring time intervals - **PWM**: generating variable duty-cycle signals (e.g., motor control, LED brightness) - **Input Capture**: measuring the duration of an external signal - **Performance analysis**: measuring code execution time

Software Timers in an RTOS

Software timers are built on top of the RTOS heartbeat. A “timer daemon” task runs at high priority and manages a list of active timers:

```
// Periodic timer creation
timer_create(&t, "heartbeat", 1000, PERIODICO, callback);
timer_start(&t);

// The callback is called in the timer daemon context
void callback(timer_t *t) {
    toggle_led();  // Every 1000ms
}
```

Advantages over hardware timers: - Unlimited number (limited only by RAM) - Callbacks executed in a task context (can use mutexes, queues, etc.) - Portable across microcontrollers

Disadvantages: - Resolution limited to the RTOS tick rate - Jitter: the callback is executed when the timer daemon is scheduled, not exactly at the millisecond

One-shot vs Periodic

- **One-shot**: expires only once. Useful for timeouts (e.g., "if I don't receive a response within 500ms, signal an error")
- **Periodic**: reloads automatically. Useful for repetitive actions (e.g., sensor sampling every 100ms)

5.1.6 5.6 Time measurement and performance analysis

DWT Cycle Counter

The Cortex-M3/M4/M7 has a hardware cycle counter (DWT CYCCNT) that counts every clock cycle:

```
CoreDebug->DEMCR |= CoreDebug_DEMCR_TRCENA_Msk;
DWT->CYCCNT = 0;
DWT->CTRL |= DWT_CTRL_CYCCNTENA_Msk;

// Misura
u32 start = DWT->CYCCNT;
function_to_measure();
u32 end = DWT->CYCCNT;
u32 cycles = end - start;
// Time = cycles / clock_frequency
```

Precision: 1 clock cycle (e.g., ~6ns at 168MHz). Ideal for precise performance analysis.

Hardware timers for analysis

As an alternative to the DWT, a hardware timer (e.g., TIM2, 32-bit) can be configured to count freely:

```
// TIM2 a 1MHz (prescaler = clock/1000000)
u32 start = TIM2->CNT;
function_to_measure();
u32 end = TIM2->CNT;
u32 microsecondi = end - start;
```

5.1.7 5.7 Interrupts and I/O: the RTOS challenge

Deferred Interrupt Processing

Interrupt routines must be short. The recommended practice is **deferred processing**:

1. The routine does the bare minimum (reads the register, clears the flag)
2. It signals a task via semaphore, notification, or queue
3. The task performs the heavy processing

```
// Routine: fast (< 1us)
void ADC_IRQHandler(void) {
    u16 value = ADC1->DR;        // Read data
    ADC1->SR &= ~ADC_SR_EOC;      // Clear the flag
    queue_send_from_isr(&adc_q, &value);  // Hand over to the task
```

```
}

// Task: elaborazione pesante
void task_adc(void) {
    while (1) {
        u16 value;
        queue_receive(&adc_q, &value, WAIT_FOREVER);
        // Filter, moving average, unit conversion...
        risultato = filter_and_convert(value);
    }
}
```

Interrupt priorities and RTOS

On Cortex-M, interrupt levels are divided into two groups:

- **Above BASEPRI**: ultra-high priority interrupts that are never disabled by the RTOS. They cannot use RTOS APIs (no queues, semaphores, etc.)
- **Below BASEPRI**: interrupts managed by the RTOS. They can use `_isr` APIs (queue_send_isr, sem_signal_isr, etc.)

```
Interrupt priority (0 = highest on Cortex-M):
  0-3: NOT managed by the RTOS ("bare" routines, no OS API)
  4-15: Gestite dall'RTOS (possono usare API _isr)

SysTick: typically low priority (e.g. 15)
PendSV:  lowest possible priority (255)
```

Previous chapter: Memory Next chapter: Reliability - Watchdog, Errors and Updates

---

Previous chapter: Memory Next chapter: Reliability - Watchdog, Errors and Updates

Chapter 6

Reliability: Watchdog, Errors, OTA

6.1 Chapter 6 - Reliability: Watchdog, Error Handling and Updates

An embedded system must function even when things go wrong. Unlike a PC application where the user can close and reopen the program, an embedded microcontroller is often installed in inaccessible places and must operate for months or years without human intervention. Reliability is not optional: it is a requirement.

6.1.1 6.1 Types of errors in embedded systems

Hardware errors

- **Brown-out**: the supply voltage drops below the minimum. The processor may execute incorrect instructions before resetting
- **Bit flip**: cosmic radiation or electromagnetic interference can flip a bit in RAM (rare, but real in space or high-altitude systems)
- **Peripheral locked**: an I2C bus in a stall, a sensor that does not respond
- **Clock failure**: the external crystal stops oscillating

Software errors

- **Stack overflow**: the task exceeds its stack (see Ch. 2)
- **Null pointer access**: access to address 0x00000000
- **Division by zero**: causes an error on Cortex-M
- **Memory corruption**: a task overwrites data of another task
- **Deadlock**: two tasks blocked by each other (see Ch. 3)
- **Starvation**: a task never receives CPU time

Logical errors

- **Watchdog timeout**: a task does not complete its cycle in time
- **Check failure**: a condition that "should never be false" is false
- **Arithmetic overflow**: a calculation produces a result out of range

6.1.2 6.2 Cortex-M errors

The ARM Cortex-M processor has a hierarchical error system to handle hardware problems:

General error (HardFault)

The “catch-all” error. If a more specific error is not enabled, the processor enters HardFault. Common causes: - Access to an invalid address - Execution of an invalid instruction - Error during the handling of another error (double fault)

Memory management error (MemManage Fault)

Generated by the protection unit when a protected region is violated: - Writing to a read-only region (e.g., stack canary) - Access to a region with “No access” permission - Execution of code from a non-executable region

Bus error (BusFault)

Error on the system bus: - Access to a non-existent address - Unaligned access to a peripheral that requires alignment - Error during instruction fetch

Usage error (UsageFault)

Error in the use of the processor: - Undefined instruction - Unaligned access (if not permitted) - Division by zero (if checking is enabled) - Attempt to switch to ARM state (Cortex-M only supports Thumb)

Error status registers

The Cortex-M provides registers that indicate the precise cause of the error: | Register | Information | |———-|————-| | CFSR (Configurable Fault Status Register) | Combines MMFSR, BFSR, UFSR | | MMFSR | Memory management fault: which MPU violation | | BFSR | Bus fault: type of bus error | | UFSR | Usage fault: type of usage error | | HFSR | Hard fault: escalation or forced | | MMFAR | Address that caused the Memory management fault | | BFAR | Address that caused the Bus fault |

Reading these registers in the fault handler allows for precise diagnosis of the cause of the problem.

6.1.3 6.3 Fault handler in an RTOS

The problem

When a fault occurs in a task, what should the RTOS do?

- **Total reset**: simple but drastic. All tasks restart from scratch
- **Remove the task**: isolate the problem, other tasks continue
- **Restart the task**: if the task is repeatable, restart from the beginning
- **Emergency handler**: call a cleanup function before taking action

Saving registers

A good fault handler saves diagnostic information before taking action:

```
=== ERRORE GENERALE ===
Task: "sensore" (ID: 3)
PC:  0x08001234  (indirizzo dell'istruzione che ha causato l'errore)
LR:  0x08001200  (chi ha chiamato la funzione)
SP:  0x2001E7F0  (puntatore stack al momento dell'errore)
CFSR: 0x00020000 (INVSTATE - tentativo di eseguire istruzione invalida)
```

This information is fundamental for debugging. The PC indicates where the problem occurred, the LR indicates who called the function, and the CFSR indicates the type of error.

Recovery policies for tasks

A robust RTOS allows configuring the recovery policy for each task:

```
// Task critico: riavvia automaticamente
os_job("sensore", ..., FAULT_RESTART);

// Task non critico: rimuovi e basta
os_job("display", ..., FAULT_REMOVE);

// Task con pulizia: chiama gestore poi riavvia
os_job("comunicazione", ..., FAULT_EMERGENCY | FAULT_RESTART);
```

6.1.4 6.4 Watchdog Timer

Concept

The watchdog timer (WDT) is a hardware timer independent of the processor. If it is not "kicked" within a programmed time, it resets the processor. It is the last line of defense against software hangs.

```
// Configurazione
watchdog_init(tempo_limite_ms);
watchdog_start();

// Nel loop principale (o nel task dedicato)
while (1) {
    esegui_operazioni();
    watchdog_kick();    // "Sono ancora vivo"
}
```

If the software hangs (infinite loop, deadlock, crash), the watchdog is not updated and resets the entire system after the timeout period.

IWDG vs WWDG on STM32

STM32 has two watchdog timers:

IWDG (Independent Watchdog): - Independent clock (LSI ~32KHz) - Works even if the main clock fails - Configurable timeout from ~125us to ~32s - Once enabled, it cannot be disabled (until reset)

WWDG (Window Watchdog): - Clock derived from the APB bus - Has a "window": the update must occur within a precise interval, not too early and not too late - Generates an interrupt before the reset (allows for save operations)

Watchdog and RTOS

In an RTOS, the watchdog must monitor **all** tasks, not just one. The strategies:

Approach 1: Watchdog task

```
Task watchdog (alta priorit ):
  while (1) {
    if (task_1_vivo && task_2_vivo && task_3_vivo) {
      watchdog_kick();
      resetta_flag;
    }
    sleep(tempo_limite / 2);
  }

Ogni task: imposta il proprio flag vivo ad ogni ciclo
```

Approach 2: Notification chain

```
Task 1     notifica     Task 2     notifica     Task 3     notifica     aggiorna
    watchdog
```

If any task hangs, the chain is broken and the watchdog expires.

6.1.5 6.5 Checks and Safety

Classic check

The check is the simplest verification mechanism:

```
assert(ptr != NULL);         // Se falso, interruzione()
assert(indice < DIM_ARRAY); // Controllo limiti
```

On a microcontroller, `interruzione()` typically causes an infinite loop or a reset. The information is minimal: it is only known that a check has failed.

Safety: advanced control

A Safety system goes beyond simple control:

1. **Identify the task**: which task caused the error
2. **Record information**: message, file, line, variable values
3. **Apply the policy**: remove, restart, or emergency handler
4. **Continue execution**: other tasks are not affected

```
// Controllo con messaggio
SAFEGUARD(ptr != NULL, "Buffer non allocato");

// Se ptr    NULL:
// 1. Log: "SAFEGUARD FAIL: Buffer non allocato [task: sensore, riga: 42]"
// 2. Chiama gestore emergenza se configurato
// 3. Rimuove o riavvia il task secondo la politica
// 4. Lo scheduler continua con gli altri task
```

Severity levels

A robust system distinguishes between different levels:

- **Warning**: anomalous but non-critical situation, the task continues
- **Error**: the task cannot continue, it is removed/restarted
- **Panic**: the system cannot continue, total reset

6.1.6 6.6 Protection against corruption

Stack Canary + MPU

As seen in Chap. 2, the combination of software canary and hardware MPU protection is the best defense against stack overflow.

Data structure integrity

Critical kernel structures can be protected with:

- **Magic number**: a constant value at the beginning of the structure. If corrupted, the structure is invalid
- **Checksum**: a CRC calculated on the state of the structure, verified periodically

- **Redundancy**: duplication of critical variables (counter a + counter b, they must be equal)

```c
typedef struct {
    u32 magic;          // Deve essere 0xCAFEBABE
    u32 stato;
    u32 contatore;
    u32 checksum;       // CRC32 dei campi precedenti
} struttura_critica;
```

ECC (Error Correcting Code)

Some microcontrollers (such as the H5xx) have ECC on RAM: they can correct single-bit errors and detect double-bit errors. This protects against bit flips caused by interference.

6.1.7 6.7 Reset and Recovery

Reset types on STM32

Type	Cause	Effect
Power-On Reset	Power-up	Full reset
NRST Pin	External pin	Full reset
IWDG Reset	Watchdog expired	Full reset
WWDG Reset	Window watchdog	Full reset
Software Reset	`NVIC_SystemReset()`	Full reset
Brown-Out Reset	Low voltage	Full reset

Determining the reset cause

After a reset, the RCC_CSR register indicates the cause:

```c
if (RCC->CSR & RCC_CSR_IWDGRSTF) {
    // Reset causato dal watchdog
    log("IWDG reset detected");
}
if (RCC->CSR & RCC_CSR_BORRSTF) {
    // Brown-out
    log("Power issue detected");
}
RCC->CSR |= RCC_CSR_RMVF;  // Cancella flag
```

This information is valuable for diagnostics: if the system repeatedly resets due to a watchdog, there is a blocking bug in the software.

Persistent state across resets

RAM is not cleared by a software or watchdog reset (only by a power-on reset). It is possible to use a RAM region marked `noinit` to maintain information between resets:

```c
__attribute__((section(".noinit")))
static u32 contatore_crash;

__attribute__((section(".noinit")))
static u32 ultimo_errore_pc;
```

This allows counting crashes and identifying error patterns.

6.1.8 6.8 Firmware Update (OTA)

The problem

An embedded device installed in the field needs software updates for bug fixes or new features. However, a failed update can “brick” the device (render it unusable).

Dual-bank bootloader

The standard solution is the **dual-bank firmware update**:

```
Flash:

    Bootloader (16KB)        Sempre presente, non aggiornabile

    Bank A: Firmware             Versione corrente (in esecuzione)
    (es. 512KB)

    Bank B: Firmware             Nuova versione (in download)
    (es. 512KB)

```

The process: 1. The current firmware (Bank A) downloads the new firmware into Bank B 2. Verifies integrity (CRC, digital signature) 3. Signals the bootloader to start Bank B at the next reset 4. Reset 5. The bootloader verifies Bank B and starts it 6. If Bank B does not work (watchdog reset), the bootloader returns to Bank A

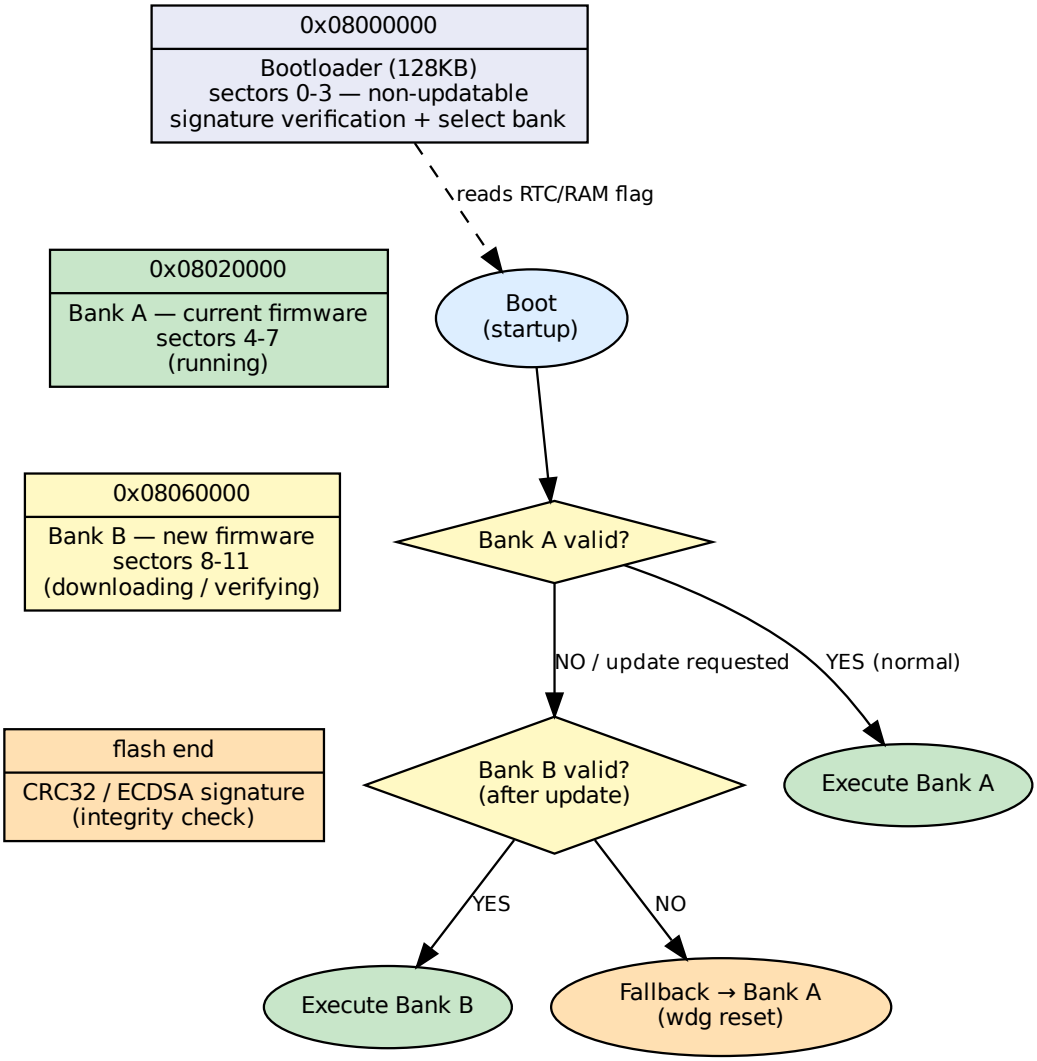

Figure 6.1: Dual-bank OTA flash layout

Firmware digital signature

To prevent the installation of unauthorized firmware:

```
Firmware = image + header
The header holds:
  - version
  - size
  - hash of the code (integrity: SHA-256)
  - signature (identity: e.g. Ed25519, ECDSA), checked with the public key in
    the bootloader
```

The bootloader verifies the signature before executing the new firmware. Without the private key (which remains on the build server), it is impossible to create fraudulent firmware. CRC is sufficient against transmission errors, but not against someone intentionally altering the image: for this reason, integrity relies on a cryptographic hash and identity on a signature.

In caOS

caOS provides a complete bootloader as a workspace application, `workspace/app_2`, for NUCLEO-H563ZI and NUCLEO-H753ZI. It follows the scheme just described:

- default map 512 + 512 + 512 KB: bootloader and slot A in bank 1, slot B in bank 2; the map is in `caos/inc/boot_image.h` and can be customized according to needs (bootloader size versus image size, guide §1.1);
- `.cimg` images with 1 KB header, mandatory SHA-256 and Ed25519 signature (`tools/caos_image.py`);
- network update: the PC pushes the image via TFTP (`tools/caos_tftp`), both to the bootloader in recovery and to the running image;
- the new image starts **in trial mode**, with the IWDG armed and attempts counted in a backup register; if it is not confirmed within three boots, the bootloader reverts to the previous one (rollback).

The transition from the bootloader to the image occurs with `ca_os_end()`, which shuts down caOS and resets the hardware as if after a reset. The image side is in the kernel (`caos/inc/boot_image.h`, flag `EN_BOOT_IMAGE`). Complete guide: `workspace/app_2/doc/app_2_user_guide.md`.

Previous chapter: Embedded I/O

End of Section 1 - General Concepts
Section 2: How caOS implements these concepts

Part I

caOS Implementation

Chapter 7

caOS Overview

7.1 Chapter 7 - Overview of caOS

7.1.1 7.1 What is caOS?

Coppi **A**ngelo **O**perating **S**ystem (caOS) is a lightweight operating system designed for ARM Cortex-M microcontrollers. Born as an adapted version of a project for Raspberry Pi (Cortex-A), it has been completely rewritten to work on the Cortex-M architecture, supporting 9 different STM32 microcontrollers distributed across 6 different families.

Basic Principles

- **Pure bare metal**: no dependency on external libraries such as ST HAL. Direct access to hardware registers
- **Easy to port**: general logic is separated from specific implementation for each microcontroller family
- **Single include**: all `.c` files in the project include only `caos.h`, which in turn includes all necessary modules
- **Simplified types**: `u8`, `u16`, `u32`, `i8`, `i16`, `i32`, `cstr` instead of standard types

Main Features

Category	Features
Scheduling	weight-based proportional (similar to CFS), 7 priority levels, 1 tick per switch, context switch only on task change
Synchronization	Mutex, Recursive Mutex, Semaphore, Condition Variable, Interrupt-safe Spinlock
Communication	Queue (FIFO/LIFO), Event Groups (32-bit), Task Notification, Stream Buffer, Message Buffer
Memory	Dynamic allocation (SRAM) with owner tracking, stack allocation in CCM/DTCM
Protection	Memory Protection Unit (MPU) to protect stacks and heap boundaries, error detection
Timers	Software Timer (one-shot and periodic), up to 16 simultaneously

Category	Features
Debug	Asynchronous two-channel audit log, UART command-line interface, detailed task information
Reliability	Safety checks with recovery policies for tasks, error handler with diagnostic information

7.1.2 7.2 Project Structure

Three-Level Organization

caOS is organized in three distinct levels:

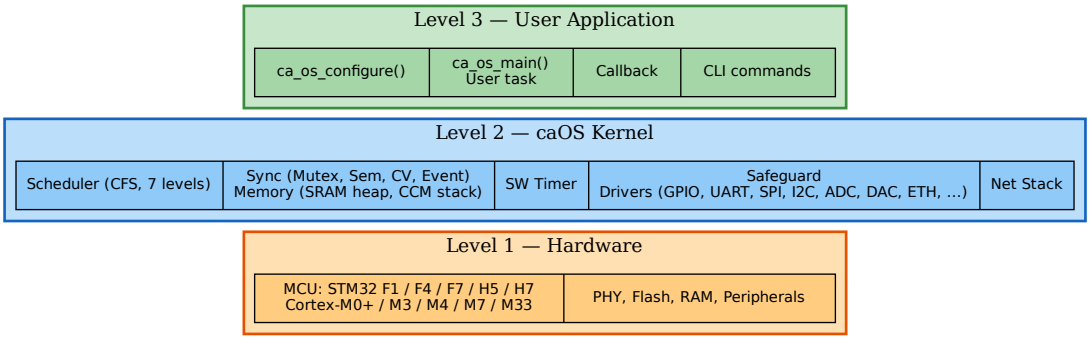

Figure 7.1: Three-level organization

Folder Structure

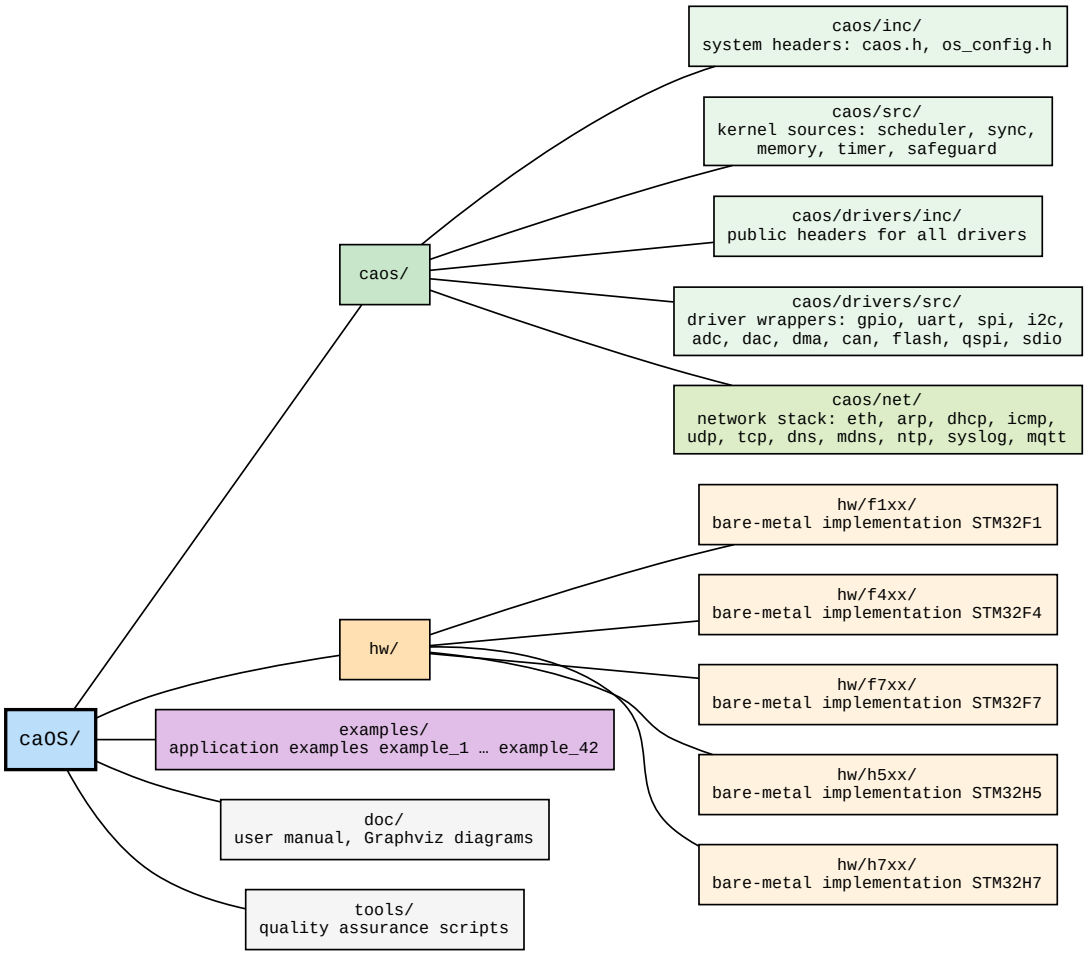

Figure 7.2: Folder structure

Include Schema

All `.c` files in the project use a single include:

```
1 #include "caos.h"
```

`caos.h` includes all modules automatically: `common.h`, `scheduler.h`, `sync.h`, `log.h`, `queue.h`, `event.h`, `notify.h`, `timer.h`, `memory.h`, `mpu.h`, `safeguard.h`, `stream.h`, `message.h`, `cli.h`, `gpio_driver.h`, `uart.h`, `atomic.h`, `memaux.h`, etc.

This approach simplifies the management of includes and avoids dependency issues between headers.

7.1.3 7.3 Supported Microcontrollers

MCU	Core	Clock	Flash	SRAM	TCM	Status
STM32F103C8T6	Cortex-M3	72MHz	64KB	20KB	-	Base (no MPU, no FPU)
STM32F407VET6	Cortex-M4F	168MHz	512KB	128KB	64KB CCM	Complete
STM32F429ZIT6	Cortex-M4F	180MHz	2MB	256KB	64KB CCM	Complete
STM32F446ZET6	Cortex-M4F	180MHz	512KB	128KB	-	Complete
STM32F746ZGT6	Cortex-M7	216MHz	1MB	320KB	64KB DTCM	Complete
STM32H563ZIT6	Cortex-M33	250MHz	2MB	640KB	-	Complete
STM32H747XIH6	Cortex-M7+M4	480MHz	2MB	1MB	128KB DTCM	In development (clock issue)
STM32H753ZIT6	Cortex-M7	480MHz	2MB	512KB	128KB DTCM	Complete
STM32U575ZIT6	Cortex-M33	160MHz	2MB	784KB	-	Complete (no ETH)

Differences between families

Feature	F1xx (M3)	F4xx (M4F)	F7xx (M7)	H5xx (M33)	H7xx (M7)	U5xx (M33)
FPU (Floating Point Unit)	No	Yes	Yes (double)	Yes	Yes (double)	Yes
MPU (Memory Protection Unit)	No	Yes (8 regions)	Yes (8/16)	Yes (16)	Yes (16)	Yes (16)
TCM (TCM - Tightly Coupled Memory)	No	CCM 64KB	DTCM 64KB	No	DTCM 128KB	No
GPIO Registers	CRL/CRH	MODER/OTYPER	MODER/OTYPER	MODER/OTYPER	MODER/OTYPER	MODER/OTYPER
GPIO Clock RCC Registers	APB2ENR	AHB1ENR	AHB1ENR	AHB2ENR	AHB4ENR	AHB2ENR1

7.1.4 7.4 caOS Modules

Complete Overview

Module	Header	Description
Kernel		
Scheduling	scheduler.h	RTOS core: tasks, context switch, suspend/resume
Atomic	atomic.h	Interrupt-safe spinlocks, LDREX/STREX atomic operations
SysTick	systick.h	System timer configuration
Synchronization		
Sync	sync.h	Mutex, Recursive Mutex, Semaphores, Condition Variables, Critical Sections
Communication		
Queue	queue.h	FIFO/LIFO queues (static and dynamic) with timeouts
Event	event.h	32-bit Event Groups (wait for any/all)
Notify	notify.h	Direct task notifications (zero overhead)
Stream	stream.h	Circular byte stream buffer with activation level
Message	message.h	Message buffers with atomic framing
Memory		
Memory	memory.h	Dynamic allocation with proprietary tracking
MPU	mpu.h	Memory protection (conditional on `__MPU_PRESENT`)
MemAux	memaux.h	Memory/string functions (newlib replacement)
Debug and diagnostics		
Log	log.h	Asynchronous two-channel audit log (audit + stdout)
CLI	cli.h	UART command-line interface
ITM	itm.h	SWO/ITM output for debugging
Measure	measure.h	Profiling via TIM2
Reliability		
SafeGuard	safeguard.h	Task monitoring with recovery policies
Panic	panic.c	Critical error handler with diagnostic info
Bus	bus.h	BusFault exception handler
Drivers		
GPIO	gpio_driver.h	GPIO abstraction with weak functions
UART	uart.h	UART debug with weak functions
Cryptography		
CRC32	crc32.h	Hardware CRC32 calculation (data integrity)

Module	Header	Description
HASH	hash.h	Hardware SHA-1 / SHA-256 with multithreading context swap
AES	aes.h	Hardware AES-256 ECB/CBC/CTR/GCM with context swap
RNG	rng.h	Hardware True Random Number Generator
Keys Store	keys_store.h	Secure storage of cryptographic keys via MPU
Utilities		
Utils	utils.h	Utility types and functions

7.1.5 7.5 Configuration

caOS configuration is centralized in file `os_config.h` (automatically included by `common.h` via `config.h`):

```
// Output debug
ENABLE_ITM          0|1     // Debug via SWO (Instrumentation Trace Macrocell)
ENABLE_DBG_UART     0|1     // Debug via UART
ENABLE_STDOUT       0|1     // stdout channel (ca_stdout_*)
ENABLE_CLI          0|1     // Command-line interface

// UART debug
UART_DBG_NUM        1-12    // UART number for debug
UART_DBG_BAUDRATE   ...     // Baudrate (es. 115200)
```

Disabled features become empty macros with no overhead:

```
// Se ENABLE_STDOUT == 0:
#define ca_stdout_printf(...)       0   // Compila in nulla
#define ca_stdout_set_repeater(hook)    // idem
```

7.1.6 7.6 Build System

Toolchain

caOS uses arm-none-eabi-gcc (included in STM32CubeIDE) and CMake.

Main Commands

```
source ./source_this        # Set up the toolchain PATH (once per session)
./bootstrap Debug           # Configure CMake (Debug or Release)
./do                        # Compila
./distclean                 # Clean everything
./rebuild                   # distclean + bootstrap + do
```

Microcontroller Selection

In `cpu.cmake`:

```
set(CURR_MCU "F407")  # F103|F407|F429|F446|F746|H563|H747|H753|U575
```

Changing this line and executing `./rebuild` is sufficient to compile for a different microcontroller. The build system automatically selects the correct startup files, linker scripts, drivers and configuration.

Programming

```
./prog.sh -j -f elfs/f407.elf     # J-Link
./prog.sh -s -f elfs/h753.elf     # ST-Link
```

7.1.7 7.7 Entry point: ca_os_main()

The user application does not write `main()` — this function is managed by the kernel. The user implements `ca_os_main()`, which is called after system initialization:

```
#include "caos.h"

void ca_os_main(void) {
    // The hardware is already initialized (clock, GPIO, UART, MPU...)
    // The scheduler is already initialized
    // The log is already active

    // Crea i task dell'applicazione
    ca_os_job("task_a", CA_TH_LEVEL3, my_task_a, NULL,
              STACK_MEDIUM, CA_JOB_STD, CA_FAULT_ASSERT);

    ca_os_job("task_b", CA_TH_LEVEL2, my_task_b, NULL,
              STACK_SMALL, CA_JOB_STD, CA_FAULT_RESTART_THREAD);

    // Start the scheduler (never returns)
    ca_os_run(true);
}
```

7.1.8 7.8 Configurable Tick

Unlike most RTOS that use a fixed tick (typically 1ms), caOS uses a configurable tick per family of microcontrollers via `OS_TICK_US` in `objmap.h`:

MCU	OS_TICK_US	Clocks/tick
F103	2 ms	144K
F4xx	250 us	42K
F746/F767	200 us	43.2K
H563	100 us	25K
H747/H753	100 us	40K/48K
U575	250 us	40K

The tick only costs the SysTick: context switches occur when tasks change, not at every tick (S2_02 §8.4, *Fette*). Therefore, the scheduler cost depends on task switches and the number of tasks, because each context switch checks the canary of all stacks: measurements and table in S2_02 §8.5, *Scheduler Cost*.

The suspension APIs automatically convert milliseconds to ticks:

```
ca_os_sleep(100);  // Sleeps 100ms regardless of the configured tick
// Internally: tick = (100 * 1000) / OS_TICK_US
```

Next chapter: The caOS Kernel

Chapter 8

caOS Features

8.1 caOS Features

Overview of the features offered by caOS, organized by functional area.

8.1.1 1. Scheduler and Kernel

Execution model

Feature	Detail
Scheduling model	weighted proportional, virtual time (inspired by Linux CFS), 1 tick per slice, switch only on task change
Priority levels	7 (from `CA_TH_LEVEL0` to `CA_TH_LEVEL6`)
Task creation	`ca_os_job()` — allocates stack + control block (TCB)
Thread pool	`EN_POOL=1` — pre-allocated reusable pool for dynamic jobs
Block pool	`EN_BLOCK_POOL=1` — fixed-size block allocation O(1)
Context switch	PendSV at end of slice (SysTick); tick configurable per MCU via `OS_TICK_US`
Stack per family	CCM/DTCM for MCUs that have it; SRAM otherwise
MAX_TASK	Configurable per MCU (e.g., H753: 93, U575: 93, F103: limited by SRAM)

System tick

MCU	OS_TICK_US	Clocks/tick
F103	2 ms	144K
F4xx	250 µs	42K
F746/F767	200 µs	43.2K
H563	100 µs	25K
H747/H753	100 µs	40K/48K

MCU	OS_TICK_US	Clocks/tick
U575	250 µs	40K

The tick only costs the SysTick; context switching occurs when the task changes (see S2_02 §8.4, *Slices*).

`ca_os_sleep(ms)` uses an **absolute deadline in ticks** (immune to `yield`); the limit for a single call is ~24.8 days (2^{31} ticks). Details in the Kernel chapter → *Timed suspension.*

Synchronization

Primitive	Header	Notes
Mutex	sync.h	With priority inheritance
Recursive mutex	sync.h	Reentrant from the same task
Semaphore	sync.h	Binary and counting
Condition variable	sync.h	`ca_cond_wait` / `ca_cond_signal`
Spinlock	atomic.h	ISR-safe, LDREX/STREX
RWLock	sync.h	`EN_RWLOCK` — multiple readers / exclusive writer
Barrier	sync.h	`EN_BARRIER` — N-task synchronization
Critical section	atomic.h	`ca_enter_critical` / `ca_exit_critical`

Inter-task communication

Primitive	Header	Features
Queue	queue.h	FIFO/LIFO, static and dynamic, timeout; `CAQUEUE_STATIC_SIZE`
Event Group	event.h	32-bit, wait ANY or ALL
Task Notify	notify.h	Zero overhead, direct between tasks
Stream Buffer	stream.h	Circular bytes with trigger level
Message Buffer	message.h	Messages with atomic framing

Memory

Module	Features
Dynamic allocation	`ca_memory_allocate` — heap with proprietary tracking (task)
MPU	Stack and heap protection (`__MPU_PRESENT`); 8 or 16 regions per MCU
MemAux	`ca_memcpy`, `ca_strlen`, `ca_strncmp` — newlib replacement
Profiling	`ca_measure_start/stop` via DWT CYCCNT (no HW timer occupied)

Reliability

Module	Function
SafeGuard	Recovery policy for tasks: `CA_FAULT_ASSERT`, `CA_FAULT_RESTART_THREAD`, `CA_FAULT_EXEC_EMERGENCY`
Panic	Critical error handler with diagnostic dump via UART/ITM
WDT	Hardware Watchdog IWDG/WWDG, reconfigurable IWDG enabled, reset cause (`ca_wdt_reset_cause()`)
BusFault	Handler `bus.h` with fault address logging

Debug and diagnostics

Tool	Description
CLI (`cli.h`)	UART command-line interface; handlers registerable via `ca_cli_register`
Stdout	Asynchronous channel `ca_stdout_printf` (one task, one queue); `ca_stdout_set_repeater` forwards every line to syslog, flash, file
ITM/SWO	SWO output for debugging with Segger J-Link
Software timer	`EN_SW_TIMER` — up to 16 one-shot and periodic software timers

---

8.1.2 2. Hardware Drivers

Each driver follows a two-level scheme:

```
caos/drivers/src/<periph>.c              extern declarations + API pubblica
hw/<family>/drivers/<periph>_<family>.c      bare-metal CMSIS, no HAL
```

Supported Peripherals

Driver	Header	Families	Notes
GPIO	gpio_driver.h	F1/F4/F7/H5/H7/U5	CRL/CRH on F1xx; MODER on all others
UART	uart.h	F1/F4/F7/H5/H7/U5	Debug + application; RX IRQ
SPI	spi.h	F1/F4/F7/H5/H7/U5	Polling; SPI v3 on H5/U5
I2C	i2c.h	F1/F4/F7/H5/H7/U5	Polling
ADC	adc.h	F1/F4/F7/H5/H7/U5	Polling; F1xx: EXTTRIG+EXTSEL=7 for SWSTART

Driver	Header	Families	Notes
DAC	dac.h	F4/F7/H5/H7/U5	F1xx stub (F103C8T6 no DAC)
DMA	dma.h	F1/F4/F7/H5/H7/U5	Completion semaphore; `in_use_dma` bitmask
EXTI	exti.h	F1/F4/F7/H5/H7/U5	`callbacks[16]`; pending clear differs by family
FLASH	flash.h	F1/F4/F7/H5/H7/U5	F1=16bit, F4/F7=32bit, H7=256bit, H5/U5=128bit
QSPI	qspi.h	F4/F7/H7/H5	F1=stub; F4 MCU_ID guard; H5=OCTOSPI (XSPI)
SDIO	sdio.h	F4/F7/H7/H5/U5	SDHC polling; CLKDIV formula differs by family
CAN	can.h	F1/F4/F7/H7/H5	bxCAN (F1/F4/F7), FDCAN (H7/H5)
TIMER	timer.h	F1/F4/F7/H5/H7/U5	General TIM; U575: no TIM12/13/14
RTC	rtc.h	F1/F4/F7/H5/H7/U5	BCD calendar; access via PWR unlock
WDT	wdt.h	All	IWDG (max 32.7 s; 131 s on H5/U5) + WWDG; reset cause
Temp Sensor	temp_sensor.h	H5/H7/U5	Factory calibration TS_CAL1/CAL2
ETH	eth.h	F4/F7/H7	RMII; HW checksum offload; not on H5/U5
CRC32	crc32.h	All	Hardware CRC
HASH	hash.h	F4/F7/H5/H7/U5	Hardware SHA-1/SHA-256; multithreading context swap

Driver	Header	Families	Notes
AES	aes.h	All	AES-128/256 ECB/CBC/CTR/GCM; HW where available (CRYP H7), otherwise software; context swap
RNG	rng.h	F4/F7/H5/H7/U5	Hardware True RNG
USB CDC	usb_cdc.h	—	(EN_USB_CDC, in development)
USB MSC	usb_msc.h	—	(EN_USB_MSC, in development)
USB NCM	usb_ncm.h	—	(EN_USB_NCM, in development)
USB DFU	usb_dfu.h	—	(EN_USB_DFU, in development)

GPIO RCC differences by family

Family	Register	Bus
F1xx	RCC->APB2ENR	APB2
F4xx	RCC->AHB1ENR	AHB1
F7xx	RCC->AHB1ENR	AHB1
H5xx	RCC->AHB2ENR	AHB2
H7xx	RCC->AHB4ENR	AHB4
U5xx	RCC->AHB2ENR1	AHB2

8.1.3 3. Network Stack

The stack is active with `EN_NET=1` (requires `EN_ETH=1` on MCUs with physical ETH).

Architecture

```
Applicazione

     Servizi applicativi
     MQTT    Modbus    iperf    HTTP    TFTP

     TCP/IP
     tcp_service    udp_server/client
     ip_defrag    route_service
```

```
Infrastruttura L2/L3
ARP    DHCP    DNS    mDNS
NTP    Syslog    Packet Tracer

Buffer pool 64 2048B   |  Ring queue

ETH driver (RMII, HW offload)
```

Modules and status

Module	File	Capacity	HW Status
Buffer pool	net_buf.c	64 × 2048B, O(1), metadata L2/L3/L4	
Ring queue	net_queue.c	Lock-free SPSC ISR/task	
L2 dispatcher	net.c	EtherType → handler table	
Parser/Builder	net_proto.c	ARP, IPv4, UDP, ICMP, DHCP, NTP, DNS, mDNS, Syslog	
ARP service	arp_service.c	Cache + blocking resolve	
Routing	route_service.c	Longest-prefix + GW + CLI	
UDP server	udp_server.c	Max 8 slots	
UDP client	udp_client.c	Max 16 handles, ephemeral ports	
DHCP service	dhcp_service.c	DORA + renew T1/T2	
NTP service	ntp_service.c	3 servers, callback on_sync/on_fail	
DNS service	dns_service.c	Query A record, blocking with timeout	
mDNS service	mdns_service.c	RFC 6762 responder	
Syslog service	syslog_service.c	Queue 8×128B, fire-and-forget	
TCP client	tcp_service.c	PCB pool 4 connections, retransmit	
TCP server	tcp_service.c	Listen table 2, `ca_tcp_accept` blocking	
IP defrag	ip_defrag.c	RFC 791; max 4 sessions, timeout 15s, payload 1480B	

Module	File	Capacity	HW Status
MQTT client	mqtt_service.c	QoS 0; CONNECT/PUB/SUB/PING	
Modbus TCP	modbus_service.c	Client FC01/FC03/FC06/FC16	
iperf	iperf_service.c	TCP client/server; ~25 Mbps avg, 39 Mbps peak	
HTTP server	http_service.c	GET/POST/HEAD/OPTIONS; route table; CLI via HTTP	
TLS 1.3 server	tls.c	TLS_AES_128_GCM_SHA256, X25519, ECDSA P-256 certificate; transport independent	
HTTPS server	https_service.c	Port 443, same routes as HTTP over TLS 1.3	5 Core
Packet tracer	packet_tracer_service.c	Ring 8×20B; hook RX/TX; CLI `trace on/off/filter`	
TFTP	tftp_service.c	RFC 1350; GET/PUT; CLI; OTA-ready	

Network examples

Example	Functionality
39	UDP client/server, DHCP, ARP, NTP, DNS, mDNS, Syslog
40	TCP client — blocking HTTP GET
41	TCP server — echo RFC 862
42	MQTT client — pub/sub
43	Modbus TCP client — CLI `modbus`
44	iperf TCP — CLI `iperf`
45	HTTP and HTTPS server + CLI via HTTP
48	IP defrag service
49	TFTP client/server — CLI `tftp`

8.1.4 4. Cryptography

Hardware accelerators (CRYP, HASH, RNG) are used without HAL where available; where missing, AES, SHA-256 and curves (X25519, Ed25519, ECDSA P-256) run in software.

Hardware accelerators

Module	Header	Algorithms	Notes
CRC32	crc32.h	CRC-32	HW on all families

Module	Header	Algorithms	Notes
HASH	hash.h	SHA-1, SHA-256	Context swap for multithreading
AES	aes.h	AES-128/256 ECB/CBC/CTR/GCM	HW or software; context swap; GCM IV: `[nonce:12][0x00000002:4]`
RNG	rng.h	Hardware TRNG	`ca_rng_get()`

Application infrastructure (`caos/crypto/`)

Module	File	Function	Status
Keys Store	keys_store.c	2048B MPU-protected area, max 20 keys; access `temp_enable`/`lock_completely`	HW tested
AES Channel Service	aes_channel_service.c	Synchronous redblack AES-256-GCM pipe; wire `[IV:12][cipher][tag:16]`; mandatory wipe with `ca_aes_channel_free()`	HW tested 100/100
Keystore Service	keystore_service.c	KDF from password, CLI `kstore`, automatic key ratchet	HW tested
Software primitives	sha256 / sha512 / kdf / x25519 / ed25519 / ecdsa_p256	SSH and TLS 1.3; ECDSA P-256 with RFC 6979 nonce	HW tested (ex66)

Crypto examples

Example	Functionality
46	Encrypted ping-pong between two tasks via `ca_queue_static_t` + AES-256-GCM
47	Keystore CLI: `kstore makekey`, `kstore start`, persistent key management

Chapter 9

caOS Kernel: Scheduler and Tasks

9.1 Chapter 8 - The caOS Kernel: Scheduling and Task Management

This chapter describes how caOS implements the concepts of kernel, scheduling and stack management.

9.1.1 8.1 The Task in caOS

Task Container (ca_thread_context_t)

Every task in caOS is represented by a `ca_thread_context_t` structure of exactly **180 bytes** (verified with `_Static_assert`, `packed` and aligned to 4). This structure contains everything necessary to describe a task:

```
typedef struct __attribute__((packed, aligned(4))) ca_thread_context {
    u32 digest;             //   0 Validity signature (0xCACAFEF8/FC/F9/FD)
    u32 r[13];              //   4 Registers R0-R12
    u32 lr;                 //  56 Link Register
    u32 pc;                 //  60 Program Counter
    u32 xpsr;               //  64 Program Status Register
    u32 psp;                //  68 Process Stack Pointer
    u32 stack_start;        //  72 Stack start (high address)
    u32 stack_end;          //  76 Stack end (above the canary)
    u16 index;              //  80 Position in the task list (changes!)
    u16 priority;           //  82 EFFECTIVE priority (1,2,4..64): prio_base
   raised by PI
    u16 num_alloc;          //  84 Allocated heap blocks
    volatile u16 status;    //  86 Current state
    volatile u32 notify_value; // 88 Task notification value
    u32 nswitch;            //  92 Context switch counter
    u32 running;            //  96 Tick totali in esecuzione
    u32 sleep;              // 100 Absolute wake-up deadline (ticks)
    void *wait_list;        // 104 Wait list the task is linked into, NULL if
   none
    u32 result;             // 108 Return value
    struct ca_thread_context *next_task_wait; // 112 Link in the wait list
    ca_task_fn_t thread_exec;    // 116 Entry function
    u32 p1;                 // 120 Parametro task
    u32 emerg_param;        // 124 Emergency handler parameter
    ca_emergency_fn_t emergency_exec; // 128 Emergency handler
    u32 runtime_enter;      // 132 CYCCNT at the last entry
    u32 runtime_peak_max;   // 136 Durata massima (WCET) in cicli
    u32 runtime_total;      // 140 Total cycles consumed
    u32 runtime_wdt;        // 144 Task watchdog threshold (0 = off)
    u16 n_assert;           // 148 Safeguard counter
```

```
    u16 n_restart;          // 150 Restart counter
    u16 n_memfault;         // 152 Memory error counter
    u16 prio_base;          // 154 Priority given at creation / by set_priority
    u16 stack_usage_pct;    // 156 0-1000 (0.0%-100.0%)
    u16 fault_type;         // 158 Recovery policy
    struct ca_mutex_s *pi_held; // 160 Owned mutexes (list, priority inheritance
    )
    struct ca_mutex_s *pi_wait; // 164 Mutex the task is blocked on
    char name[12];          // 168 Nome task
} ca_thread_context_t;          // Totale: 180 byte
```

`wait_list` **(starting from 09/27) replaced** `blocked`, a step counter for refresh waiting for nobody to use it anymore. Same offset and same size: the structure thus remained 172 bytes. It is used to remove a task from its wait list while it is waiting — see §8.8.

180 bytes starting from 10/05: `pi_held` and `pi_wait` for priority inheritance (§8.8). The context lives in the TLB, so `MAX_TASK` = TLB size / 180: **22** on 4 KB TLBs (F407, F429, F446, F746), **90** on 16 KB TLBs (H753, H747, U575, H563); the F767 stays at 25 (arena PSP constraint). `ca_scheduler_init()` stops with a message if `MAX_TASK * sizeof(ca_thread_context_t)` exceeds `_tlb_area_size`.

Digest: validity signature

The `digest` field identifies the task type and validity:

Value	Meaning
`0xCACAFEF8`	Standard task (CA_JOB_STD)
`0xCACAFEFC`	Safe task — PSP bounds checking (JOB_SAFE)
`0xCACAFEF9`	Task with floating point (JOB_FLOAT_POINT)
`0xCACAFEFD`	Safe task + floating point (CA_JOB_SAFE_FLOAT_POINT)
`0`	Removed/invalid task

The digest is periodically checked by the idle task. If corrupted → task marked `CA_ST_TH_DIGEST_ERROR` and removed from the scheduler.

Task States

```
CA_ST_TH_INIT           0x80    // Just created
CA_ST_TH_RUN            0x40    // Ready/running
CA_ST_TH_RUNNING        0xC0    // INIT | RUN (active)
CA_ST_TH_SLEEP          0x04    // In sospensione (sveglio a deadline 'sleep')
CA_ST_TH_BLOCKED        0x01    // Blocked on mutex/semaphore/queue
CA_ST_TH_SUSPENDED      0x100   // Suspended manually
CA_ST_TH_STOP           0x02    // Task terminato
CA_ST_TH_REMOVE         0x08    // Marked for removal
CA_ST_TH_STACK_OVERFLOW 0x10    // Stack overflow detected
CA_ST_TH_DIGEST_ERROR   0x20    // Corrupted digest
```

The state `CA_ST_TH_RUNNING` (0xC0) is an OR of INIT and RUN: the scheduler checks `status & CA_ST_TH_RUNNING` to determine if a task is eligible.

Task Types

Type	Digest	Stack Check	FPU	Minimum Stack
CA_JOB_STD	0xCACAFEF8	Canary only	No	STACK_SMALL
JOB_SAFE	0xCACAFEFC	Canary + PSP limits check	No	STACK_SMALL
JOB_FLOAT_POINT	0xCACAFEF9	Canary only	Yes (S16-S31)	STACK_MEDIUM
CA_JOB_SAFE_FLOAT_POINT	0xCACAFEFD	Canary + PSP limits + FP	Yes (S16-S31)	STACK_MEDIUM

FP tasks require at least `STACK_MEDIUM` because saving the S16-S31 registers adds 64 bytes to the stack frame.

9.1.2 8.2 Task Creation

API

```
ca_task_handle_t ca_os_job(const char *name,      // Name (max 10 chars)
              u16 priority,           // CA_TH_LEVEL0..CA_TH_LEVEL6
              ca_task_fn_t func,            // Funzione task: u32 func(void *arg)
              u32 par1,               // Parametro
              ca_stack_size_t stack_size,// Stack size
              ca_job_type type,       // CA_JOB_STD, JOB_SAFE, JOB_FLOAT_POINT ...
              u8 fault_type);         // CA_FAULT_ASSERT, CA_FAULT_RESTART_THREAD...
ca_task_handle_t ca_os_job_suspend(...);   // same signature, created SUSPENDED

bool ca_os_remove_job_handle(ca_task_handle_t h);              // Removes the task
bool ca_os_set_priority_handle(ca_task_handle_t h, u16 prio);  // Cambia priorit  a runtime
bool ca_os_suspend_handle(ca_task_handle_t h);
bool ca_os_resume_handle(ca_task_handle_t h);
bool ca_os_remove_all_jobs(void);     // Rimuove tutti i task
```

Handles, not indices

`ca_os_job()` returns a **handle** (`ca_task_handle_t`), `CA_TASK_HANDLE_NONE` if the creation fails. The handle names the container slot (fixed for the entire lifetime of the task) plus a **generation**: when the task ends, its handle no longer refers to anything, even when the slot is reused. The `_handle` forms resolve and act at masked IRQ, and return `false` if the task is finished.

The **thid** (`ctx->index`, the one printed by `top`) is instead a **position** in the list: when a task is removed, the last one takes its place (swap-with-last), so a thid preserved over time can name **a different task**. The APIs acting on another task by thid (`ca_os_remove_job`, `ca_os_suspend`, `ca_os_resume`, `ca_os_wake_up`, `ca_os_signal`, `ca_os_set_priority`, `ca_os_block`, `ca_notify_send`) are **deprecated**: with `-Werror` their use does not compile. A thid is valid only at the instant it is read; to convert it immediately (e.g. a number typed in CLI) there is `ca_os_handle_from_thid()`.

What happens internally

1. **Allocate task container**: from the TLB area (fixed zone in RAM, defined by the linker)
2. **Allocate stack**: from CCM/DTCM, aligned to 32 bytes (MPU requirement)

3. **Fill stack**: pattern `0xDEADC0DE` for the watermark, but only on the deep part: from `stack_end` up to the address that the task reaches at 65% usage (`STACK_FILL_FROM_PCT`), i.e. 35% of the stack. Count the alarm (usage over 75%), not the exact figure of a task using little: under threshold `top` prints `Stack= <65%`. The filling is done in 1 KB blocks, each at masked IRQ with MPU guard suspended: in a single shot it kept IRQs off for 84.8 µs (16 KB, U575 Release), equal to the margin of a UART without FIFO, and each detached CLI command creates such a task
4. **Set exception frame**: prepares the stack as if the task had been interrupted:

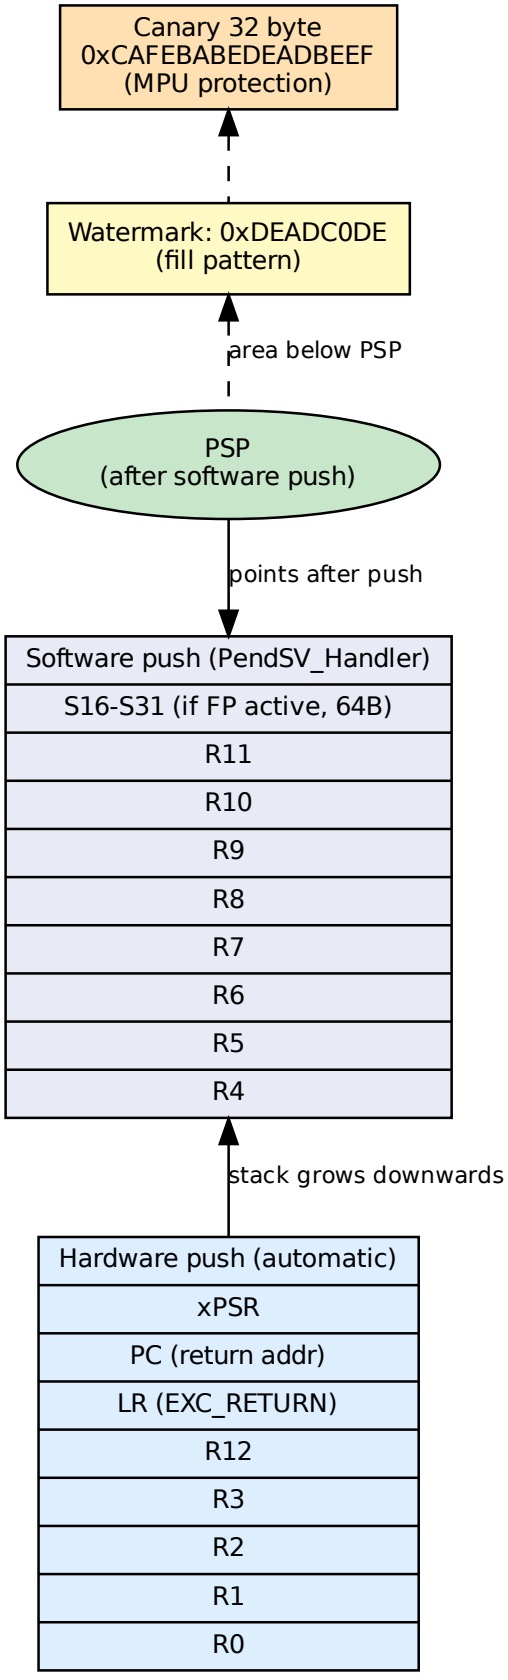
```
Stack (grows downward):
                                                          inizio_stack
      xPSR               0x01000000 (bit Thumb)
      PC                     ca_thread_launch_thread
      LR                 0xFFFFFFFD (EXC_RETURN)
      R12                0
      R3                 0
      R2                 0 (riservato)
      R1                 par1
      R0                 func

     [S16-S31]          (only if JOB_FLOAT_POINT, 64 bytes)

      EXC_RETURN         0xFFFFFFFD (0xFFFFFFED with the FP slot)

      R11..R4            0
                                                             PSP (saved in the
   task container)
        ...              contenuto precedente (non toccato)
                                                             65% used
    RIEMPI_STACK         0xDEADC0DE (watermark, 35% profondo)

    CANARY (32B)         0xCAFEBABEDEADBEEF (protezione MPU)
                                                          fine_stack
```



exception stack frame

5. **Write canary**: 32 bytes of `0xCAFEBABEDEADBEEF` pattern at the base of the stack
6. **Check canary**: immediate check post-write
7. **Add to task list**: digest and initial state (`INIT`, or `SUSPENDED` for `ca_os_job_suspend`) are written **before**; the insertion and reading of the handle occurs with IRQ masked. The two allocations (container and stack) are also masked, because PendSV returns the resources of removed tasks to the same free-list; if the stack is missing, the container is returned.

Launch wrapper

The PC points to `ca_thread_launch_thread`, a wrapper that:

```
static void ca_thread_launch_thread(ca_task_fn_t f, u32 p1) {
    (void)ca_thread_start_task();      // Mark as RUN
    u32 res = f((void *)(uintptr_t)p1);  // Run the task function
    ca_thread_end_task(res);           // Marca come STOP
    while(1) { __WFI(); }
}
```

9.1.3 8.3 Stack Allocation

CCM/DTCM Allocator

Stacks are not allocated from the heap, but from a dedicated allocator on CCM (F4xx) or DTCM (F7xx/H7xx). Advantages:

1. **Zero wait states**: CCM/DTCM is directly connected to the core
2. **Physical isolation**: Stack and heap in separate memories cannot overlap

The allocator uses a bump pointer with exact-fit free-list to recycle the stacks of removed tasks:

```
CCM/DTCM:
                                                  _psp_stack_top (top)
     Stack Task 0          primo stack allocato

     Stack Task 1

     Stack Task 2

        ...               ccm.stack_current
      (free)
                                                  _psp_stack_base (limite)
      Area TLB             Array contenitori task (ca_thread_context_t[MAX_TASK])

```

Why you cannot pass your own stack

Other kernels allow creating a task with an application-supplied stack (in FreeRTOS `xTaskCreateStatic`), to know from the linker where each stack lives. caOS does not, by design:

- **the location is already known**: every stack is described in the task container (`stack_start` , `stack_end`), readable at run time and with `task/stack` from the CLI;
- **stacks are protected**: MPU guard and canary on each one (§8.7), which an arbitrary application stack would not have in a guaranteed way;
- **stacks live in fast memory**: CCM/DTCM, the same as MSP and PSP. An application buffer would usually end up in ordinary SRAM, where the heap also lives.

Available Stack Sizes

```
typedef enum {
    STACK_TINY   = 256,
    STACK_SMALL  = 512,
    STACK_MEDIUM = 1024,
    STACK_LARGE  = 2048,
    STACK_XLARGE = 4096
} ca_stack_size_t;
```

The idle task uses `STACK_MEDIUM`. For application tasks, `STACK_MEDIUM` is a good starting point; tasks that use `sprintf` or large local structures require `STACK_LARGE`.

9.1.4 8.4 Scheduling Algorithm

caOS has **a single policy**: proportional, similar to Linux's CFS. Each task receives the CPU in proportion to its weight; tasks at the same level divide it equally and no task ever starves. The scheduler tick happens at every tick, but context switching only occurs when the scheduler chooses a different task from the currently running one.

Virtual Time

```
vtime = nswitch << log2(64 / priority)      /* u32, compared by signed
    difference */
```

`nswitch` counts the steps in which the task was running and still ready. The levels are powers of two, so the weight is a shift (`__CLZ`), never a division. A task LEVEL6 (priority 64) accumulates vtime slowly and is chosen often, a LEVEL0 (priority 1) quickly and is chosen rarely.

Selection: the task with the lowest vtime wins. In case of tie:

1. the highest actual priority;
2. the one that consumed less CPU (lower `runtime_total`).

A vtime tie is almost always a simultaneous wake-up: two tasks woken up in the same tick both fall back to the same value (see below). The winner then accumulates vtime, and the next round goes to the other.

Level | Weight | Approximate CPU |
|——-|– ——|– ————–| | CA_TH_LEVEL0 | 1 | ~0.78% | | CA_TH_LEVEL1 | 2 | ~1.57% | | CA_TH_LEVEL2 | 4 | ~3.15% | | CA_TH_LEVEL3 | 8 | ~6.28% | | CA_TH_LEVEL4 | 16 | ~12.56% | | CA_TH_LEVEL5 | 32 | ~25.12% | | CA_TH_LEVEL6 | 64 | ~50.24% |

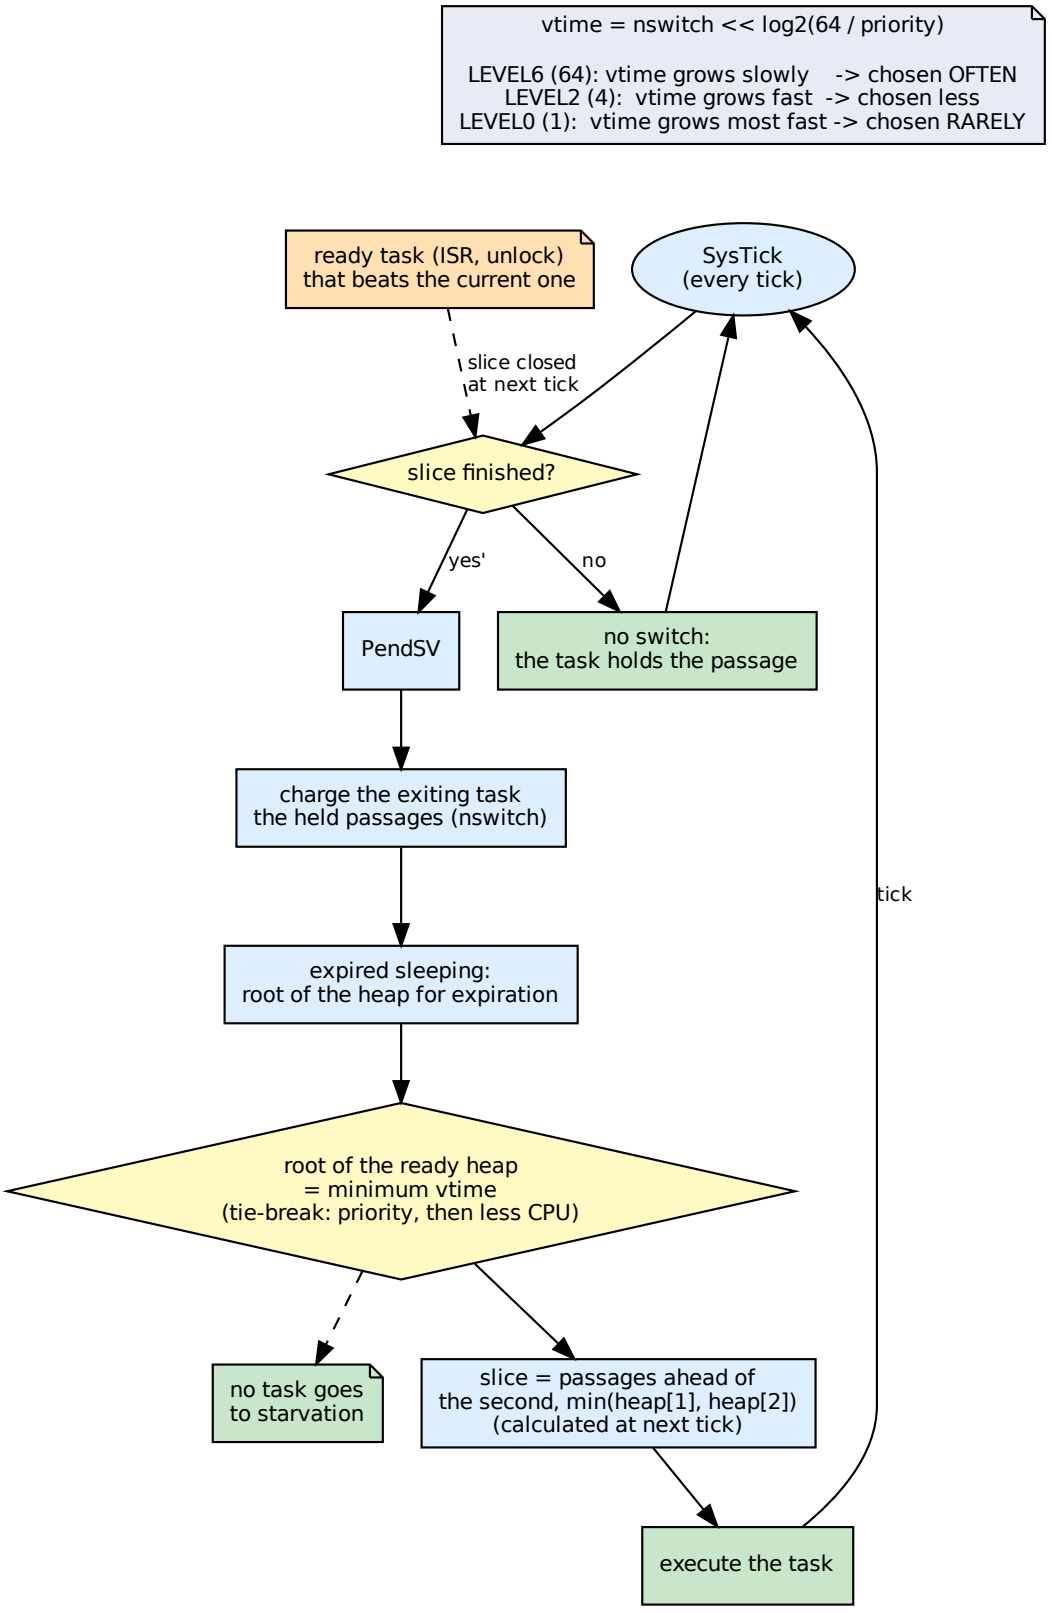


Figure 9.1: caOS CFS scheduling algorithm

Two heaps: ready and sleeping

The choice does not scan the list of tasks. Ready tasks are in a **min-heap** ordered by the selection criterion (vtime, priority, `runtime_total`): the next task is the root. Sleeping tasks are in a second min-heap ordered by **deadline**: the scheduler only looks at the root and wakes up expired sleepers.

- The cost is in **state changes**: a task that becomes ready, blocks, sleeps, is suspended or removed enters or exits a heap in O(log n). All pass through a single point, `task_set_status()`.
- The running task remains in the heap: at every switch only `runtime_total` and `nswitch` change, and it gets repositioned.
- The idle task is not in the heap: it is chosen when the ready heap is empty.
- A task's position in the two heaps is in an array indexed by **slot**, not in the TCB (which remains 180 bytes).

Slices: only context switch when task changes

From the CFS result is derived for how many steps the chosen task will stay ahead of the others, i.e. its **slice**:

```
rivale = min(heap[1], heap[2])          /* the two children of the root are not ordered */
fetta  = 1 + ceil((vtime(rivale) - vtime(task)) / peso(task))     /* 1 in parity */
```

A LEVEL4 ready next to a LEVEL0 pays 4 vtime per tick instead of 64: its slice is 16 ticks, and within those 16 ticks there is only one context switch instead of 16.

The SysTick counts every tick but raises PendSV only when the slice is finished (`ca_scheduler_tick()`). The ticks kept without switching are **charged** to the task at the end of the slice (`nswitch`, `running`): the vtime is what it would have with a full passage at every tick, and thus the order of choices remains the same.

The slice ends early when something changes that the count didn't see:

- **a task becomes ready** (waking up from ISR, unlock, new task): if it beats the current task, the switch occurs at the next tick;
- **a sleeper expires**: the slice never goes beyond the expiration of the first sleeper;
- **a priority changes** (priority inheritance) or **a task is released**: the decision is made at the next tick.

Two limits, in `objmap.h` of the board (default in `scheduler.c`):

define	value	meaning
`CA_SLICE_MAX_TICKS`	32	longest slice: limits the delay of the canary and watchdog checks for tasks
`CA_SLICE_MIN_TICKS`	2	shortest slice: tasks of the same level alternate every 2 ticks

The slice calculation is not in PendSV, whose masked interrupt section is the floor of IRQ latency: PendSV only arms the next tick, and it is that SysTick which calculates the length. The result does not change, because between the choice and that tick the keys remain the same and a task that entered in the meantime is already in the heap.

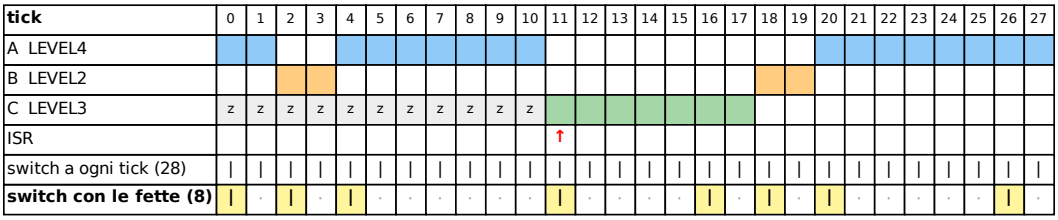

Figure 9.2: Slices: A LEVEL4 and B LEVEL2 always ready, C LEVEL3 made ready by an ISR

Line `slices` of `sched` counts the ticks kept without switching.

The minimum and task reentry (`s_min_vtime`)

`s_min_vtime` (static) is the minimum vtime among ready tasks, updated at every choice and **never lowered**. A task that becomes ready below `s_min_vtime` `64` — just created, restarted, or returning from sleep or wait — is **raised** there:

- reenters next to the least served task, **without** the credit of all the time it did not run: a sleeper, or a new task with `nswitch = 0`, otherwise it would win every passage until it recovers, starving others;
- the credit of **64** (one passage of the lowest level) is placed just **under** the task at the minimum, so it runs before him, like Linux with `min_vruntime`. Placed exactly at the minimum would tie with the current task, and the tie decided by `runtime_total` would sometimes give it the wrong.

During a slice the minimum includes the passages already held by the current task: they are charged before calculating the reentry.

When the minimum exceeds 2^{31} all vtimes are lowered by the same amount (multiple of 64, exact for every weight): distances do not change and `nswitch` (`u32`) never overflows.

Priority Change

The **actual** priority changes with priority inheritance and with `ca_os_set_priority`. It always passes from `ca_scheduler_set_eff_priority()`, which **scales** `nswitch` because the vtime must remain continuous: otherwise, the end of a boost (LEVEL6 → LEVEL2) would multiply the vtime of the task by 16, leaving it without CPU until the others catch up.

The Idle

The idle **does not participate** in the CFS: it is chosen only if no other task is ready. Its turn:

1. periodic time-based checks: digest and PSP every 5 ticks, stack watermark and heap canary every 100 ticks;
2. `idle_wait()`, at masked IRQs: if another task is ready → `ca_os_yield()`, otherwise `WFI`.

The idle slice goes up to the first sleeping task expiring (at most `CA_SLICE_MAX_TICKS`): the SysTick wakes it from WFI at every tick, but without context switch. So the switches at rest depend on the sleeping tasks, not on the tick.

Wake-up from ISR

An ISR that makes a task ready (`ca_scheduler_wake_waiter`, signals, wake-up):

- if it interrupted a **real task**: the awakened task starts at the next tick (latency at most one tick: 100–250 µs, 2 ms on F103). An interrupt never shortens the tick of the current task;
- if it interrupted the **idle**: immediate switch (PendSV) and SysTick restarted from zero, so the incoming task gets a full tick. The already elapsed fraction accumulates (`ca_os_tick_restart_quantum()`) and becomes a tick when it completes one: the clock remains exact. On H563, a QSPI wake-up drops from ~262 µs to ~6 µs.

Line `clock` of `sched` compares ticks with `CYCCNT` (where it counts in WFI): on H563 the deviation stays within ~15 ppm even under hundreds of wake-ups per second.

Why an ISR does not preempt a switch of a real task RTOSes with fixed priority (FreeRTOS, Zephyr, ThreadX) switch at the exit of the ISR if the awakened task is more important than the interrupted one. caOS does not, by design:

- **the tick is a contract.** Preempting the switch would shorten the tick of the interrupted task and lengthen that of the incoming one: `running`, `nswitch` and thus the vtime would count transitions that do not correspond to ticks, and fairness — the very reason of the scheduler — would depend on the interrupt rate;
- **ticks are tight.** caOS runs at 100–250 µs (others typically at 1 ms or more), and with slices a switch only costs when the task changes. So the worst latency of an awakened task is one tick, **bounded and known**;
- **the case that really needs it is covered.** When the CPU is free (idle is running) the switch happens immediately. When it is occupied by a real task, waiting for the tick wastes nothing: one job is finished to start another;
- **what cannot wait a tick must go in the ISR.** Refilling a buffer, responding to hardware, taking a timestamp: short work in the ISR, processing at the task. Those needing task latencies under a tick reduce `OS_TICK_US` on their own board. Briefly: preemption from ISR buys latency under the tick at the price of fairness; with tight ticks that latency is worth little, fairness is not.

9.1.5 8.5 Context Switching

PendSV Mechanism

Context switching follows the classic Cortex-M pattern with two phases:

Phase 1 — SysTick/yield: requests context switching by setting PendSV. SysTick does it at the end of timeslice; a task that yields, blocks or sleeps does it immediately:

```
void ca_os_yield(void) {
    if (SCB->ICSR & SCB_ICSR_PENDSVSET_Msk) return; /* already pending */
    SCB->ICSR |= SCB_ICSR_PENDSVSET_Msk;
    __DSB();
    __ISB();   /* no WFI: whoever yields is ready when it resumes; only the idle
     sleeps */
}
```

Phase 2 — PendSV Handler: performs the actual context switch (in assembly):

1. Saves R4-R11 and EXC_RETURN to the current stack (PSP)
2. If FP task, also saves S16-S31
3. Calls `ca_scheduler_switch_context(current_psp)`:
   - Saves PSP in the current task container
   - Reads the exception frame from the stack to update PC, LR, registers
   - Calls `ca_task_manager_priority_next()`: charges the slice, checks canaries of all stacks, wakes up expired sleepers, chooses the root, arms the tick
   - Updates MPU protection for the new task's canary
   - Returns the PSP of the new task
4. Restores R4-R11 from the new stack
5. If FP task, restores S16-S31
6. Returns (hardware restores R0-R3, R12, LR, PC, xPSR)

Context Switch Statistics

At every context switch, caOS updates, for the outgoing task:

- `running` — execution ticks
- `nswitch` — steps (the base of vtime)

and `g_scheduler_tick`, the number of context switches. At the end of a slice, `running` and `nswitch` also receive the steps held without switching (`slice_settle()`), so that they count ticks as if switching occurred at every tick. The charging is limited to `CA_SLICE_MAX_TICKS`: a clock jump (return from Stop) is not time charged to the task.

```
cpu_permille = (task->running * 1000) / g_scheduler_tick;
```

Scheduler cost

Measured with `sched` on ex87, Release build. `pick` is the time of choosing the next task, inside the context switch; `slices` the steps per second held without switch.

Three loads: *at rest* (the tasks of the examples sleep or wait), `e87 start queue` (ISR every 50 µs, one item at a time towards a consumer) and `e87 start mv_queue` (as `queue`, with the consumer changing index: more tasks, more state changes).

MCU	clock	tick	load	switch/s	cycles per switch	of which `pick`	slices/s	CPU in scheduler
H753	480 MHz	100 µs	at rest	1 504	1 748	1 448	123	0.54%
			`queue`	9 547	1 311	1 001	5 767	2.60%
			`mv_queue`	12 013	1 763	1 456	5 040	4.41%
H563	250 MHz	100 µs	at rest	1 504	862	752	122	0.51%
			`queue`	8 039	736	618	6 211	2.36%
			`mv_queue`	10 645	1 037	921	5 429	4.41%
F767	216 MHz	200 µs	at rest	1 502	1 484	1 232	59	1.03%
			`queue`	8 103	1 159	898	2 518	4.35%

MCU	clock	tick	load	switch/s	cycles per switch	of which `pick`	slices/s	CPU in scheduler
			`mv_queue`	9 961	1 534	1 276	2 323	7.07%
F446	168 MHz	250 µs	at rest	1 503	1 132	886	45	1.01%
			`queue`	5 585	962	715	2 219	3.19%
			`mv_queue`	8 331	1 394	1 148	1 203	6.91%
U575	160 MHz	250 µs	at rest	1 504	744	628	44	0.69%
			`queue`	7 280	635	496	1 863	2.89%
			`mv_queue`	9 797	943	811	1 068	5.77%

At rest, context switches are ~1 500 per second on all MCUs, regardless of the tick: they are made by the sleepers (stdout, cli, example tasks), not by SysTick. Under load `slices` shows how many steps the slices hold without switch: where the tick is finer (100 µs) there are more context switches themselves.

The cost of a context switch has a wanted linear part: **at every context switch PendSV checks the canary of all stacks**, not only that of the exiting task. A task that has not run cannot have damaged its own canary, but another could have; safety comes before cycles, and the check remains complete.

The number of context switches per second does not depend on the tick but on task changes: at rest from sleepers, under load from alternating tasks. The tick (`OS_TICK_US` in `objmap.h`) costs only the SysTick:

MCU	tick
H753, H747, H563	100 µs
F746, F767	200 µs
F407, F429, F446, U575	250 µs
F103	2 ms

The figures apply to the MCUs in the table: on another platform with different clock and tick, they must be remeasured. `sched` prints the distribution from the last call (context switch, task, idle woken up, CPU free in WFI) relative to the real tick time; two calls a few seconds apart give the window.

Interrupt Latency

How long after its event does an ISR start, in the worst case. The measurement is of ex87: TIM3 at the **same NVIC priority as UART RX** and its ISR reads its own counter at the input, so the value read *is* the service delay of a received byte. When the delay falls above another handler the probe records which one (PendSV, SysTick, SVC or the IRQ number).

```
1 e87 lat [sec] [churn|heap|spin]
```

opens a free-running measurement window, to be filled with the load you want; `churn` adds tasks that are constantly born and die (~1000 per second), so that task creation and removal also end up in the measurement. `heap` adds a task that keeps the heap fragmented (64 blocks from 16 to 512 bytes, one freed and one allocated at random at every step, without pauses); `spin`

an always-ready task that touches nothing, to separate the cost of a specific load from that of a task that never sleeps. Besides the maximum, the probe reports the **maximum per source** (thread mode with the interrupted PC, PendSV, SysTick, SVC, IRQ).

The probe period must be incommensurable with the tick. With TIM3 at a submultiple of the tick, the phase between TIM3 and context switching remains fixed for the entire window: TIM3 always hits the same point of the switch, and the maximum depends on the phase picked at opening. For `e87 lat` TIM3 therefore runs at **53 µs** (first): the phase scrolls and in 10 s passes through all points of the switch. The phases of `e87 start` remain at 50 µs.

Build **Release** (in Debug the numbers are much higher and should not be declared), 10 s windows (~189,000 samples), maximum over three repeated runs.

Tasks alive during measurement. Boards with ETH (F767, H753, H563) run 10 tasks: `idle`, `stdout`, `cli`, `example_87`, `e87_rx`, `e87_rxt`, the three network tasks (`net`, `arp`, `dhcp`) and `cli_cmd` which runs `e87 lat`. Those without ETH (F446, U575) run 7: the same minus the three network tasks. The *churn* adds `e87_churn` and the current child: 12 and 9 tasks.

Loads. *at rest*: example tasks sleep or wait, only `stdout` and the tick work. *churn*: as above. *flood*: `examples/example_87/stress_peer.py` sends a ping every 2 ms (ETH interrupt, task `net` busy, ICMP replies).

MCU	clock	tick	tasks alive	at rest	churn	flood	flood + churn	worst
F767	216 MHz	200 µs	10 / 12	9.8 µs	12.6 µs	15.2 µs	16.1 µs	**16.1 µs**
F446	168 MHz	250 µs	7 / 9	9.6 µs	12.4 µs	—	—	**12.4 µs**
U575	160 MHz	250 µs	7 / 9	6.2 µs	8.8 µs	—	—	**8.8 µs**
H753	480 MHz	100 µs	10 / 12	5.1 µs	7.0 µs	7.8 µs	8.7 µs	**8.7 µs**
H563	250 MHz	100 µs	10 / 12	4.2 µs	6.3 µs	7.3 µs	6.4 µs	**7.3 µs**

(*tasks alive*: without / with churn.)

In all measurements, slow samples fall into **PendSV**: context switching runs entirely at masked interrupts (`CPSID I`), and an ISR arriving during the switch waits for it to finish. No peripheral handler appears; critical sections in thread mode (task creation) are light. Therefore, the latency floor is the duration of the longest context switches — those that, by switching tasks, also wake up some sleepers — which depends on clock, core and number of tasks (canary checking goes through all of them). The slices do not shorten those switches, but remove all those that pick the same task: collisions between an IRQ and PendSV become much less frequent.

The margin to compare is that of a UART character at 115200 baud without FIFO, ~87 µs: the worst case measured (F767, flood + churn, 12 tasks) uses less than a fifth. **What these numbers do not cover.** They apply to the kernel with the number of tasks in the table. With more tasks, the switch lengthens, because the canary checks go through them all. Outside the measurement are also the critical sections of the application and drivers (IRQs disabled, spinlocks), the time spent in ISRs with priority higher than UART, Debug builds, and untested MCUs (F103, F407, F429, F746, H747). Latency does not depend on the tick.

Scheduler lock (`ca_os_sched_lock`)

```
void ca_os_sched_lock(void);
void ca_os_sched_unlock(void);
```

Prevents context switches away from the task that takes it until the matching unlock. Interrupts **stay enabled** and are served; if a switch is requested in the meantime (end of slice, wake-up from ISR) the PendSV stays on the task, remembers it, and the switch happens at the last `ca_os_sched_unlock()`. It can be nested. It must not be used from an ISR.

Rule: the holder of the lock **must not block** (sleep, waits on semaphores, queues, events): the PendSV would not switch task and the caller would continue without having waited. If the task holding it is removed because of a fault, the lock goes with it.

What it is for. It is the third way between two tools that cost more than needed when only the other tasks have to stay out:

tool	excludes	cost
`ca_enter_critical()` / IRQ spinlock	tasks and ISRs	interrupt latency for the whole section
mutex	only those who take it	waiting, PI, everyone must take it
`ca_os_sched_lock()`	all other tasks	no IRQ delayed

First use: the heap. `ca_memory_allocate` and `ca_memory_free` are not called from ISRs, but they searched for the free block (next-fit on the chain) with IRQs disabled. The only code outside the tasks that touches the heap is the cleanup of removed tasks in the PendSV, and that is exactly what the lock defers. Measurement of 18/10 with `e87 lat 10 heap` (Release, 10 s windows):

	heap: max thread mode		samples 2 µs thread mode	
MCU	before	after	before	after
F767	15.32 µs	4.00 µs	84,281	423
F446	14.79 µs	4.01 µs	86,537	427
U575	10.34 µs	2.65 µs	17,075	115
H753	7.28 µs	2.17 µs	9,641	11
H563	7.03 µs	< 2 µs	658	0

The **declared maximum does not change**: under load it is set by the PendSV, and the PendSV rises with any always-ready task, not with the heap (`spin`, which does not touch the heap, brings the F767 to 15.2 µs; with the lock, `heap` and `spin` give the same numbers). What changes is the **frequency**: an ISR serving the UART or the network, while a task works on the heap, sees ~4 µs instead of ~15 for all that time. ex87 (the lost wake-up bench) 19/19 on the five boards with the lock active.

Why not `ca_os_run(false)`. It also stops the scheduler, but it is the pre-start "scheduler not active" state: a `CA_SAFEGUARD` triggered in that state takes the fatal branch and halts the board (`[SAFEGUARD FATAL] ... Mode: HALT (IRQ/no-sched)`, tried on H753 with ex68), instead of removing just the task. With `ca_os_sched_lock()` the safeguard stays per-task.

9.1.6 8.6 Idle task and maintenance

The idle task at every iteration:

1. **Every 5 ticks** (`IDLE_CHECK_TICKS`): `update_check_task_validity()` verifies digest and saved PSP of all tasks; if corrupted → `CA_ST_TH_DIGEST_ERROR` / `CA_ST_TH_STACK_OVERFLOW`. The check and verdict occur at masked IRQs, one task at a time, so that a task removed and replaced mid-check is not mistaken for another
2. **Every 100 cycles**: `ca_scheduler_update_all_stack_usage()` — recalculates the watermark with binary search O(log n)
3. **DSB + WFI**: synchronizes memory and puts the core to sleep

9.1.7 8.7 Stack protection

Triple protection

1. **Software canary (32 bytes)**: at the base of every stack, pattern `0xCAFEBABEDEADBEEF`. Verified at every tick
2. **MPU region**: the same area is protected in read-only. A write generates an immediate MemManage Fault
3. **PSP limits check** (SAFE task): the idle task verifies that the PSP of each task is within limits `stack_end..stack_start`

MPU protection is updated at every context switch to point to the base of the stack of the task just loaded.

Without MPU (F103 Cortex-M3)

- MPU functions become empty macros (`#define ca_mpu_init()`)
- Only software canary check remains
- Overflow is detected at the next tick (no immediate protection)

9.1.8 8.8 Suspension, Blocking and Wake-up

Timed Suspension

```
ca_os_sleep(100);  // 100ms      convertito in tick
```

Internally: 1. Converts ms to tick: `tick = ca_os_tick_x_ms(ms)` 2. Marks the task as `CA_ST_TH_SLEEP` and sets `sleep` as **absolute deadline in tick**: `sleep = ca_os_tick() + tick` 3. Calls `ca_os_yield()` 4. The scheduler wakes up the task when the current tick reaches the deadline, with wraparound-safe comparison: `(i32)(ca_os_tick() - sleep) >= 0` 5. Upon reaching the deadline, the task returns to `CA_ST_TH_RUN`

> **Note — time base.** The `sleep` field is an absolute deadline expressed in ticks of `systick_counter`, which advances **only** in `SysTick_Handler` (one increment per real tick) and is therefore immune to voluntary `yield`. Previous versions decremented a counter (`sleep--`) at every context switch (PendSV), including every `ca_os_yield()`: with many tasks yielding sleep resulted in being much shorter than required (measured ~50× on F4VE). The comparison via `(i32)(now - sleep)` handles the wraparound of the 32-bit counter (~49.7 days @ 1 ms/tick).
>
> **Limit.** The `ca_os_tick_x_ms()` conversion works on 64-bit (until 27/09 `ms * 1000` overflowed beyond ~71 minutes) and limits the result to $2^{31}1$ ticks, the maximum that the signed deadline comparison can represent: approximately 24.8 days at 1 ms/tick, 4.9 days at 200 µs/tick. Longer sleeps must be implemented in application loops, not with a single `ca_os_sleep`.

Periodic anti-drift suspension

```
void ca_os_sleep_until(u32 *last_wake_ms, u32 period_ms);
```

Calculate the remaining time to the next wake-up instant and sleep for exactly that duration. `*last_wake_ms` is advanced by `period_ms` on each call, maintaining synchronization with absolute time.

```
static u32 task_periodic(void *arg) {
    (void)arg;
    u32 last_wake = ca_os_tick_ms();
```

```
4
5       while (1) {
6           ca_os_sleep_until(&last_wake, 100);   /* woken every exact 100ms */
7           do_work();
8       }
9       return 0;
10  }
```

Function	Synchronization	Cumulative Drift	Typical Use
`ca_os_sleep(ms)`	Relative (from now)	Yes	Simple delays
`ca_os_sleep_until(&last, ms)`	Absolute (from initial tick)	No	Precise periodic tasks

Block and Wake-up

```
1 ca_os_wait_prepare();        // The current task marks itself BLOCKED (inside the
      lock)
2 ca_os_sleep_prepare(ticks); // ...or SLEEP with a deadline (wait with timeout)
3 ca_os_yield();               // ...and yields the CPU after releasing it
4 ca_os_wake_up_handle(h);     // Wakes from SLEEP (CA_ST_TH_SLEEP)
5 ca_os_signal_handle(h);      // Wakes from BLOCKED (CA_ST_TH_BLOCKED)
```

`wake_up` and `signal` operate on different states: using the wrong function has no effect. Kernel primitives do not use either of them: they wake up with `ca_scheduler_wake_waiter(ctx)`, which applies to both states (below).

Timed waits: in list, like those without timeout

All blocking primitives (code, semaphores, mutexes, recursive mutexes, condition variables, event groups, stream and message buffers, notifications) follow **the same scheme**, with or without timeout:

1. under the primitive's lock, the task rechecks the condition, **registers in the wait list**, and **parks**: `BLOCKED` without timeout, `SLEEP` until expiration with timeout (`ca_os_wait_prepare()` / `ca_os_sleep_prepare()`);
2. releases the lock and yields the CPU;
3. upon awakening, under the lock, **exits the list** and checks what happened.

The timeout value is in milliseconds and means the same for all of them: `CA_NO_WAIT_TIME` (0) does not wait, `CA_WAIT_FOREVER` (`0xFFFFFFFF`) waits with no deadline, any other value is a deadline (`common.h`). Until 19/10 queues, notifications and event groups used `0` for "forever", the opposite of semaphores, mutexes and streams: the same number meant two opposite things depending on the object.

Parking occurs *inside* the critical section: a wakeup arriving between unlock and parking would find the task still `RUNNING` and would be lost (the "lost wakeup" measured by the ex87 bench). The expiration is an absolute tick calculated on entry: subsequent loops do not extend it. At expiration, it is the scheduler refresh that puts the task back into `RUN` (§8.8, timed suspension): no timer is needed.

Until 09/27, waits **with** timeout did not register: they polled with `ca_os_sleep(10)`. Two consequences, both measured:

	polling (before)	in list (now)
delay from signal to awakening	up to 10 ms (45-50 ticks on H753)	0 ticks
to whom the element goes	to whoever checks first (ex4: 107 vs 15)	to whoever waited longer (ex4: 42/40)

Who wakes up. `ca_scheduler_wake_waiter(ctx)` brings a task `RUN` in `BLOCKED` or `SLEEP`, for **context** (never by index: the index is a position and changes when a task below terminates). Returns `false` **only** if the task is terminating (`REMOVE`, overflow, digest, watchdog).

Direct handover. Mutexes, semaphores and rwlocks *deliver* the resource to the waiter that is removed from the list: the mutex changes owner, the semaphore counter is not incremented. For the waiter, therefore, *being removed from the list* means *being served*, even if it has expired in the meantime. The one releasing skips waiters that are terminating: if delivered to a task that will not run again, the mutex would remain theirs forever and the count would be lost.

Mutex owner. The mutex (even recursive) records the owner with its **handle** (`owner`), not with the index: a moved owner in the list from the removal of another task would no longer pass the `ca_mutex_unlock()` check (safeguard, then HardFault). **Priority inheritance (Zephyr schema, from 05/10).** `priority` is the *actual* priority that the scheduler uses as weight, `prio_base` is the one assigned at creation or by `ca_os_set_priority_handle()`. Actual = maximum between `prio_base` and the priority of every task waiting on a mutex owned (`pi_held`, linked list by `pi_next` in the mutex). It is recalculated at every change in the set — a waiter arrives or leaves (lock, timeout, removal), a mutex is passed (unlock), `prio_base` changes — and the change continues on the owner of the mutex the task itself is waiting on (`pi_wait`), for at most `CA_PI_MAX_CHAIN` steps (default 4, `sync.h`): each step runs with IRQ masked, so the chain is limited by construction. The previous schema kept only one `prio_bkup` and restored it at any unlock: releasing the second of two mutexes removed the boost due to the other, a waiter in timeout left the owner boosted, the boost did not follow the chain, and a `set_priority` on an already boosted owner was lost. Recursive mutexes do not have priority inheritance. Verification: ex91 (`pi_*`).

Task removed while waiting. A terminated task (kill, fault, return) while in a wait list remained linked: the list pointed to a freed and reused context from a task created after. Now the `wait_list` field indicates in which list it is, and the scheduler detaches it before freeing it (and at task restart).

Condition variable. `ca_cond_wait()` releases the mutex *before* parking and parks only if it is still in the list. Marked `BLOCKED` with still code to execute, the task was removed from the CPU at the next tick **keeping the mutex** that the notifier needs.

Notifications. The task in `ca_notify_wait()` subscribes to a dedicated wait list, and `ca_notify_send*()` wakes up the recipient only if it is really waiting for a notification. Previously it would wake any task `BLOCKED`, even one blocked on a semaphore.

> **Wake-up order: FIFO.** Priority does not enter the wait list order: the scheduler is a weighted CFS, not strict priority, and a priority-ordered list would starve low-priority tasks on a very busy queue. Priority acts after wake-up, in the scheduler. A timeout expiry does not depend on priority; priority determines how soon a task, already woken, resumes execution.

> **Polling remains only** for `send` with stream and message buffer timeouts when the buffer is full (1 ms).

Verification. The ex87 bank (phases `fair`, `tmo`, `kill`) and the `twait` command in examples 5, 6, 7, 9, 14, 15, 17, 20 (`twkill` in ex20) — see respective S03 chapters.

9.1.9 8.9 System Startup

The complete caOS startup sequence:

Previous chapter: caOS Overview Next chapter: Synchronization in caOS

Chapter 10

Synchronization in caOS

10.1 Chapter 9 - Synchronization in caOS

This chapter describes how caOS implements the synchronization primitives presented in Chapter 3.

10.1.1 9.1 Synchronization Architecture

SpinlockIrq as base

All synchronization primitives in caOS (mutex, semaphore, condition variable, queue) internally use a `ca_spinlock_irq_t` to protect their data structures. The interrupt-safe spinlock is implemented with LDREX/STREX and disables interrupts locally:

```
typedef struct {
    volatile u32 lock;   // SPINLOCK_FREE (0) o SPINLOCK_LOCKED (1)
    volatile u32 irq_state; // Saved PRIMASK state
} ca_spinlock_irq_t;
```

This ensures that modifications to synchronization structures are atomic even in the presence of interrupts.

Wait Queue

When a task blocks on a primitive (mutex busy, semaphore at zero, queue empty), it is inserted into a **wait queue**: a linked list of waiting tasks, using the `next_task_wait` field of the task container.

```
typedef struct {
    ca_thread_context_t *head;  // First waiting task
    ca_thread_context_t *tail;  // Last waiting task
} ca_wait_queue_t;
```

The wait queue is FIFO: the first task to block is the first to be woken up. Operations: - `ca_wait_queue_enqueue()` — adds a task to the queue - `ca_wait_queue_dequeue()` — removes and returns the first task - `ca_wait_queue_remove()` — removes a specific task (for timeout)

10.1.2 9.2 Mutex

Structure

```
typedef struct {
    volatile u32 owner;          // owner's handle (ca_task_handle_t)
    volatile u8 locked;          // 0 = free, 1 = locked
    ca_wait_queue_t wait_queue;      // Waiting tasks
    ca_spinlock_irq_t internal_lock; // Internal protection
```

```
} ca_mutex_t;
```

API

```
ca_mutex_t mtx;
ca_mutex_init(&mtx);              // Inizializza

ca_mutex_lock(&mtx);              // Blocks if taken
ca_mutex_trylock(&mtx);           // Does not block, returns true/false
ca_mutex_timedlock(&mtx, 100);    // Blocks at most 100ms
ca_mutex_unlock(&mtx);            // Release (owner only)
ca_mutex_is_owner(&mtx);          // Check ownership
```

Lock Behavior

1. Acquires `internal_lock` (spinlock IRQ)
2. If `locked == 0`: acquires, sets `owner` to the task handle, releases spinlock
3. If `locked == 1`: priority inheritance on the owner, then inserts the task into the wait queue and parks it (BLOCKED, or SLEEP until expiry for `timedlock`) **before** releasing the spinlock, yield
4. On wake-up: if no longer in list, `unlock` has already passed the mutex and returns; otherwise (expiry) retry or return `false`

The owner is an **handle**, not the task index: the index is a position in the list and changes when a task that is below it terminates. With the index, a moved owner would no longer pass the `ca_mutex_unlock()` check (safeguard, then HardFault) — found on 27/09 by the `twkill` command of ex20.

Unlock Behavior

1. Acquires `internal_lock`
2. Checks ownership: only the owner can release
3. If wait queue not empty: removes the first task **that will still run** (skips those that are terminating), transfers ownership to it and wakes it up, from BLOCKED or from SLEEP
4. Otherwise: `locked = 0`
5. Releases spinlock

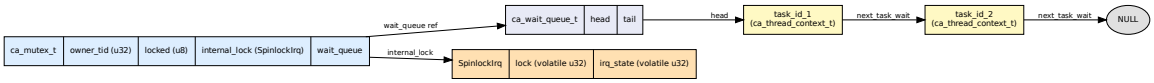

Figure 10.1: Internal structure of ca_mutex_t

Timedlock

The task waits in the same wait list as `ca_mutex_lock()`, in `SLEEP` until expiry: `unlock` wakes it up immediately and in arrival order (FIFO), expiry wakes it up from the scheduler refresh. `timeout_ms = 0` is equivalent to `ca_mutex_trylock()`.

Until 27/09 it was polling (sleep 10 ms + retry): the mutex went to whoever tried again first, up to 10 ms after release. The common scheme for all primitives is described in S2_02 §8.8, “Timeout waits”.

10.1.3 9.3 Recursive Mutex

```
typedef struct {
    volatile u32 owner;          // owner's handle
    volatile u16 lock_count;     // Re-entry counter
    ca_wait_queue_t wait_queue;
    ca_spinlock_irq_t internal_lock;
} ca_recursive_mutex_t;
```

Difference from standard mutex

If the calling task is already the owner, `ca_rmutex_lock()` increments `lock_count` without blocking. `ca_rmutex_unlock()` decrements the counter and releases only when `lock_count == 0`.

```
ca_recursive_mutex_t rmtx;
ca_rmutex_init(&rmtx);

ca_rmutex_lock(&rmtx);    // count = 1
ca_rmutex_lock(&rmtx);    // count = 2 (stesso task, OK)
ca_rmutex_unlock(&rmtx);  // count = 1
ca_rmutex_unlock(&rmtx);  // count = 0     mutex free
```

10.1.4 9.4 Semaphore

Structure

```
typedef struct {
    volatile u32 count;          // Available resources
    u32 max_count;               // Maximum (0 = unlimited)
    ca_wait_queue_t wait_queue;
    ca_spinlock_irq_t internal_lock;
} ca_semaphore_t;
```

API

```
ca_semaphore_t sem;
ca_sem_init(&sem, "SEM_ABC", 0, 10); // nome (8 byte), iniziale=0, max=10

ca_sem_wait(&sem);                 // Decrements, blocks if 0
ca_sem_trywait(&sem);              // Does not block
ca_sem_timedwait(&sem, 100);       // Max 100ms (0 = like trywait)
ca_sem_post(&sem);                 // Hand over to a waiter, or increment
ca_sem_getvalue(&sem);             // Reads count
```

Differences from mutex

	Mutex	Semaphore
Ownership	Yes	No
Value	0/1	0..N
Release	Only owner	Any task/ISR
Typical use	Critical section	Producer/consumer

`ca_sem_post()` with waiting tasks **delivers** the unit directly to the first waiter that runs (FIFO) and does not increment `count`; without waiters it increments. `ca_sem_wait()` and `ca_sem_timedwait()` wait in the same list, BLOCKED or SLEEP until timeout (S2_02 §8.8).

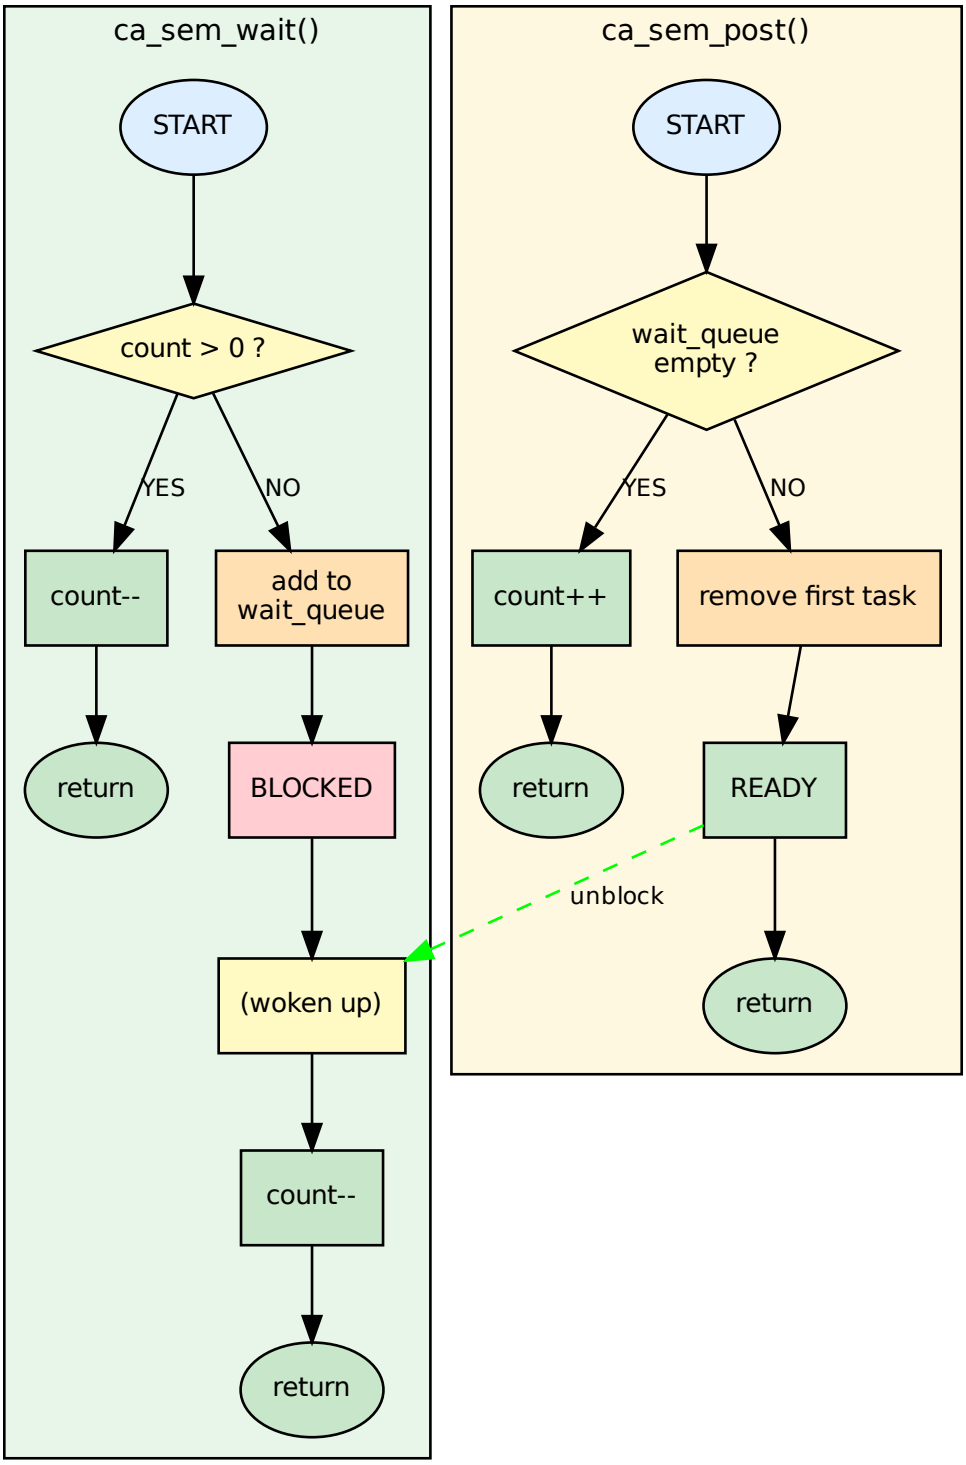

Figure 10.2: Flowchart semaphore wait/post

10.1.5 9.5 Condition variable

Structure

```
typedef struct {
    ca_wait_queue_t wait_queue;
    ca_spinlock_irq_t internal_lock;
} ca_condvar_t;
```

API

```
ca_condvar_t cv;
ca_mutex_t mtx;
ca_cond_init(&cv);

// Attendente
ca_mutex_lock(&mtx);
while (!condizione) {
    ca_cond_wait(&cv, &mtx);      // Releases mtx, blocks, takes mtx back
}
ca_mutex_unlock(&mtx);

// Semaphore
ca_mutex_lock(&mtx);
condizione = true;
ca_cond_signal(&cv);              // Wakes ONE task
ca_cond_broadcast(&cv);           // Wakes ALL
ca_mutex_unlock(&mtx);
```

`ca_cond_wait` executes: 1. Inserts the task into the wait queue (under the cv lock) 2. Releases the mutex 3. If it is still in the list (no signal in the meantime), parks itself and yields the CPU 4. Upon waking up, exits the list and reacquires the mutex before returning

The order matters. Parked (BLOCKED) **before** releasing the mutex, the task was removed from the CPU at the next tick while holding the mutex, and the one who had to signal couldn't acquire it. And a signal arriving between release and parking would not be lost: the task is no longer in the list and won't park.

Timeout: `ca_cond_timedwait(&cv, &mtx, timeout_ms)` returns `false` if it expires (or for a spurious wakeup: the caller always rechecks its condition).

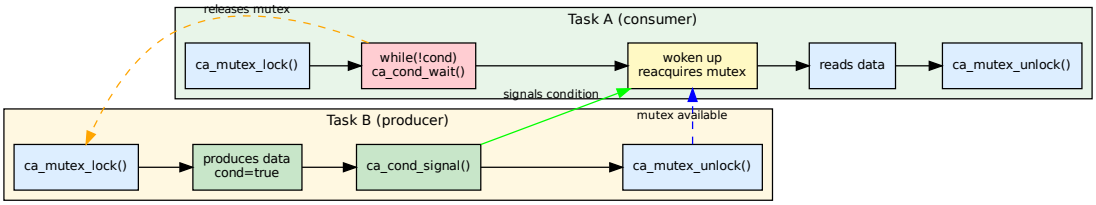

Figure 10.3: Sequence diagram CondVar producer-consumer

10.1.6 9.6 Critical Sections

API

```
ca_enter_critical();     // Disable IRQs with nesting
// ... critical code ...
ca_exit_critical();      // Re-enables only at nesting 0

u32 level = ca_critical_nesting_level();
```

Implementation with nesting counter: the first `ca_enter_critical()` disables interrupts (`CPSID I`), the subsequent ones only increment the counter. `ca_exit_critical()` decrements and re-enables only when the counter returns to zero.

10.1.7 9.7 Code

caOS offers two implementations: **static queue** (inline buffer) and **heap queue** (buffer allocated from the heap).

Static Queue

Definition and usage:

```
// Global definition: 10 slots of sizeof(u32)
CAQUEUE_STATIC_DEFINE(my_queue, 10, sizeof(u32));

// Produttore
u32 dato = 42;
ca_queue_static_send(&my_queue, &dato, 100);        // Timeout 100ms
ca_queue_static_send_front(&my_queue, &dato, CA_WAIT_FOREVER);   // LIFO

// Consumatore
u32 ricevuto;
ca_queue_static_receive(&my_queue, &ricevuto, 100);

// Da ISR
ca_queue_static_send_isr(&my_queue, &dato);          // Never blocks
ca_queue_static_receive_isr(&my_queue, &ricevuto);

// Utilities
ca_queue_static_peek(&my_queue, &dato);               // Reads without removing
ca_queue_static_is_empty(&my_queue);
ca_queue_static_count(&my_queue);
ca_queue_static_reset(&my_queue);                     // Empty
```

Mailbox (one-item queue). `ca_queue_static_overwrite()` and `ca_queue_heap_overwrite()` write the only slot of a queue with `max_items == 1`, whether it is empty or holds data not yet read: the receiver always finds the latest value, never an old one. They never wait and can also be called from an ISR; on a queue longer than one item they refuse (`false`) without touching it. It is the equivalent of FreeRTOS `xQueueOverwrite`. Verification: `overwrite` command of ex4.

```
CAQUEUE_STATIC_DEFINE(state, 1, sizeof(u32));        // a single slot
u32 v = measure();
ca_queue_static_overwrite(&state.q, &v);             // replaces, does not wait
```

Heap Queue

```
ca_queue_t q;
ca_queue_heap_init(&q, sizeof(MyStruct), 20);  // 20 slots of sizeof(MyStruct)
// ... same API as static (send, receive, isr, peek) ...
ca_queue_heap_destroy(&q);                     // Libera buffer heap
```

Internal Implementation

The queues use a circular buffer with indices `head` (read) and `tail` (write). Two separate wait queues: - `wait_send`: tasks blocked because the queue is full - `wait_recv`: tasks blocked because the queue is empty

A send operation that finds the queue full inserts the task into `wait_send`. A receive operation that empties the queue wakes up the first task in `wait_send` (if present).

10.1.8 9.8 Event Groups

Structure

```
typedef struct {
    volatile u32 bits;                      // 32 flag
    ca_wait_queue_t wait_queue;
    ca_spinlock_irq_t lock;
    ca_event_waiter_meta_t waiters[MAX_TASK];   // Metadati per task
} ca_event_group_t;
```

Every waiting task has its own criteria saved in `ca_event_waiter_meta_t`: - `wait_bits`: which bits it waits for - `wait_mode`: ANY or ALL - `auto_clear`: clear bits after match

API

```
ca_event_group_t eg;
ca_event_init(&eg);

// Setter (from task or ISR)
ca_event_set(&eg, CA_EVENT_BIT(0) | CA_EVENT_BIT(1));
ca_event_set_isr(&eg, CA_EVENT_BIT(2));
ca_event_clear(&eg, CA_EVENT_BIT(0));

// Attendente
u32 bits = ca_event_wait_any(&eg, 0x03, true, 1000);   // ANY, auto-clear, 1s
u32 bits = ca_event_wait_all(&eg, 0x03, false, 1000);   // ALL, no clear, 1s

// Query
u32 current = ca_event_get(&eg);
ca_event_reset(&eg);  // Clear all bits
```

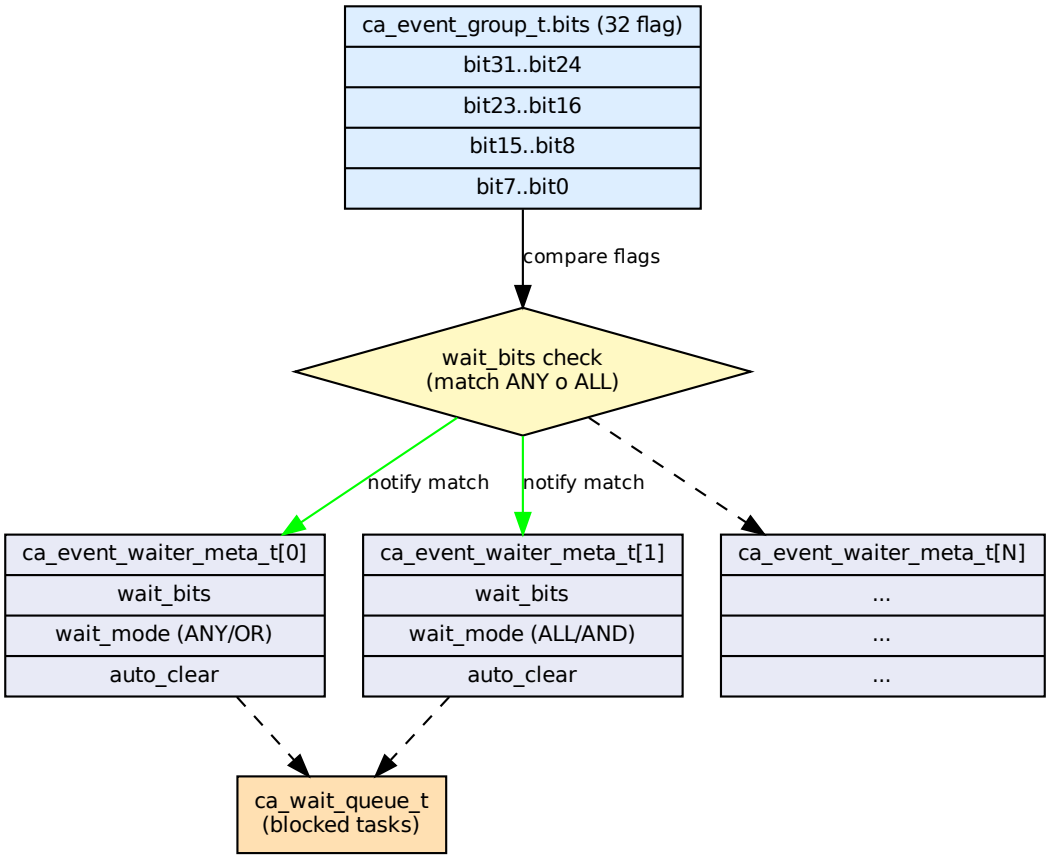

Figure 10.4: Event Group Structure 32-bit

10.1.9 9.9 Task Notification

Concept

Each task container has an integrated `notify_value` (u32) field. No external structure required.

API

```
// Send (6 possible actions)
ca_notify_send(task_idx, value, CA_NOTIFY_ACTION_SET_BITS);     // OR
ca_notify_send(task_idx, value, CA_NOTIFY_ACTION_CLEAR_BITS);   // AND NOT
ca_notify_send(task_idx, value, CA_NOTIFY_ACTION_OVERWRITE);    // Sostituisci
ca_notify_send(task_idx, value, CA_NOTIFY_ACTION_INCREMENT);    // ++
ca_notify_send(task_idx, value, CA_NOTIFY_ACTION_SET_IF_EMPTY);// Write only if
    empty
ca_notify_send_isr(task_idx, value, action);                    // Da ISR

// Ricezione
u32 val = ca_notify_wait(true, 1000);   // Blocks, clear on wake-up
u32 val = ca_notify_wait(false, 1000);  // Blocca, no clear

// Helper
ca_notify_give(task_idx, value);        // = send with OVERWRITE
```

```
ca_notify_give_inc(task_idx);           // = send with INCREMENT
ca_notify_take(timeout_ms);             // = wait con clear
ca_notify_peek(timeout_ms);             // = wait without clear
ca_notify_get(task_idx);                // Non-blocking read
ca_notify_clear(task_idx);              // Azzera
```

`CA_NOTIFY_ACTION_SET_IF_EMPTY` writes the value only if no notification is pending, i.e. if `notify_value` is 0 (the same test as `ca_notify_wait`). If one is already there it touches nothing, wakes nobody and `ca_notify_send` returns `false`: the sender knows the previous data has not been read yet. It is the equivalent of FreeRTOS `eSetValueWithoutOverwrite`. A value of 0 is not a notification: sending it with this action leaves nothing pending.

10.1.10 9.10 Stream Buffer

Circular byte buffer for continuous data streams (e.g. UART reception):

```
// Static definition
CA_STREAM_STATIC_DEFINE(uart_rx, 256);

// Or dynamic
ca_stream_buffer_t sb;
ca_stream_init(&sb, 256);

// Configurazione
ca_stream_set_trigger(&sb, 10);  // Wake the receiver after 10 bytes

// Producer (also from ISR)
ca_stream_send(&sb, data, len, timeout_ms);
ca_stream_send_isr(&sb, data, len);

// Consumatore
u32 letti = ca_stream_receive(&sb, buf, max, timeout_ms);

// Utilities
ca_stream_bytes_available(&sb);
ca_stream_space_available(&sb);
```

The **activation level** is a useful feature: the receiver is not woken up on every byte, but only when at least N bytes are available.

> The two waits are not symmetric. The **receiver** parks itself and is woken up to handle by the producer (`ca_scheduler_wake_waiter_handle()`) when the activation level is reached. The **sender** with a full buffer instead still does **polling**: `ca_os_sleep(1)` and retries, until timeout. It resumes therefore up to 1 ms after space has been freed. The same applies for `ca_message_send()`. With `timeout = 0` no waiting occurs: the stream writes as much as it can and returns the number of bytes written, the message (atomic) writes nothing and returns `false`. In both cases the return value must be checked.

10.1.11 9.11 Message Buffer

Like the stream, but with framing: each message is preceded by a 2-byte header (length). Send and receive are atomic.

```
CA_MESSAGE_STATIC_DEFINE(msg_buf, 512);

// Produttore
ca_message_send(&msg_buf, &my_struct, sizeof(my_struct), timeout);
ca_message_send_isr(&msg_buf, &my_struct, sizeof(my_struct));

// Consumatore
```

```
u16 len = ca_message_receive(&msg_buf, buf, max_len, timeout);

// Query
u16 next_size = ca_message_peek_size(&msg_buf);
u16 count = ca_message_count(&msg_buf);
```

10.1.12 9.12 Read-Write Lock (`ca_rwlock_t`)

Concept

The **Read-Write Lock** allows concurrent read access to N simultaneous tasks, while maintaining exclusive write access. It is more efficient than a mutex when reads are frequent and writes are rare (configuration data, tables, cache).

Write-preferring strategy: a waiting writer blocks new readers, preventing write starvation in the presence of continuous readers.

Structure

```
typedef struct {
    volatile u16  readers;       /* active readers */
    volatile u8   writer_active; /* scrittore in corso */
    ca_wait_queue_t   read_queue;    /* waiting readers */
    ca_wait_queue_t   write_queue;   /* waiting writers */
    ca_spinlock_irq_t internal_lock;
} ca_rwlock_t;
```

API

```
ca_rwlock_t rw;
ca_rwlock_init(&rw);

/* Read (N simultaneous tasks) */
ca_rwlock_read_lock(&rw);     /* block if a writer is active or waiting */
/* ... read shared data ... */
ca_rwlock_read_unlock(&rw);

/* Write (exclusive) */
ca_rwlock_write_lock(&rw);    /* block while readers > 0 or another writer */
/* ... modify shared data ... */
ca_rwlock_write_unlock(&rw);  /* wake waiting writers (priority) or the readers
   */
```

Wake-up Policy

On write release: 1. If there are writers waiting (`write_queue` not empty) → wake up the first writer 2. Otherwise → wake up all readers waiting (`read_queue`)

This ensures that the writer will not wait indefinitely even in the presence of continuous readers.

Comparison with Mutex

	Mutex	RWLock
Concurrent readers	1	N unlimited
Writing	Exclusive	Exclusive
Overhead	Lower	Higher

	Mutex	RWLock
Ideal use	Short critical sections	Read-heavy data structures

Configuration

```
#define EN_RWLOCK  1   /* in os_config.h */
```

10.1.13 9.13 Barrier (`ca_barrier_t`)

Concept

The **Barrier** is a synchronization point: N tasks block until all have arrived, then they all resume simultaneously. It is the classic pattern for coordinating parallel tasks that must proceed in synchronous phases.

```
task_A
task_B
task_C

           ca_barrier_wait()       all blocked here

                                        only one returns true (the trigger)
          ripartono tutti simultaneamente
```

The barrier is **auto-reset**: after release it automatically clears and is reusable in the next cycle without re-initialization.

Structure

```
typedef struct {
    volatile u32  count;         /* numero task da sincronizzare */
    volatile u32  arrived;       /* tasks arrived in this phase */
    volatile u32  phase;         /* current phase (auto-incremented) */
    ca_wait_queue_t   wait_queue;
    ca_spinlock_irq_t internal_lock;
} ca_barrier_t;
```

The `phase` field allows to distinguish successive cycles: a task that has just crossed the barrier sees `phase == N` while tasks from the previous cycle saw `phase == N-1`.

API

```
ca_barrier_t barrier;
ca_barrier_init(&barrier, 3);   /* 3 tasks must arrive */

/* in every participating task: */
bool is_trigger = ca_barrier_wait(&barrier);
/* returns true only for the last task to arrive (the "trigger") */
/* all the others return false */
```

Typical usage

```c
#define N_WORKERS 4
static ca_barrier_t phase_barrier;

static u32 worker(void *arg) {
    const u32 idx = ca_os_thid_from_handle(ca_os_self_handle());
    (void)arg;
    while (1) {
        /* PHASE 1: parallel processing */
        do_phase1_work(idx);

        /* synchronization: waits for everyone */
        ca_barrier_wait(&phase_barrier);

        /* PHASE 2: all phase-1 data are ready */
        do_phase2_work(idx);

        ca_barrier_wait(&phase_barrier);
    }
    return 0;
}

void ca_os_main(void) {
    ca_barrier_init(&phase_barrier, N_WORKERS);
    for (u32 i = 0; i < N_WORKERS; i++)
        ca_os_job("worker", CA_TH_LEVEL2, worker, (void *)(uintptr_t)i,
    STACK_SMALL, CA_JOB_STD, CA_FAULT_ASSERT);
    ca_os_run(true);
}
```

Difference with Event Group

	Event Group (WAIT_ALL)	Barrier
Producers/consumers	Distinct	Same tasks
Auto-reset	Configurable	Always
Number of phases	Single	Unlimited cyclic
Typical use	Data aggregation	Synchronization of parallel phases

Configuration

```c
#define EN_BARRIER  1   /* in os_config.h */
```

10.1.14 9.14 Block Pool (`ca_block_pool_t`)

Concept

The **Block Pool** is a fixed-size block allocator. Compared to the generic heap (`ca_memory_allocate`), it offers:

- **O(1)** for both allocation and deallocation
- **Zero fragmentation**: all blocks have the same size
- **ISR-safe**: usable from interrupt handlers
- **Determinism**: worst-case predictable, no scanning

It is the ideal mechanism for embedded systems with hard real-time requirements or certification constraints (DO-178C, IEC 61508).

Structure

```
typedef struct {
    void         *free_list;   /* first free block (in-place linked list) */
    u32           block_size;  /* size of each block (>= 4, multiple of 4) */
    u32           total;       /* total number of blocks */
    volatile u32  free_count;  /* currently free blocks */
    ca_spinlock_irq_t lock;        /* ISR-safe spinlock */
} ca_block_pool_t;
```

Free list in-place

The free block list does not use external structures: the first 4 bytes of each free block contain the pointer to the next free block. When the block is allocated, the user overwrites those 4 bytes with their own data — no memory overhead.

```
pool_buf (N    block_size byte):

    *next              *next              *next                          NULL

     (free)       (free)       (free)               (free)

  free_list (pool->free_list)
```

API

```
/* Dichiarazione */
static u8 __attribute__((aligned(4))) buf[8 * 64];
static ca_block_pool_t bp;

/* Inizializzazione */
ca_block_pool_init(&bp, buf, sizeof(buf), 64);
/*     8 blocchi da 64 byte */

/* Allocation (O(1), ISR-safe) */
void *blk = ca_block_alloc(&bp);    /* NULL if the pool is exhausted */

/* Release (O(1), ISR-safe) */
ca_block_free(&bp, blk);

/* Query */
u32 free  = ca_block_pool_free_count(&bp);  /* free blocks */
u32 total = ca_block_pool_total(&bp);       /* total blocks */
```

Task switching via queue

The typical pattern is: producer allocates, inserts pointer into a queue, consumer receives and frees:

```
/* Produttore */
MyData *blk = (MyData *)ca_block_alloc(&bp);
if (blk == NULL) { alloc_fail++; continue; }
blk->value = read_sensor();
```

```
u32 ptr = (u32)(uintptr_t)blk;
ca_queue_static_send(&queue.q, &ptr, CA_WAIT_FOREVER);

/* Consumatore */
u32 ptr = 0;
ca_queue_static_receive(&queue.q, &ptr, 500);
MyData *blk = (MyData *)(uintptr_t)ptr;
process(blk);
ca_block_free(&bp, blk);
```

The cast `(u32)(uintptr_t)` is valid on Cortex-M where all pointers are 32 bits.

Sizing

```
N_BLOCKS = sizeof(buf) / block_size

buffer richiesto = N_BLOCKS    block_size byte
(must be 4-byte aligned)
```

The pool must be sized to contain the maximum number of blocks simultaneously in flight (allocated but not yet freed). If the pool is exhausted, `ca_block_alloc` returns NULL without blocking — the caller must handle this case.

Comparison with heap

	`ca_memory_allocate` (heap)	`ca_block_pool_t`
Block size	Variable	Fixed
Fragmentation	Possible	None
Allocation time	O(N) worst	O(1)
ISR-safe	No	Yes
Overhead	Per block	Only pool header

Configuration

```
#define EN_BLOCK_POOL  1   /* in os_config.h */
```

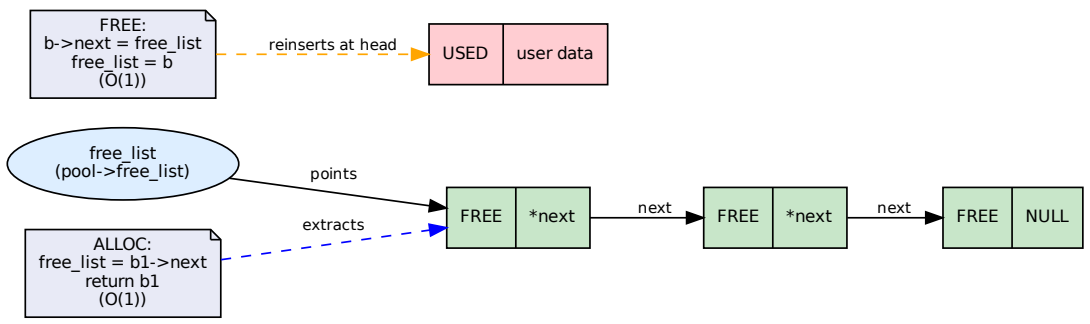

Figure 10.5: Block Pool O(1) Architecture

Previous chapter: caOS Kernel Next chapter: Memory Management in caOS

Chapter 11

Memory Management in caOS

11.1 Chapter 10 - Memory Management in caOS

This chapter describes how caOS implements memory management and protection via MPU, introduced in Chapter 4.

11.1.1 10.1 Memory Layout

Two memories, two uses

caOS physically separates stacks from the heap by leveraging TCM memory:

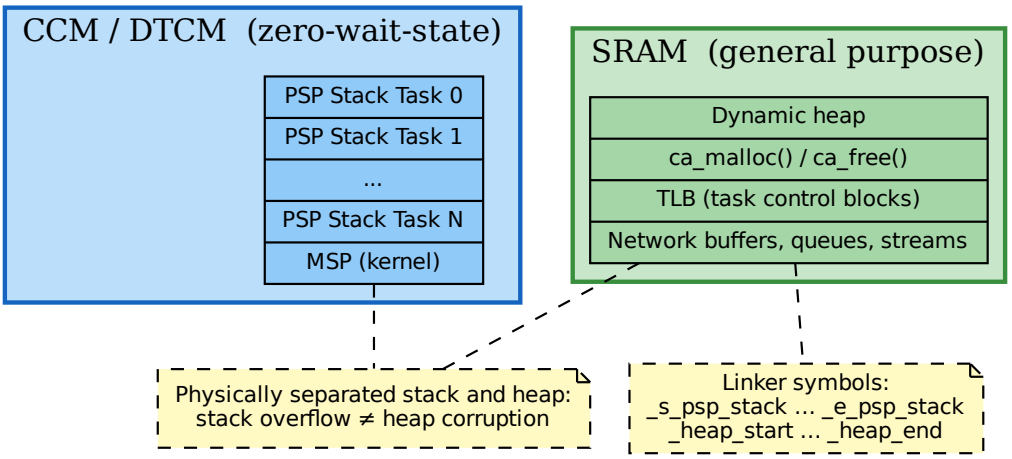

Figure 11.1: Two memories, two uses

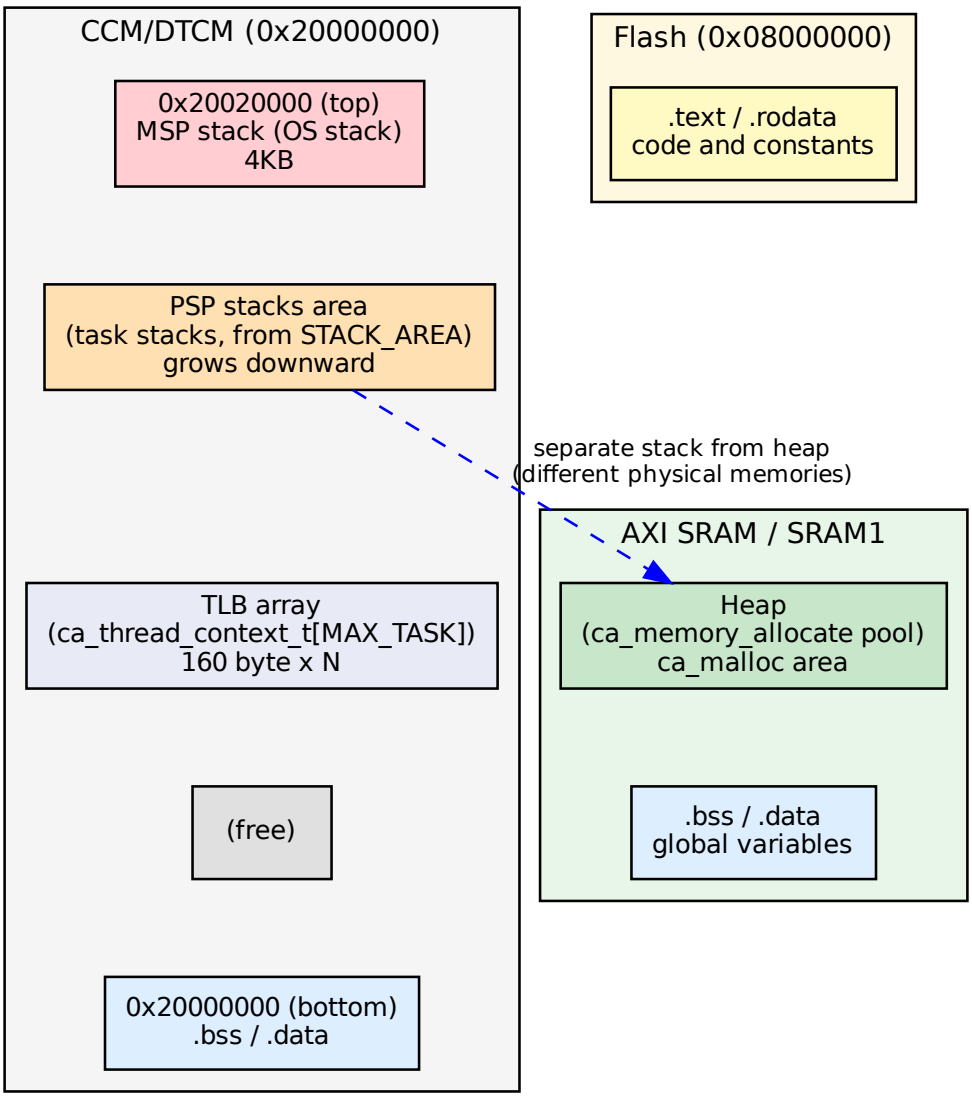

Figure 11.2: STM32H753 memory layout

This separation has important advantages: - **Stacks and heap cannot overlap** (physically different memories) - **Faster stacks** (CCM/DTCM has zero wait states) - **Isolated corruption**: a stack overflow does not corrupt the heap

Linker symbols

The boundaries of the areas are defined in the linker script and accessible as symbols:

```
extern u32 _tlb_area_base;      // Base TLB (array contenitori task)
extern u32 _s_psp_stack;        // Limite basso stack PSP
extern u32 _e_psp_stack;        // Top stack PSP
extern u32 _msp_stack_base;     // Base MSP
extern u32 _msp_stack_top;      // Top MSP
```

```
extern u32 _heap_start;         // Inizio heap (SRAM)
extern u32 _heap_end;           // Fine heap (SRAM)
```

11.1.2 10.2 Heap Allocator

Initialization

```
ca_memory_init(&_heap_start, &_heap_end);
```

The heap occupies the SRAM between the symbols `_heap_start` and `_heap_end`. The size varies by MCU (from a few KB on the F103 to hundreds of KB on the H753).

API

```
// Allocazione
void *ptr = ca_memory_allocate(256);           // Alloca 256 byte (del task chiamante)
void *shr = ca_memory_allocate_shared(256);    // Alloca 256 byte senza proprietario

// Liberazione
u32 freed_size;
ca_memory_free(ptr, &freed_size, true);        // Libera e azzera

// Query
u32 avail = ca_memory_get_avail_memory();      // Byte liberi
u32 total = ca_memory_get_total_size();         // Dimensione totale
u32 usage = ca_memory_get_task_usage(task_idx); // Byte usati da un task
ca_memory_check_t chk; ca_memory_check(&chk);  // Integrita' della catena + spazio (largest_free)

// Debug
ca_memory_list();                               // Stampa lista blocchi
ca_memory_dump(ptr, lines);                     // Hexdump
ca_memory_dump_avail();                         // Mostra blocchi liberi
ca_memory_info(ptr);                            // Info su un blocco
```

Proprietary tracking

The most important feature of the caOS allocator is **proprietary tracking**: every allocated block records the **slot** of the task that allocated it (`owner_slot`).

The slot is the fixed cell of the task container, not its position in the task list: that changes when a task below it terminates, and an owner registered by position would end up naming another task (and causing it to free memory that is not its own).

When a task dies (removed, crash, safeguard), the scheduler automatically calls:

```
ca_memory_free_all_owned_by(task_slot);
```

This frees all blocks allocated by the task, preventing memory leaks. The `num_alloc` field in the task container keeps track of active blocks for each task.

Memory without an owner: `ca_memory_allocate_shared`

Tracking has a downside: an object created by a task and passed to others (a queue, a delivered buffer) dies with the task that created it. For these cases, `ca_memory_allocate_shared()` is identical to `ca_memory_allocate()` but **does not register the owner** (`owner_slot = 0xFFFF`, as with allocations made before the scheduler): the block survives the task's exit and is only freed with `ca_memory_free()`, which is common to both. The responsibility for freeing it lies with the code that uses it: no automatic cleanup collects it.

Concurrency: scheduler lock, not IRQ disabled

Allocation and deallocation exclude other tasks with `ca_os_sched_lock()` (§8.5), not by disabling interrupts: no ISR touches the heap, and the cleanup of tasks removed in PendSV cannot start while a task holds the lock. The chain scan, which on a fragmented heap reached ~15 µs on F446/F767, no longer delays ISRs. Diagnostic functions (`ca_memory_check`, `list`, `dump`, ...) remain with IRQs disabled. `HEAP_SCHED_LOCK 0` in `memory.c` restores the previous behavior for comparison.

Cleanup on free

`ca_memory_free(ptr, &size, true)` zeroes out data before freeing the block. This prevents accidental reuse of sensitive data and facilitates debugging.

Secret area (`EN_TAMP`, paid version only)

On U575 and H563, the **SRAM2** (64 KB) is in the list of hardware tamper "secrets": a tamper in confirmed mode erases it, one in potential mode blocks access to it. However, in the linker script, SRAM2 is inside the single RAM region, and therefore inside the heap: without precautions, a tamper would erase live blocks. On the H563, SRAM2 is just 32 KB below the top of the heap, and the allocator carves blocks right from the top.

With `EN_TAMP = 1`, caOS removes it from the heap **on its own, at startup**, immediately after `ca_memory_init` and before any allocation: it does not depend on the application remembering to do so.

```
1 void *ca_memory_reserve_secret(u32 *size);   /* chiamata da caos.c al boot;
    idempotente */
2 void *ca_memory_secret(u32 *size);           /* l'area, NULL (*size = 0) se la
    MCU non ce l'ha */
```

- The area is determined by the hardware: `CA_SECRET_AREA_BASE` / `CA_SECRET_AREA_SIZE` in the objmap (U575 `0x20030000`, H563 `0x20040000`, 64 KB). On other MCUs it is not defined and `ca_memory_secret()` returns `NULL`.
- It is a heap block marked as occupied and without an owner, which no one frees (`ca_memory_free` rejects it). The block **headers** remain outside the SRAM2: the one for the reserved block is on an 8-byte boundary just below (U575 `0x2002FFE0`), the one for the next free block at the beginning of the SRAM3. The tamper erases only the content, which the allocator does not check, and the chain remains intact (verified with `memlist` after a real tamper on the U575).
- The heap loses 64 KB.
- `keys_store` takes its 2 KB from here (§13.9); the remaining **62 KB are available to the application** for other data to be erased in case of intrusion. The area is 64 KB anyway even if `keys_store` is not compiled.
- With the FREE package, the heap is limited and may not reach the SRAM2: in that case, the area is RAM that no one manages and it is provided as is. However, the tamper is only in the paid version.

The actual tamper is described in the chapter Backup SRAM and tamper.

11.1.3 10.3 MPU Protection

Initialization

```
1 ca_mpu_init();  // Chiamata da main() prima dello scheduler
```

Configure the MPU with the base regions.

System-reserved regions

caOS reserves **3 MPU regions** for the kernel (`OS_REGIONS`):

Region	Usage	Type
0	Canary MSP (Main Stack)	Read-only, 32 bytes
1	Current task stack guard (PSP canary)	Read-only, 32 bytes
2	Extended guard (*deep guard* on ARMv7-M) / top PSP canary if `PSP_CHECK_TOP`	Read-only

Regions 1-2 are updated at every context switch to protect the current task's stack.

Above these, three regions are reserved **only if the corresponding peripheral is active** — therefore they are not contiguous and must be read from the `objmap.h`:

Region	Usage	Condition
3	`.usb_dma` — USB descriptors and buffers	`EN_USB`
4	`.net_pool` — Network buffer zero-copy pool	`EN_NET`
5	`.eth_dma` — ETH descriptor rings	`EN_ETH`

> Precisely because these regions **are not contiguous**, the number of *occupied* regions is not a valid index for the first free one: with NET enabled and USB disabled, the count is 4, while region 4 is occupied by NET. `ca_mpu_add_region()` uses `ca_mpu_first_free_region()`, which scans the regions looking for the first one that is truly disabled (`RASR.ENABLE` on ARMv7-M, `RLAR.EN` on ARMv8-M) **and not reserved** (`ca_mpu_region_is_reserved()`): it always skips kernel regions (0..`OS_REGIONS`-1) and those peripheral regions `USB/NET/ETH_MPU_REGION` defined in `objmap.h`, even if they are currently turned off.
>
> Checking only the enable bit was not enough: before `ca_os_run()` the canaries are not yet armed, so a region requested by `ca_os_configure()` would receive region 1, which the stack guard reprograms at every context switch. The protection would disappear at the first switch without any error (ex26/ex46/ex47, key store; fixed on 09/23). For protection that must last, verify with `mpu` **after** the system is running.

User regions

The remaining regions (from 6 upwards, up to 8 or 16 depending on the part) are available for the application:

```
// Proteggi una regione custom
int region = ca_mpu_add_region(addr, size, MPU_ACCESS_RDONLY);

// Aggiorna permessi di una regione
ca_mpu_update_region(region, addr, size, MPU_ACCESS_RDWR);

// Query
u32 total = ca_mpu_get_total_regions();       // 8 o 16, vedi MPU_REGION_COUNT
u32 free = ca_mpu_get_available_regions();    // Libere per l'utente
u32 busy = ca_mpu_get_busy_regions();         // Occupate

```

```
// Debug
ca_mpu_dump_regions();  // Stampa tutte le regioni attive
```

The number of regions **does not** follow the core: it is an implementation choice of the part, declared in `MPU_REGION_COUNT` in its `objmap.h`.

Part	Core	HW Regions	Free with ETH active
F103	M3	8	— (no ETH)
F407 / F429 / F446	M4	8	2 (F446: 3, no ETH)
F746	M7	8	2
U575	M33	8	3 (no ETH)
H563 / H747 / H753	M33 / M7	16	10

> Be careful not to deduce the count from the core: **U575 is an M33 but has 8 regions**, not 16 like the H563. The tight budget of the 8-region parts is the reason why the two heap boundaries are switched to software canaries.

Canary protection: flow at every context switch

In `ca_scheduler_switch_context()`:

```
// Aggiorna protezione canary per il nuovo task
ca_mpu_protect_canary_psp_start(GET_CANARY_LOWER(g_current_task));
```

This reconfigures MPU region 1 to point to the base of the new task's stack. If the task writes into the canary zone (overflow), the MPU generates an immediate MemManage Fault.

Heap boundary protection: software canary, not MPU

The heap boundaries are protected by a **software canary**, not by MPU regions: 32 bytes at each end (one hexdump line) filled with the `0xAABBCCDD` pattern, placed **outside** the block chain and therefore not allocatable.

```
bool ok = ca_memory_check_canary();   // verificato dall'idle ogni 100 cicli
ca_memory_restore_canary();           // ripristina il marcatore dopo la
    segnalazione
```

The pattern is deliberately different from `START_CHECK_CANARY` (the block checksum seed) and stack canaries, so that an hexdump can distinguish them.

> **Why not the MPU.** Until 08/20/2026, two MPU regions protected the heap boundaries. They were removed: the allocator is **next-fit** and cannot exceed START/END anyway, so those regions covered the least likely case, while an overrun *inside* the heap — which is what actually happens — was not covered in any way. The software canary offers the same coverage and returns **2 MPU regions** to the budget on all families: on F407/F429/F746 with ETH active, it goes from 0 to 2 free regions.

The reaction to a corrupted canary is **message + immediate reset**, not `CA_SAFE_FAIL`: heap corruption is a *global* state, not a fault of the task that detects it, and with `RESTART` policy, the safeguard would enter a loop that cyclically destroys the idle.

Conditionality: `__MPU_PRESENT`

All MPU functions are conditional:

```
#if __MPU_PRESENT
void ca_mpu_init(void) { /* implementazione reale */ }
#else
#define ca_mpu_init()   /* no-op */
#endif
```

On Cortex-M3 (F103) without MPU, all functions become empty macros. Application code does not need `#ifdef`: it compiles on all targets.

11.1.4 10.4 MemAux: newlib replacement

caOS does not use the standard C library (newlib) for memory and string functions. The `memaux` module provides optimized implementations:

```
// Memoria
ca_memset_u32(dst, value, n_words);  // Azzeramento/fill a 32 bit
ca_memcpy(dst, src, n_bytes);        // Copia
ca_memcmp(a, b, n_bytes);            // Confronto

// Stringhe
ca_strlen(str);
ca_strncpy(dst, src, max);
ca_strcmp(a, b);
ca_strncmp(a, b, n);
```

Advantages: - **No dependency on newlib**: reduces binary size by tens of KB - **No calls to `_sbrk`**: newlib requires `_sbrk` for `malloc`, which conflicts with the custom allocator - **Total control**: no unverified external code

11.1.5 10.5 Summary: who allocates what and where

What	Where	Allocator
Task stack (PSP)	CCM/DTCM	CCM incremental allocator
Task containers	TLB area (SRAM/DTCM)	Static array
Main stack (MSP)	Top CCM/DTCM	Defined by linker
Heap (malloc)	SRAM	ca_memory_allocate
Static queue buffer	.bss (SRAM)	Compile-time (macro)
Heap queue buffer	SRAM heap	ca_memory_allocate
Stream/Message buffer	SRAM heap or .bss	User choice
Global variables	.data/.bss (SRAM)	Compile-time

Previous chapter: caOS Synchronization Next chapter: Drivers and I/O in caOS

Chapter 12

Drivers and I/O in caOS

12.1 Chapter 11 - Drivers and I/O in caOS

This chapter describes how caOS implements hardware drivers and the I/O system, introduced in Chapter 5.

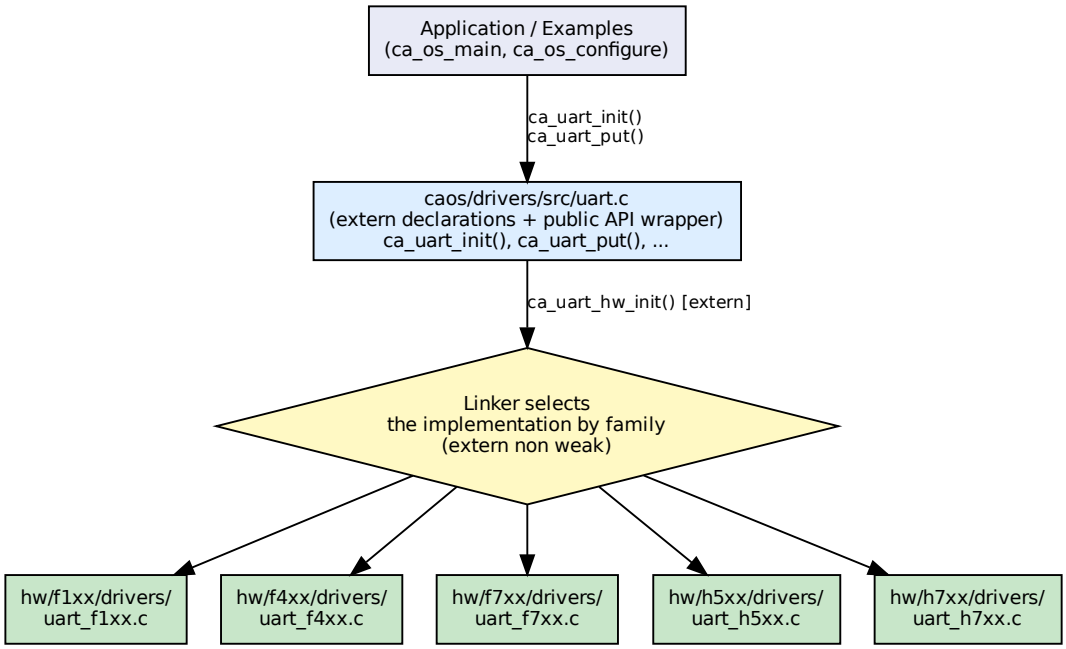

Figure 12.1: caOS driver architecture

12.1.1 11.1 The Extern pattern

Two-level architecture

Each driver in caOS consists of two files:

```
caos/drivers/src/gpio_driver.c          Logica generica + extern declarations
hw/f4xx/drivers/gpio_driver_f4xx.c      Implementazione HW bare-metal (CMSIS)
```

The generic file declares HW-specific functions with `extern` (without implementation). The family-specific file provides the concrete implementations. The linker resolves the references during the link phase: if a family does not implement a function, the linker reports an error.

HW functions **are not** `weak`: every family must implement all of them.

Concrete example: GPIO

Generic file (`caos/drivers/src/gpio_driver.c`):

```
extern GPIO_TypeDef* ca_gpio_get_io_port(ca_gpio_port_t port);
extern bool          ca_gpio_hw_init_port(ca_gpio_port_t port);
extern bool          ca_gpio_hw_configure(ca_gpio_port_t port, ca_gpio_pin_t pin
    ,
                                          ca_gpio_mode_t mode, ...);

// Logica comune: opera sui registri GPIO via le extern
void ca_gpio_configure(u8 port, u8 pin, u8 mode, u8 otype, u8 speed, u8 pull, u8
     af) {
    GPIO_TypeDef *hw = ca_gpio_get_io_port(port);
    if (hw == NULL) return;
    hw->MODER  &= ~(3U << (pin * 2));
    hw->MODER  |=  (mode << (pin * 2));
    // ... ecc
}
```

F4xx specific file (`hw/f4xx/drivers/gpio_driver_f4xx.c`):

```
// Implementazione: mappa ID porta     registro hardware
GPIO_TypeDef* ca_gpio_get_io_port(ca_gpio_port_t port) {
    static GPIO_TypeDef * const ports[] = {GPIOA, GPIOB, GPIOC, GPIOD, GPIOE,
    ...};
    if (port >= ARRAY_SIZE(ports)) return NULL;
    return ports[port];
}
```

HW functions declared extern for drivers

Driver	Extern function	Responsibility
GPIO	`ca_gpio_get_io_port(port)`	Maps port ID → GPIO_TypeDef*
GPIO	`ca_gpio_hw_init_port(port)`	Enables RCC clock for port
UART	`ca_uart_hw_configure_gpio(num)`	Configures pins and AF for UART
UART	`ca_uart_hw_init(num, baud, inst)`	Configures UART registers
UART	`ca_uart_hw_put(inst, msg)`	Transmits string
UART	`ca_uart_hw_recv_handler(inst)`	Handles ISR reception

GPIO clock per family

GPIO clock enabling changes for each STM32 family:

Family	Register	Bit
F1xx	RCC->APB2ENR	RCC_APB2ENR_IOPxEN
F4xx	RCC->AHB1ENR	RCC_AHB1ENR_GPIOxEN
F7xx	RCC->AHB1ENR	RCC_AHB1ENR_GPIOxEN
H5xx	RCC->AHB2ENR	RCC_AHB2ENR_GPIOxEN
H7xx	RCC->AHB4ENR	RCC_AHB4ENR_GPIOxEN

Family	Register	Bit
U5xx	RCC->AHB2ENR1	RCC_AHB2ENR1_GPIOxEN

Each `gpio_driver_<famiglia>.c` implements `ca_gpio_init_port()` with the correct register.

Special case: F1xx

The F1xx has completely different GPIO registers (CRL/CRH with 4 bits per pin). The `gpio_driver_f1xx.c` driver also replaces the basic configuration functions, not just the port mapping.

12.1.2 11.2 GPIO Driver

API

```
// Configurazione
ca_gpio_configure(port, pin, mode, otype, speed, pull, af);
ca_uart_configure_gpio(uart_num);  // Configura pin per UART

// I/O
ca_gpio_write(port, pin, state);   // Usa BSRR (atomico)
ca_gpio_read(port, pin);           // Legge IDR
ca_gpio_toggle(port, pin);         // Toggle via ODR

// Inizializzazione
ca_gpio_init_port(port);           // Abilita clock RCC
```

Atomic writing via BSRR

caOS uses the BSRR (Bit Set/Reset Register) register for GPIO writes. A single write instruction sets or resets a pin, without the read-modify-write sequence that would be necessary with ODR. This is inherently thread-safe.

12.1.3 11.3 Debug UART

Architecture

The debug UART in caOS is a textual output channel, the sender of **stdout**:

```
Task                ca_stdout_printf() / put()     coda     task "stdout"
    sender()

    repeater() (opzionale)
ISR                 ca_stdout_echo() / flush()   (eco della CLI, svuotamento: ISR
    -safe)
Fault handler       PUT() diretto sul sender, senza coda
```

The `sender` is the function that physically writes the message; the `STDOUT` macro selects it according to the configuration: - `ca_uart_dbg_put`: Debug UART (the ST-LINK VCP on Nucleo boards) - `ca_itm_put`: SWO (debug probe) - `ca_lpuart_put`: LPUART, low-power console (see below)

Configuration

In `os_config.h` the channel is selected; the UART instance depends on the board and is located in `hw/<fam>/<mcu>/objmap.h` (USART3 on Nucleo-144, i.e., the ST-LINK VCP; USART1 on F103, F407, and H747):

```
ENABLE_ITM          0                   // os_config.h: output ITM
UART_DBG_BAUDRATE   CA_UART_BAUD_115200   // os_config.h
ENABLE_DBG_UART     1                   // objmap.h
UART_DBG_NUM        3                   // objmap.h: USART3 sulle Nucleo-144
```

UART initialization and transmission

The console does not have a separate driver: it is the generic UART `UART_DBG_NUM`, opened by the kernel in `ca_os_init()` (with `ENABLE_DBG_UART`):

```
ca_uart_init(UART_DBG_NUM, UART_DBG_BAUDRATE,
             STDIN_ON_UART ? ca_cli_rx_byte : NULL,   // RX -> CLI
             UART_DBG_PINMAP);                        // GPIO dentro
    ca_uart_init
```

The stdout sender is instead chosen by the application in `ca_os_configure()`, with the `STDOUT` macro (which equals `ca_uart_dbg_put`, `ca_itm_put`, ... according to the config):

```
ca_stdout_init();
ca_stdout_set_sender(STDOUT);
ca_stdout_create_thread();
```

Internally: 1. `ca_uart_init()` configures the pins according to `UART_DBG_PINMAP`, then the registers with `ca_uart_hw_init()` 2. `ca_uart_dbg_put()` is the sender-compatible wrapper: it calls `ca_uart_put(UART_DBG_NUM, ...)`, busy-waits on TXE 3. Reception is interrupt-driven: the ISR calls `ca_uart_recv_handler()`, which passes each byte to `ca_cli_rx_byte()`

RX: FIFO and cyclic emptying

Without a FIFO, the UART holds **one** byte: at 115200 baud, the ISR has ~87 us to read it before an overrun (ORE), and the lost byte never reaches the parser. This was the cause of the "CLI paste losing characters" (U575: `cli_stat` overrun=4).

On **U5, H5, and H7**, the 8-level RX FIFO is enabled (`USART_CR1_FIFOEN`, writable only with `UE=0`, therefore set before enable). Consequently, `ca_uart_recv_handler()` **loops** as long as `ca_uart_hw_recv_handler()` returns data (cap of 16 per interrupt, so that a line receiving continuously does not hold the ISR forever); a byte discarded due to a line error (FE/NE/PE, return 2) does not interrupt the loop. The margin increases from 1 to 8 characters (~700 us). F1/F4/F7 do not have a FIFO on the USART: there, only ISR latency matters (measured with ex87, see S2_02). Verified on 09/29 on U575: 20 examples with the bench typing at 0 ms between characters, overrun 0. The LPUART is not affected.

LPUART — low-power console

On U5xx/H5xx/H7xx, the LPUART driver (`caos/drivers/src/lpuart.c`) offers an alternative console designed for battery-powered systems:

- **kernel clock HSI16 + HSIKERON**: the baudrate is independent of the sysclk (no retune after `pwr freq` or wake from Stop) and reception remains functional in Stop;
- with `wake=true`, the reception of a character **wakes the MCU from Sleep/Stop** and the byte is delivered to the CLI (it is not lost);
- TX polling (`ca_lpuart_put`, sender-compatible), RX interrupt-driven.

Console configuration in `os_config.h`:

```
STDOUT_ON_LPUART   1        // STDOUT = ca_lpuart_put
STDIN_ON_LPUART    1        // STDIN  = ca_cli_data_from_isr
LPUART_STD_BAUD    115200U
LPUART_STD_WAKE    1        // console armata come wake da Sleep/Stop
```

With both active, `EVAL_LPUART_STD` expands to `ca_lpuart_std_cli()` called by `ca_os_init` (on_rx → `ca_cli_rx_byte`). **Note**: `EN_LPUART` must be defined **before** the STDOUT block in `os_config.h`.

Warning (test with jumpers on the ST-LINK VCP): the board's debug UART (`ENABLE_DBG_UART` in `objmap.h`) must be disabled if its pins are bridged with the LPUART pins — the USART push-pull TX would be in contention. Pins per board and jumper method: see example 62.

12.1.4 11.4 Stdout and repeater

One channel, one task

caOS has **one** textual output channel, the stdout. Tasks write to a static queue of `STDOUT_QUEUE_DEPTH` lines of `DEFAULT_MSG_SIZE` bytes (the depth is in `hw/<fam>/<mcu>/objmap.h`); a dedicated task, "stdout", empties it to the sender. It is the **only** console writer once started: no line will be mixed with another halfway through. The application starts it in `ca_os_configure()`:

```
EVAL_STDOUT(
    ca_stdout_init();
    ca_stdout_set_sender(STDOUT);
    ca_stdout_create_thread();
)
```

API

```
// Da task
ca_stdout_printf("Debug: %d\r\n", val);
ca_stdout_printf_n("Con newline: %d", val);  // aggiunge \r\n
ca_stdout_put("Stringa raw");
ca_stdout_put_n("Con newline");
ca_stdout_put_str(pstr);                     // p_str
ca_stdout_put_str_n(pstr);

// ISR-safe
ca_stdout_echo(buf, len);   // eco della CLI: lo scrive il task stdout fra due righe
ca_stdout_flush();          // scarta le righe in coda (es. all'apertura di una console CDC)

// Statistiche
u32 queued, dropped;
ca_stdout_stats(&queued, &dropped);          // righe in coda e perse (coda piena)
u32 echo_lost = ca_stdout_echo_dropped();    // byte di eco persi
```

Do not print from an ISR. Printing functions format into a task buffer and may block on the queue: an ISR raises a flag or a notification (`ca_notify_give_isr`) and the line is written by the task that wakes up.

Repeater: where to send lines besides the console

The old two-channel audit log is gone: the operating system provides the **mechanism**, the application decides the **policy**. `ca_stdout_set_repeater()` installs a hook called with every line, after the sender:

```
static u16 to_syslog(p_str line)
{
    ca_syslog_send(6U /* informational */, line->data);   // o flash, file, ...
    return 0;
}

void ca_os_main(void) {
```

```
    ca_stdout_set_repeater(to_syslog);
    /* ... */
}
```

The repeater runs in the stdout task — a normal task, scheduler active — so it **can block**, and it is subject to the same backpressure as the sender's queue. The string belongs to the stdout task and is valid only during the call: it must be copied if it needs to persist. It is **never called from a fault handler**: `panic.c` writes directly to the sender with `PUT()`, without a queue, by design (a flash write from handler mode could remain hung on an ISR that will never be serviced).

Conditional compilation

With `ENABLE_STDOUT == 0` all functions become empty macros (those that return a value evaluate to `0`, `false` or `NULL`):

```
#define ca_stdout_printf(...)        0
#define ca_stdout_set_repeater(hook)
```

Application code does not need `#ifdef`. The overhead without stdout is zero.

12.1.5 11.5 CLI (Command Line Interface)

Concept

The CLI is an interactive text interface via UART. It allows querying the system in real-time: task status, memory, MPU, drivers, network peripherals.

Architecture

```
UART RX ISR      ca_cli_rx_byte()      buffer circolare      Coda      Thread CLI
        parser      risposta
```

1. The UART ISR receives a byte and calls `ca_cli_rx_byte()`
2. Bytes are accumulated in a buffer until `\r` or `\n`
3. The complete line is inserted into the CLI queue
4. The CLI thread traverses the handler chain and calls the first one that recognizes the command

Echo. The echo of typed characters no longer exits from the ISR: it goes into a dedicated ISR-safe queue (`ca_stdout_echo()`, 128 one-byte slots) and the stdout drain thread, the sole console writer, empties it before each line. Previously, the echo written by the ISR could end up **inside** a line that a task was outputting byte by byte (`19788t37` in an app_2 capture). Before the drain starts, or without a sender, the CLI still writes directly. Echo bytes that do not fit into the queue are counted in `cli_stat`. A line from a task that arrives while typing still breaks the input line, just like in a PC shell.

Chain of Responsibility

CLI commands are managed via a chain of dynamically registered handlers. Each driver or service adds its own node to the chain via `ca_cli_register()`:

```
static bool my_cli_handler(c_str *pcmd) {
    c_str cmd = *pcmd;
    const char *p = ca_skip_sp(cmd->data);
    if (ca_strncmp(p, "help", 4) == 0) {
        CLI_PUT_N("mydrv info      mostra stato\r\n");
```

```
        return false;   // false = passa al prossimo handler
    }
    if (ca_strncmp(p, "mydrv", 5) == 0) {
        CLI_PRINTF_N("stato: ok");
        return true;    // true = comando gestito
    }
    return false;
}

static ca_cli_node_t s_cli_node = { my_cli_handler, NULL };

// Registrazione (una sola volta, es. in init)
static bool s_registered = false;
if (!s_registered) { ca_cli_register(&s_cli_node); s_registered = true; }
```

Rules: - `return true` — command handled, chain stops - `return false` — proceed to the next node - `help` always returns `false` to show all handlers in the chain - **DO NOT hold mutexes while calling** `CLI_PRINTF_N`/`CLI_PUT_N` (they contain `ca_os_sleep`)

Commands carrying a secret

Typed lines end up in the **history** (up/down arrows, `cli_stat` lists them): a command with a password would remain in RAM and be recallable. Two functions, introduced for `link pass <password> <nome>` of `workspace/app_3`:

Function	Effect
`ca_cli_set_secret_prefix("link pass ")`	as soon as the line being typed starts with the prefix, the following characters return as echo as `*` and the line **does not enter** the history
`ca_cli_hist_forget("link pass")`	clears history entries starting with the prefix, and the ISR line buffer if not currently typing

The handler also clears its own copy of the command after extracting the secret. The bench test of app_3 (`workspace/app_3/test_app3.py`) verifies that the password never appears either in the console or in `cli_stat`.

Built-in driver CLI commands

Driver	Flag `os_config.h`	Commands
`gpio_driver.c`	`EN_CLI_GPIO`	`gpio info <P> <n>`, `gpio all <P>`, `gpio get <P> <n>`, `gpio set <P> <n> <0|1>`, `gpio tog <P> <n>`
`uart.c`	`EN_CLI_UART`	`uart info`
`i2c.c`	`EN_CLI_I2C`	`i2c info`, `i2c scan <1..4>` (with timeout — does not block without devices)

Driver	Flag `os_config.h`	Commands
`adc.c`	`EN_CLI_ADC`	`adc info`, `adc read <1..3> <ch>`, `adc volt <1..3> <ch>`, `adc isr <1..3> <ch>`, `adc stop <1..3>`
`dac.c`	`EN_CLI_DAC`	`dac info`, `dac set <1|2> <0-4095>`, `dac run <1|2>`, `dac stop <1|2>`
`eth.c`	`EN_CLI_ETH`	`eth link`, `eth stats`, `eth dump`
`rtc.c`	`EN_CLI_RTC`	`rtc info`, `rtc set YYYY-MM-DD HH:MM:SS`, `rtc alarm <a|b> HH:MM:SS`, `rtc cal <ppm>`, `rtc unix [<sec>]`
`flash.c`	`EN_CLI_FLASH`	`flash info [s]`, `flash dump [addr]`, `flash erase <addr> <n>`, `flash erase_s <s>`, `flash test <s>`
`timer.c`	`EN_CLI_TIMER`	`timer info [n]`, `timer start <n>`, `timer stop <n>`, `timer free <n>`, `timer cnt <n>`, `timer pwm <n> <ch> <duty>`
`dma.c`	`EN_CLI_DMA`	`dma info`
`spi.c`	`EN_CLI_SPI`	`spi info`, `spi read <n> <addr>`, `spi write <n> <addr> <val>`
`wdt.c`	`EN_CLI_WDT`	`wdt info`
`rng.c`	`EN_CLI_RNG`	`rng get`
`crc32.c`	`EN_CLI_CRC`	`crc32 calc <addr> <len>`
`sdio.c`	`EN_CLI_SDIO`	`sdio info`, `sdio read <block>`
`keys_store.c`	`EN_CLI_KSTORE`	`kstore info`, `kstore list`
`qspi.c`	`EN_CLI_QSPI`	`qspi info`, `qspi read <addr> [len]`, `qspi erase <addr>`, `qspi test <addr>`
`can.c`	`EN_CLI_CAN`	`can info`, `can recv <n>`, `can send <n> <id> [b0..b7]`

Driver	Flag `os_config.h`	Commands
`led.c`	`EN_CLI_LED`	`led info`, `led on <n>`, `led off <n>`, `led tog <n>` (n=1..number of board LEDs)
`lptim.c`	`EN_CLI_LPTIM`	`lptim info [n]`, `lptim start <n>`, `lptim stop <n>`, `lptim free <n>`
`pwr.c`	`EN_CLI_PWR`	`pwr info`, `pwr freq <1-99>`, `pwr restore`, `pwr alarm <s>`, `pwr sleep <s>`, `pwr stop <s>`, `pwr stopms <ms>`, `pwr standby <s>` (`pwr dbg` where the family supports it)
`fat_service.c`	`EN_CLI_FAT`	`fat fdisk`, `fat mkfs`, `fat mount`, `fat umount`, `fat free`, `fat pwd`, `fat cd <dir>`, `fat ls [dir]`, `fat mkdir <dir>`, `fat rmdir <dir>`, `fat touch <file>`, `fat rm <file>`, `fat cat <file>`

Network service CLI commands

Service	Flag `os_config.h`	Commands
`net_proto.c`	`EN_CLI_NET`	`ip info`, `ip set <ip>`, `ip flush`, `ip link up|down`, `ip mtu <N>`, `ping <ip> [count=N] [time=T]`
`arp_service.c`	`EN_CLI_ARP`	`arp info`, `arp flush`, `arp del <n|ip>`, `arp add <mac> <ip>`, `arp req <ip>`
`route_service.c`	`EN_CLI_ROUTE`	`route info`, `route gw <ip>`, `route add <ip/prefix> gw <ip>`, `route del <n>`, `route flush`

Service	Flag `os_config.h`	Commands
`dhcp_service.c`	`EN_CLI_DHCP`	`dhcp info`, `dhcp renew`
`ntp_service.c`	`EN_CLI_NTP`	`ntp info`, `ntp sync`, `ntp server <n> <ip>`
`dns_service.c`	`EN_CLI_DNS`	`dns info`, `dns resolve <host>`, `dns server <ip>`
`mdns_service.c`	`EN_CLI_MDNS`	`mdns info`, `mdns announce`
`syslog_service.c`	`EN_CLI_SYSLOG`	`syslog info`, `syslog put [sev=0..7] <msg>`
`udp_server.c`	`EN_CLI_UDP_SRV`	`udp info`, `udp list`, `udp kick <id>`, `udp send <id> <msg>`
`tcp_service.c`	`EN_CLI_TCP`	`tcp list`, `tcp info <h>`, `tcp slist`, `tcp buf`, `tcp bufreset`, `tcp rxdrop`
`tftp_service.c`	`EN_CLI_TFTP`	`tftp get <ip> <file>`, `tftp put <ip> <file> [size]`, `tftp info`
`http_service.c`	`EN_CLI_HTTP`	`http info`, `http routes`
`mqtt_service.c`	`EN_CLI_MQTT`	`mqtt stat`, `mqtt pub <topic> <msg>` (QoS 0), `mqtt disc`
`modbus_service.c`	`EN_CLI_MODBUS`	`modbus rdreg <addr> [count]` (FC03), `modbus wrreg <addr> <val>` (FC06), `modbus rdcoil <addr> [count]` (FC01), `modbus stat`
`iperf_service.c`	`EN_CLI_IPERF`	`iperf client <ip> [port=5001] [dur_s=10]`, `iperf server [port=5001] [idle_s=3]`
`packet_tracer_service.c`	`EN_CLI_TRACE`	`trace on`, `trace off`, `trace info`, `trace filter src|dst|clear`
`ssh_transport.c`	`EN_CLI_SSH`	`ssh test`

Crypto CLI commands

Module	Flag `os_config.h`	Commands
`sha256.c`	`EN_CLI_SHA256`	`sha256 test`, `sha256 kdf [N]` (HMAC/HKDF/PBKDF2 vectors and time for a PBKDF2 with N iterations)
`sha512.c`	`EN_CLI_SHA512`	`sha512 test`
`ed25519.c`	`EN_CLI_ED25519`	`ed25519 test`, `ed25519 keygen`
`x25519.c`	`EN_CLI_X25519`	`x25519 test`
`keystore_service.c`	`EN_CLI_KSVC`	`ksvc info`, `ksvc lock`

Optional system CLI commands

Flag `os_config.h`	Commands / effect
`EN_CLI_CONFIG`	`config`: build identity (MCU, version) and value of all configuration flags
`EN_CLI_CALLTO`	`callto <addr hex> [param hex]`: calls an address in a one-shot task (**debug only**)
`EN_CLI_CAPTURE`	no command: captures CLI output in a buffer. Required for the remote SSH shell, which otherwise does not execute commands (`ssh_transport.c` emits a `#warning`)

Configuration

```
ENABLE_CLI      1  // In os_config.h     abilita il thread CLI
EN_CLI_GPIO     1  // Abilita CLI per GPIO
EN_CLI_UART     1  // Abilita CLI per UART
// ... ecc. per ogni driver
```

If `ENABLE_CLI == 0`, the entire CLI becomes empty macros.

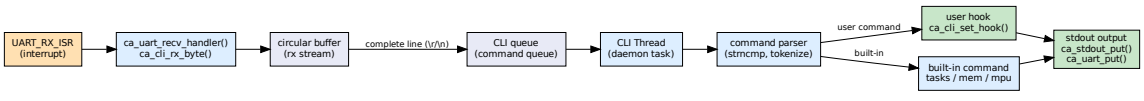

Figure 12.2: UART RX Flow - CLI

12.1.6 11.6 Hardware timers

Architecture

The `timer.c` driver manages hardware timers TIM1..TIM17 (1-based numbering, availability per family) with a bitmask `in_use` and a timer slot. Six modes:

Mode	Init	Usage
PERIODIC	`ca_timer_init_periodic(n, period_us, cb)`	periodic callback from ISR
ONESHOT	`ca_timer_init_oneshot(n, delay_us, cb)`	single callback, then the timer is released
COUNTER	`ca_timer_init_counter(n, &count_u64)`	counts external pulses (ETR), incremental reading
ENCODER	`ca_timer_init_encoder(n, &pos_i64)`	quadrature encoder, signed position
COUNTER_IRQ	`ca_timer_init_counter_irq (n, preset, cb)`	down-counter on ETR, IRQ every `preset` pulses
PWM	`ca_timer_init_pwm(n, ch, freq_hz)`	PWM output, up to 4 channels per timer

After init: `ca_timer_start(n)` / `ca_timer_stop(n)` / `ca_timer_deinit(n)`. For COUNTER/ENCODER, the reading is incremental (`ca_timer_counter_read` / `ca_timer_encoder_read`): the HW delta is accumulated in a caller's `u64`/`i64`, wrap-around safe.

PWM

```
ca_timer_init_pwm(3, 1, 1000);    /* TIM3 ch1 a 1 kHz */
ca_timer_start(3);
ca_timer_set_pwm(3, 1, 250);      /* duty 250/1000 = 25% */
```

- **Duty in permille (0–1000)**: 0.1% resolution, no float. 0 = fixed low output, 1000 = fixed high.
- **Glitch-free**: PWM mode 1 with preload (`OCxPE` + `ARPE`) — the new duty is loaded at the next period, `ca_timer_set_pwm` can be called at any rate.
- **Multi-channel**: frequency is per-timer (shared ARR), duty per-channel. Additional channels: further `ca_timer_init_pwm` on the same timer with the **same** frequency (different → `false`).
- **Automatic PSC/ARR**: maximizes duty resolution (largest possible ARR 65535).
- **Advanced timers** (TIM1/8, plus 15/16/17 on H5/H7/U5): the driver sets `BDTR.MOE` automatically.
- **Pins are the caller's responsibility** (caOS pattern, like the encoder): `ca_gpio_configure (port, pin, CA_GPIO_MODE_AF, ..., af)` before init.

Available channels by family: F1 TIM1-4 (4ch); F4/F7 TIM1-5/8 (4ch), TIM9/12 (2ch), TIM10/11/13/14 (1ch); H5/H7 also TIM12/15 (2ch), TIM13/14/16/17 (1ch); U5 also TIM15 (2ch), TIM16/17 (1ch). TIM6/7 are basic timers without outputs.

Examples: 24 (periodic/oneshot), 25 (counter/encoder), 60 (PWM LED fade).

Input capture

`ca_timer_init_capture` measures the time between rising edges on a channel: at each capture (one every 1, 2, 4, or 8 edges, parameter `div`) the callback receives, from the interrupt, the ticks elapsed since the previous capture. `ca_timer_clock_hz` indicates how many ticks make up one second.

```
bool ca_timer_init_capture(u8 num, u8 ch, ca_timer_ic_src_t src, u8 div,
    ca_timer_ic_cb_t cb);
u32  ca_timer_clock_hz(u8 num);
typedef void (*ca_timer_ic_cb_t)(u32 ticks);    /* timer interrupt */
```

- **Source**: `CA_TIMER_IC_PIN` is the channel pin, which the application must first set to its alternate function (as for PWM). `CA_TIMER_IC_LSE` and `CA_TIMER_IC_LSI` are the internal connections intended for calibration, present on only one channel per family: TIM16/TIM17 CH1 on U5, TIM16 CH1 on H5 and H7, TIM5 CH4 on F4 and F7. Elsewhere, the init rejects the internal source instead of capturing a floating pin.
- **Limits**: the counter runs at 16 bits as in the other modes, so less than 65536 ticks must pass between two captures; TIM1 and TIM8 are not supported, because their capture interrupt is a separate vector.
- The timer handlers only service the sources enabled in `DIER` and clear the flags one by one (`SR = ~flag`): a read-modify-write of `SR` would also clear a capture that arrived between the read and the write.

Example 100 captures the LSE wirelessly and measures its frequency.

LPTIM — low-power timer

The LPTIM driver (`caos/drivers/src/lptim.c`) exposes LPTIM1 on **LSI 32 kHz**: times in milliseconds (1..262144), automatic prescaler /1../128, precision limited by the LSI tolerance (±5%).

```
ca_lptim_init_periodic(1, 500, cb, wake);   /* callback a ogni ARR match */
ca_lptim_init_oneshot (1, 2000, cb, wake);  /* una volta, poi si ferma */
ca_lptim_start(1);  ca_lptim_stop(1);  ca_lptim_deinit(1);
```

- The counter remains active in **Stop** (LSI kernel); with `wake=true` the instance wakes the MCU from Stop/Sleep of the power manager at every ARR match — `ca_pwr_enter(CA_PWR_MODE_STOP, 0, 0)` accepts the input even without other sources ("blink in STOP" pattern of example 61).
- Two IP variants in family files: v1 on F7/H7 (`IER`, +EXTI 23/47 armed by the driver), v2 on H5/U5 (`DIER`/`DIEROK`). F1/F4: absent.
- LPTIM1 is shared with `pwr stopms`: with an active instance the pwr rejects stopms (guard in `ca_pwr_enter`).
- CLI: `lptim info [n] | start | stop | free`.

Examples: 61 (blink periodic/oneshot + phase C in STOP).

12.1.7 11.7 Software Timer

Architecture

caOS implements up to 16 software timers managed by a daemon task:

```
bool ca_sw_timer_init(void);  // Crea il task timer daemon
```

The timer daemon wakes up at every tick and decrements the counters of active timers. When a timer expires, it calls the callback in the context of the daemon task (not in ISR).

API

```c
// Crea timer
ca_sw_timer_handle_t t = ca_sw_timer_create(1000, CA_TIMER_PERIODIC, callback,
    arg);

// Controllo
ca_sw_timer_start(t);
ca_sw_timer_stop(t);
ca_sw_timer_reset(t);
ca_sw_timer_set_period(t, 500);  // Cambia periodo
ca_sw_timer_delete(t);           // Distrugge

// Query
u32 remaining = ca_sw_timer_get_remaining(t);
ca_sw_timer_state_t state = ca_sw_timer_get_state(t);
u8 active = ca_sw_timer_count_active();
```

The callback runs in the daemon task and can stop or rearm **its own** timer: a periodic one that calls `ca_sw_timer_stop()` from its callback remains stopped, while a one-shot that calls `ca_sw_timer_start()` restarts. The daemon rearms or stops the timer only if the callback has not changed its state (corrected on 05/10: previously the periodic one would restart anyway; see ex91 `tmr_stopcb`, `tmr_rearm`).

Callback

```c
void my_callback(void *arg) {
    // Eseguita nel contesto del timer daemon (non ISR)
    // PU  usare mutex, coda, sospensione, ecc.
    ca_gpio_toggle(PORT_A, 5);  // Toggle LED
}
```

12.1.8 11.8 Profiling with Measure

The `measure.h` module measures the clock cycles consumed by the task using `runtime_total` (cycles accumulated by the current task), not the raw DWT CYCCNT. The measurement automatically excludes preemption and IRQs: it only counts the time during which the task is actually running.

```c
u32 snap;
ca_measure_start(&snap);          // salva snapshot di runtime_total
funzione_da_misurare();
ca_measure_stop(&snap);           // snap = cicli task consumati
u32 ms = snap / (ca_os_clock_get_freq() / 1000);
```

The `snap` variable is task-local: start/stop can be nested on different variables. It does not require initialization: caOS enables DWT at startup.

Aspect	Direct DWT→CYCCNT	`ca_measure` (runtime_total)
Count IRQ/preemption	Yes	No
Nested measurements	No (single register)	Yes (local variable)
Initialization	`ca_measure_init()` (deprecated)	automatic
Result	wall-clock cycles	pure task cycles

Available on all Cortex-M3/M4/M7/M33/M55. TIM2 remains free for the application.

12.1.9 11.9 ITM (Instrumentation Trace Macrocell)

ITM is a hardware debug interface present in Cortex-M3/M4/M7 that allows sending text via the debug probe's SWO pin, without occupying a UART:

```
// Configurazione
ENABLE_ITM    1  // In os_config.h

// Uso come sender (STDOUT vale ca_itm_put con ENABLE_ITM)
ca_stdout_set_sender(ca_itm_put);
```

Advantages: no physical pins occupied, no UART peripherals used. Disadvantage: requires a connected debugger.

12.1.10 11.10 Hardware Watchdog (wdt)

The `wdt.h` driver (`EN_WDT` flag) manages the two STM32 watchdogs with the same API: the **IWDG**, which relies on the LSI and is independent of the system clock, and the **WWDG**, which counts on PCLK. The extern pattern (§11.1) follows: `caos/drivers/src/wdt.c` plus `hw/<fam>/drivers/wdt_<fam>.c` for all six families.

API

```
bool ca_wdt_init(u32 timeout_ms, ca_wdt_mode_t mode, ca_wdt_type_t type);
bool ca_wdt_enable(void);                  /* starts and reloads */
void ca_wdt_reload(void);
u32  ca_wdt_get_timeout_ms(void);          /* effective timeout, after HW
    rounding */
bool ca_wdt_is_enabled(void);
u32  ca_wdt_max_timeout_ms(ca_wdt_type_t type);
ca_wdt_reset_t ca_wdt_reset_cause(bool clear);   /* CA_WDT_RESET_NONE | _IWDG |
    _WWDG */
void ca_wdt_on_early(ca_wdt_early_cb_t cb, void *arg);   /*
    CA_WDT_MODE_INTERRUPT */
bool ca_wdt_early_supported(ca_wdt_type_t type);
```

```
ca_wdt_init(2000U, CA_WDT_MODE_RESET, CA_WDT_TYPE_IWDG);
ca_wdt_enable();
/* ... in a dedicated task, every 200-500 ms: */
ca_wdt_reload();
```

Rules

- **Timeout**: from `CA_WDT_TIMEOUT_MIN_MS` (1 ms) to `ca_wdt_max_timeout_ms(type)`, the actual maximum for the family. Values outside this range are rejected.
- **An enabled IWDG cannot be turned off**, but it can be **reconfigured**: a new `ca_wdt_init()` changes the prescaler and reload, and the subsequent `ca_wdt_enable()` reloads the counter with the new value. This is how `ca_os_reset()` and the `reboot` command arm it at 1 ms, and it is what allows an image started by a bootloader to take over an IWDG left enabled. An enabled WWDG, or a change of type, are rejected.
- **Reset cause**: `ca_wdt_reset_cause(false)` reads the RCC flags; `ca_wdt_reset_cause(true)` clears them all (`RMVF`), including those not related to watchdogs (power-on, pin, software). The flags remain at 1 across subsequent resets until someone clears them: whoever reads them at boot clears them, otherwise a watchdog reset from yesterday will be reported again today.
- **Debug**: with a debugger connected (`DHCSR.C_DEBUGEN`) the driver freezes the watchdogs while the core is in halt. Without a debugger, the DBGMCU is not touched.
- **Nominal timeouts**: the LSI is not a crystal and on some parts it deviates from the nominal value by tens of percentage points. The reload period must be chosen with a wide margin (4-10 times).

Maximums by family

Family	IWDG (prescaler)	IWDG max	WWDG max measured (PCLK1)
F1xx	/4 .. /256, LSI 40 kHz	~26 s	— (not on the bench)
F4xx	/4 .. /256	~32.7 s	49 ms (F446, 42 MHz)
F7xx	/4 .. /256	~32.7 s	38 ms (F767, 54 MHz)
H7xx	/4 .. /256	~32.7 s	279 ms (H753, 120 MHz)
H5xx	/4 .. /1024	~131 s	134 ms (H563, 250 MHz)
U5xx	/4 .. /1024	~131 s	419 ms (U575, 80 MHz)

Register differences that the driver absorbs: reset flags in `RCC->CSR` on F1/F4/F7/U5 and in `RCC->RSR` on H5/H7; instances `IWDG1`/`WWDG1` on the H7, where the WWDG1 resets the system only with `RCC_GCR.WW1RSC = 1` (RM0433 §7.7.35), set by the driver; `WDGTB` field at bit 7 on F1/F4/F7 and at 11 on H5/H7/U5.

Early warning (`CA_WDT_MODE_INTERRUPT`)

With `CA_WDT_MODE_INTERRUPT` the watchdog calls, **in interrupt context**, the callback registered with `ca_wdt_on_early()` shortly before the reset:

Watchdog	When	Where
WWDG	counter at `0x40`, one tick before the reset (EWI)	all families
IWDG	with one quarter of the timeout still to elapse (`IWDG_EWCR`, RM0481 §44.6)	H5 and U5 only

On the IWDG of F1, F4, F7 and H7 the interrupt does not exist: `ca_wdt_init()` **rejects** the mode instead of silently arming a simple reset. `ca_wdt_early_supported(type)` indicates in advance if it is available. The reset **happens anyway**: the callback is the last opportunity to save the state (for example, in a backup register, §11.11, to be read at the next boot), not a way to stay alive. Reloading the watchdog from the callback would hide the very fault that left it without a reload. No blocking calls.

```
static void last_gasp(void *arg) { ca_bkp_write(ca_bkp_count() - 1U, 0xE1u); }

ca_wdt_on_early(last_gasp, NULL);
ca_wdt_init(2000U, CA_WDT_MODE_INTERRUPT, CA_WDT_TYPE_IWDG);   /* false on F4/F7
    /H7 */
ca_wdt_enable();
```

CLI

`wdt info` (`EN_CLI_WDT=1`), registered by `ca_wdt_init()`: status, type, mode, effective timeout, maximums, and cause of the last reset. The complete example, with resets triggered and verified upon restart, is example 10.

12.1.11 11.11 Backup registers (bkp)

`bkp.h` provides access to backup registers: a few words in the backup domain that survive a system reset (software, watchdog, pin) and standby. With VBAT powered, they also survive power-off; on Nucleo boards, VBAT is connected to VDD, so a power cycle resets them.

```
u32  ca_bkp_count(void);                /* 10 (F1), 20 (F4), 32 (F7/H7/H5/U5) */
u32  ca_bkp_read(u32 idx);              /* 0 out of range */
bool ca_bkp_write(u32 idx, u32 value);  /* unlocks the backup domain (DBP) itself */
```

On the F1, each register is 16 bits. It does not have a `EN_` flag: they are just a few bytes, and they are used for the transition between the bootloader `workspace/app_2` and the images (registers 16 and 17, `caos/inc/boot_image.h`).

Backup SRAM

In the same backup domain, there is actual RAM, much larger than the registers:

MCU	Size	Address
F446, F767	4 KB	`0x40024000`
H753	4 KB	`0x38800000` (D3 domain)
H563	4 KB	`0x40036400`
U575	2 KB	`0x40036400`
F103	none	—

It is not in the linker script: it is used in blocks, like the registers.

```
u32  ca_bkp_sram_size(void);                                  /* bytes, 0 = none */
bool ca_bkp_sram_read(u32 off, void *dst, u32 len);           /* false when out of range */
bool ca_bkp_sram_write(u32 off, const void *src, u32 len);
bool ca_bkp_sram_retain(void);                                /* backup regulator on */
```

The first call enables the clock and unlocks the backup domain write (`DBP`). It survives system resets, watchdog resets, and Stop mode. For **Standby** and **VBAT**, the backup regulator is required, which `ca_bkp_sram_retain()` enables and waits for (`BRE`/`BREN`). On the U575, that bit can only be written while the regulator is the LDO: with the SMPS already active, it remains as is, and the function indicates this. On Nucleo boards, VBAT is connected to VDD, so a power-off clears it.

The driver only writes **full 32-bit words** (avoiding read-modify-write on unaligned boundaries): on memories with ECC, a shorter write remains pending until the word is completed, and a reset in between causes it to be lost. On the H753, with the first version that copied byte by byte, the upper half of the last written word was missing after a reset.

On the U575 and H563, the backup SRAM has ECC when the option byte `BKPRAM_ECC` enables it: in that case, after power-up, an area must be written before being read. Example 101 fills it, resets the MCU twice, and reads it back. The chapter Backup SRAM and tamper gathers the rules of the backup domain and describes the hardware tamper that clears it.

12.1.12 11.12 CORDIC Coprocessor (cordic)

`cordic.h` uses the CORDIC coprocessor of the **H563 and U575** for trigonometric and hyperbolic functions in q1.31 fixed-point (from -1 to 1-2^{31}). On other families, the coprocessor is not present: `ca_cordic_init()` returns `false` and every call fails.

```
bool ca_cordic_init(void);                          /* false: no CORDIC on this part */
bool ca_cordic_calc(ca_cordic_func_t func, u32 scale, i32 arg1, i32 arg2,
                    i32 *res1, i32 *res2);          /* res2 may be NULL */
```

```
bool ca_cordic_sincos(i32 angle, i32 *sin_q31, i32 *cos_q31);   /* angle = rad/pi */
bool ca_cordic_polar(i32 x, i32 y, i32 *angle, i32 *modulus);   /* angle = rad/pi */
```

`ca_cordic_calc` covers the ten coprocessor functions with the conventions of the reference manual (RM0456 §25.3.2, RM0481 §20.3.2): angles are in radians divided by , and functions that exit the q1.31 range are scaled by 2 with the `scale` parameter.

`func`	arg1	arg2	res1	res2	`scale`
`CA_CORDIC_COS, _SIN`	angle/	modulus m	m · cos or m · sin	the other	0
`CA_CORDIC_PHASE`	x	y	atan2(y,x)/	modulus	0
`CA_CORDIC_MODULUS`	x	y	modulus	phase/	0
`CA_CORDIC_ATAN`	x · 2	—	atan(x)/(· 2)	—	0..7
`CA_CORDIC_COSH, _SINH`	x/2	—	cosh/2 or sinh/2	the other	1
`CA_CORDIC_ATANH`	x/2	—	atanh(x)/2	—	1
`CA_CORDIC_LN`	x · 2	—	ln(x)/2^1	—	1..4
`CA_CORDIC_SQRT`	x · 2	—	x/2	—	0..2

The driver always performs 24 iterations, the maximum useful in q1.31: residual error is below 2^1 on circular functions and below 2^1 on hyperbolic ones, plus 2^2 rounding. A higher scale loses precision proportionally.

Each operation (configuration, arguments, results) runs in a critical section of a few dozen cycles, so multiple tasks can use the coprocessor. It is called from a task, not from an ISR. A `ca_cordic_sincos` costs 136 cycles on the U575 at 160 MHz and 213 on the H563 at 250 MHz, including checks and the critical section: the actual calculation is 6 cycles.

Like `bkp`, it does not have a `EN_` flag: code that is not called is discarded by the linker. Example 98 verifies all functions against the PC's libm.

12.1.13 11.13 FMAC filter accelerator (fmac)

`fmac.h` uses the FMAC (Filter Math Accelerator) of **H563 and U575** for FIR and IIR filters in q1.15 fixed-point. It is only in the paid version (`EN_FMAC`); on other families the unit is not present and `ca_fmac_init()` returns `false`.

```
typedef struct {
    const i16 *b;  u32 nb;     /* feed-forward b[0..nb-1] */
    const i16 *a;  u32 na;     /* feedback a[1..na], NULL for a FIR */
    u32  gain;                 /* output x 2^gain, 0..7 */
    bool clip;                 /* saturate instead of wrapping */
} ca_fmac_filter_t;

bool ca_fmac_init(void);                                  /* false: no FMAC on this part */
bool ca_fmac_start(const ca_fmac_filter_t *f);            /* coefficients, zero state, run */
u32  ca_fmac_run(const i16 *in, i16 *out, u32 len);       /* samples filtered */
void ca_fmac_stop(void);
u32  ca_fmac_flags(void);                                 /* CA_FMAC_SAT | _OVFL | _UNFL */
```

For each sample, the unit calculates (RM0456 §26.3.6, RM0481 §21.3.6)

```
y[n] = 2^gain    (    b[k] x [n-k]  +     a[k] y [n-k] )
```

with the **plus** on the feedback: `a[]` is the opposite of the denominator in the usual convention (`a[1..]` of scipy). A FIR has from 2 to 127 coefficients; an IIR (direct form 1) from 2 to 64 forward and from 1 to `nb`-1 in feedback. The coefficients are in q1.15: a filter that has coefficients greater

than 1 is scaled by 2 and `gain` returns the factor. The accumulator is q4.22 and overflows without warning (the `CA_FMAC_SAT` flag remains); with `clip` the output saturates at ±1 instead of wrapping around. An IIR must be used with `clip`: an output that wraps around re-enters the feedback and the filter can oscillate at full scale without ever recovering.

`ca_fmac_start()` loads the coefficients and clears the delay lines, so the first output sample sees null past inputs and outputs, as `lfilter`. From there, the state remains inside the unit: subsequent calls to `ca_fmac_run()` are a single stream, one output sample for every input sample, and the signal can be filtered in blocks. The 256-word local memory is divided by the driver between coefficients, input line, and output line; what remains goes to the two circular buffers as margin.

The driver works in polling, from a task: one filter at a time, used by a single task. Interrupts and DMA (the continuous ADC → FMAC → DAC flow without CPU) are not yet available.

How to design the coefficients, how to scale an IIR, and when it is better to leave the work to the CPU is explained in the chapter Digital filters with the FMAC. Example 102 verifies the sample-by-sample arithmetic and measures the frequency response of each filter on a DAC → ADC chain.

12.1.14 11.14 Operational amplifiers (opamp)

`opamp.h` uses the two OPAMPs of **U575 and H753** as a follower (gain 1) or as an internal programmable gain amplifier (PGA: ×2, ×4, ×8, ×16). On other families `ca_opamp_count()` is 0 and initialization fails.

```
u32  ca_opamp_count(void);                                  /* 0: none on
    this part */
bool ca_opamp_init(u32 num, ca_opamp_input_t in, u32 gain);  /* 1 = follower
    , 2/4/8/16 = PGA */
void ca_opamp_stop(u32 num);
u8   ca_opamp_adc_channel(u32 num, u8 *adc_num);             /* 0: not
    routed to an ADC */
```

The non-inverting input is pin `OPAMPx_VINP` (`CA_OPAMP_IN_PIN`) or, internally, the DAC channel with the same number (`CA_OPAMP_IN_DAC`: OPAMP1 ← DAC CH1, OPAMP2 ← DAC CH2). For this reason, the U5 and H7 DAC driver sets the output to *pin + internal peripherals* mode (MCR MODE 001): for those using the pin, nothing changes. The output is always on its pin and, where the MCU connects it, on an ADC channel:

OPAMP	U575: output / ADC	H753: output / ADC
1	PA3 / ADC1 ch8	PC4 / ADC1 ch4
2	PB0 / ADC1 ch15	PE7 / none

On the Nucleo-H753, PC4 is the Ethernet PHY's RMII_RXD0 (SB36 closed): with OPAMP1 enabled, the two outputs conflict. On the H753, the driver exists but has not been tested on the board.

The offset is the factory-calibrated one (U575: within ±7 mV), and the PGA gain error is ±1% (DS13737). The input must be kept below VDDA divided by the gain, otherwise the output saturates. Like `cordic`, it does not have a `EN_` flag. Example 99 verifies the follower and PGA.

The **comparators (COMP)** of the U575 and H753 do not have a driver yet: their positive input is only a pin, which the comparator does not see when the pin is a GPIO output (verified on the U575). A real test requires a wire from the DAC or OPAMP output to a comparator input.

Previous chapter: caOS Memory Next chapter: SafeGuard and Fault Recovery in caOS

Chapter 13

SafeGuard and Fault Recovery in caOS

13.1 Chapter 12 - SafeGuard and Fault Recovery in caOS

This chapter describes how caOS implements reliability, error handling and recovery, as presented in Chapter 6.

13.1.1 12.1 SafeGuard: control with recovery

The problem of traditional assertions

A standard `assert()` on an MCU typically causes a `while(1)` or a reset. The entire system stops for an error in a single task. caOS does better: the failing task is handled according to a configurable policy, and the rest of the system continues.

Macro CA_SAFEGUARD

```
// Condition only
CA_SAFEGUARD(ptr != NULL);

// Condition + message
CA_SAFEGUARD(idx < MAX, "indice fuori range");
```

When the condition is false:

1. `ca_safeguard_failed(cond_str, msg, file, line)` is called
2. The error message is printed with condition, file, line and task name
3. If the scheduler is active and we are not in ISR:
   - `ca_scheduler_manage_fault()` is called which applies the recovery policy
   - Context switch occurs via SVC to switch to the next task
4. If the scheduler is not active or we are in ISR:
   - `while(1) { __WFI(); }` loop - halt

Recovery policy

The policy is configured at task creation:

```
// Policy 1: ASSERT -- remove the task (default)
ca_os_job("task", prio, func, NULL, STACK_MEDIUM, CA_JOB_STD,
          CA_FAULT_ASSERT);

```

```
// Policy 2: RESTART -- restart the task with the same parameters
ca_os_job("task", prio, func, NULL, STACK_MEDIUM, CA_JOB_STD,
          CA_FAULT_RESTART_THREAD);

// Policy 3: EMERGENCY -- call the handler, then remove
ca_os_job("task", prio, func, NULL, STACK_MEDIUM, CA_JOB_STD,
          CA_FAULT_EXEC_EMERGENCY);

// Policy 4: EMERGENCY + RESTART -- call the handler, then restart
ca_os_job("task", prio, func, NULL, STACK_MEDIUM, CA_JOB_STD,
          CA_FAULT_EXEC_EMERGENCY | CA_FAULT_RESTART_THREAD);
```

Emergency handler

```
void my_emergency(ca_task_handle_t h, u32 param) {
    // Cleanup: close connections, save data, notify other tasks
    ca_gpio_write(PORT_A, 5, 0);  // Turn the actuator off for safety
}

ca_task_handle_t task = ca_os_job("control", ..., CA_FAULT_EXEC_EMERGENCY);
ca_task_set_emergency_exec(task, my_emergency, 0);
```

The emergency handler is called **before** restart or remove. It allows putting the system in a safe state.

SafeGuard failure flow

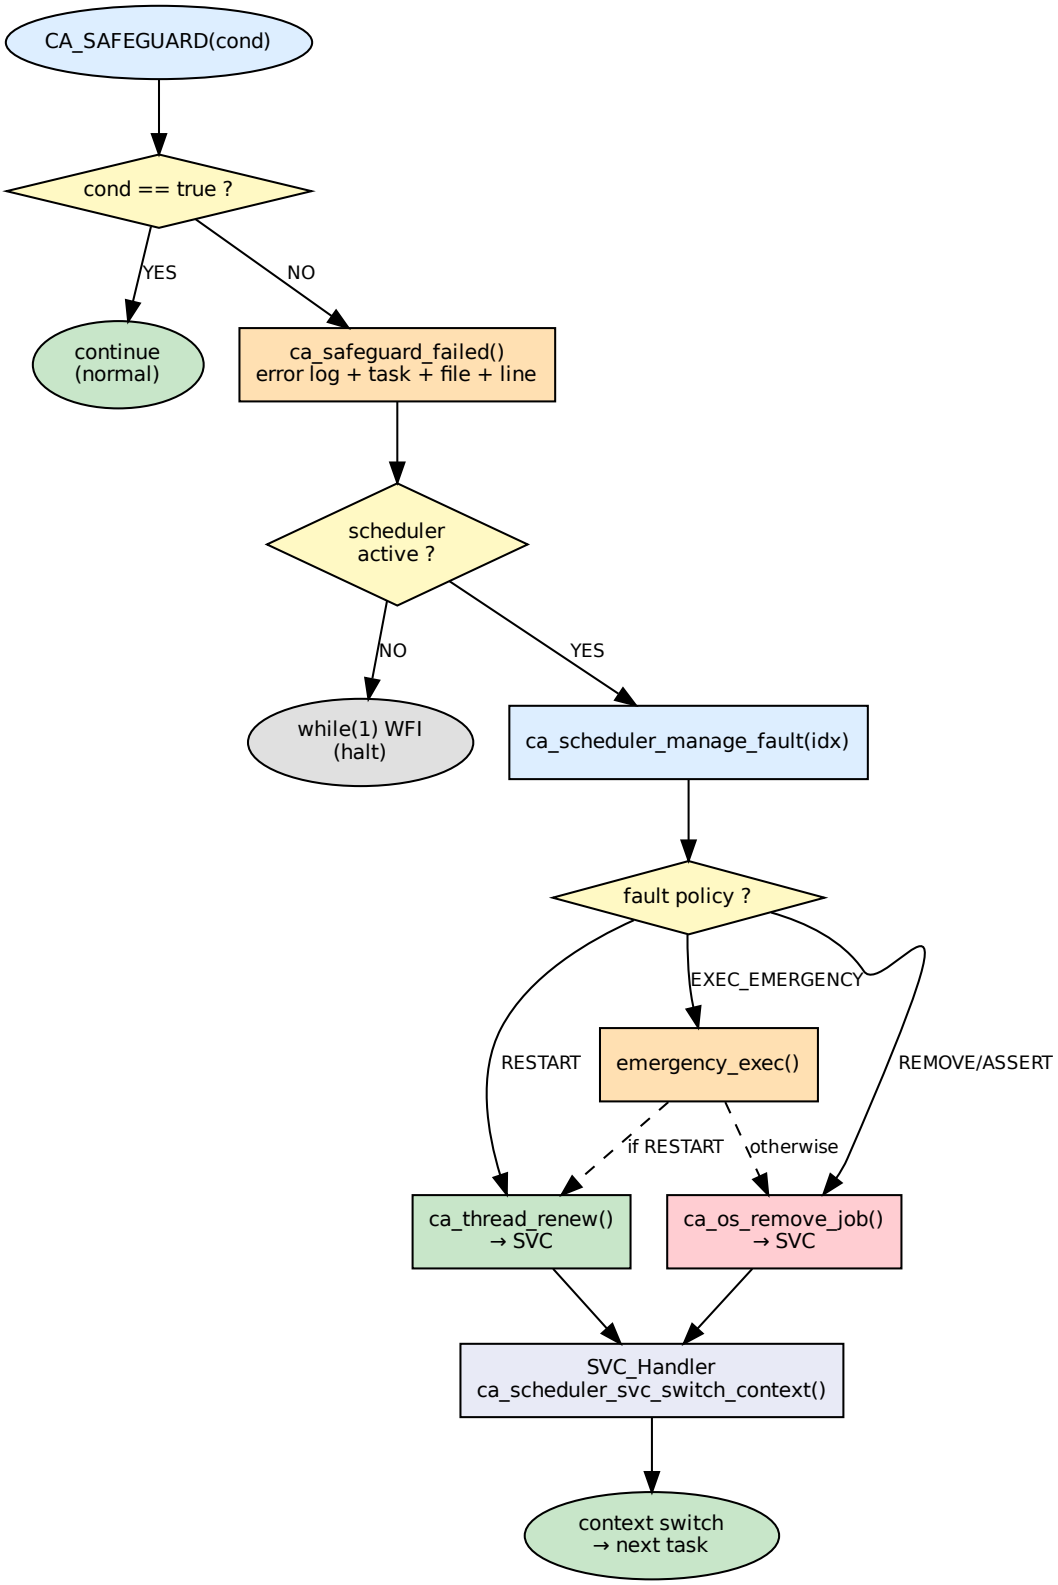

Figure 13.1: Flowchart CA_SAFEGUARD fault recovery

```
CA_SAFEGUARD(cond) fallisce
    |
    v
ca_safeguard_failed()
    |- Log: "SAFEGUARD: condizione in file:line [task: nome]"
    |
    v

Task Renew (restart)

When a task is restarted, `ca_thread_renew()`:

1. Fills with the watermark pattern `0xDEADC0DE` only the deep part of the stack (from `stack_end` up to 65% usage, `STACK_FILL_FROM_PCT`), with IRQ masked
2. Prepares a new exception frame with PC -> `ca_thread_launch_thread`, without FP context (the task reacquires it at the first FP instruction)
3. Resets registers R4-R11
4. Rewrites the canary (temporarily disabling MPU on the region)
5. Resets counters and state: `stack_usage_pct`, `num_alloc`, `notify_value`, `nswitch`, `running`, `sleep`, runtime; detaches it from any wait list (`task_unlink_wait`): restarts from zero, has no pending wait to resume
6. The task restarts from the original function with the same parameters

The memory allocated by the task is freed before the renew with `ca_memory_free_all_owned_by()`.

> The anti-recursion flag of `ca_safeguard_failed()` is cleared on **both** branches (restart and removal). Until 09/23, it was only cleared on restart: after the first safeguard handled with removal, every subsequent safeguard, of any task, ended up with IRQ disabled in `WFI` without printing anything. It exercises ex68 (`fault safeguard` then `fault sg_irq`, without reflashing).

Diagnostic Counters

Each task container maintains diagnostic counters:

```
ctx->n_assert;    // Number of failed safeguards
ctx->n_restart;   // Number of restarts done
ctx->n_memfault;  // Number of MemManage faults
```

These values are visible with `ca_scheduler_dump_task()`.

13.1.2 12.2 CPU Fault Handling: dedicated handlers and per-task recovery

The `panic.c` module together with `bus.c` and the scheduler implements a **per-task** fault management: instead of the classic global stop (`while(1)`), the task that generates the fault is handled according to its recovery policy and **the rest of the system continues**. This applies to all three Cortex-M fault exceptions — MemManage, BusFault, UsageFault — and, from the most recent version, also for the escalated HardFault.

Enabling dedicated handlers

By default, an unhandled fault **escalates** to HardFault. caOS instead enables the three dedicated handlers, so that each category is captured and decoded:

```
ca_bus_error_init();
//  SCB->SHCSR |= BUSFAULTENA | USGFAULTENA;   (MEMFAULTENA is enabled by the
    MPU init)
//  SCB->CCR   |= DIV_0_TRP;                    (division by zero     UsageFault
    )
```

`UNALIGN_TRP` is **not** enabled globally: it would break initialization and libraries that perform legitimate unaligned accesses. It is only activated locally where needed to trap unaligned access (see Example 68).

Complete decode of subtypes (CFSR)

The dump decodes **all** subtypes of the Configurable Fault Status Register:

- **MemManage** (MMFSR): IACCVIOL, DACCVIOL, MUNSTKERR, MSTKERR, MLSPERR, MMARVALID
- **BusFault** (BFSR): IBUSERR, PRECISERR, IMPRECISERR, UNSTKERR, STKERR, LSPERR, BFARVALID
- **UsageFault** (UFSR): UNDEFINSTR, INVSTATE, INVPC, NOCP, UNALIGNED, DIVBYZERO

In addition to the subtypes, the dump prints the raw **HFSR** and **CFSR** registers, the fault addresses (MMFAR/BFAR when valid), the **PC** and **LR** stacked, and the **name/index of the offending task**.

Actual output (UsageFault from division by zero on STM32H753, retrieved):

```
[USAGE FAULT]
  DIVBYZERO: divide by zero
  UFSR = 0x0200   CFSR = 0x02000000
  Stacked LR = 0x080097BF
  Stacked PC = 0x0800072E
  Task: div0 [4]
  Mode: RECOVER (task removed)
```

The complete sequence of 16 faults and their respective real dumps are in Example 68.

Recovery per-task

When the handler has identified a valid task, it calls `ca_scheduler_manage_fault()`, which applies the recovery policy configured at task creation (see §12.1: ASSERT/remove, RESTART, EMERGENCY) and forces a **direct context switch** to the next task or idle. The handler never returns to the offending code.

HardFault escalated → declassified to per-task policy

A HardFault with `HFSR.FORCED` bit is a fault that is **escalated** (fault bank disabled, or fault-in-fault). caOS declassifies it to the same remove-policy of the three dedicated handlers **if** the fault satisfies a conservative gate:

- it is `FORCED` and not from vector table (`!VECTTBL`) nor debug (`!DEBUGEVT`);
- the exception frame is on **PSP** (so task code, not kernel on MSP);
- the **CFSR is non-zero** (the original sub-fault left a trace);
- the **task is valid** and the **PSP is in range** `[stack_end .. stack_start]`.

In that case the *recover* branch clears W1C the status registers, re-enables ENA (the kernel never leaves BUS/USG/MEMFAULTENA disabled), applies the remove-policy and does the context switch. If even one condition is missing (HardFault from kernel, opaque CFSR, dead task) it goes to **controlled reset** — see §12.2.1.

12.2.1 Controlled reboot instead of halt

On an unrecoverable HardFault, caOS does not hang in `while(1)`: it executes an orderly reset.

```
// panic.c
#ifndef PANIC_REBOOT_ON_HARDFAULT
#define PANIC_REBOOT_ON_HARDFAULT 1     // 1 = reboot in campo
#endif
// ... NVIC_SystemReset();  se PANIC_REBOOT_ON_HARDFAULT
```

Set `PANIC_REBOOT_ON_HARDFAULT 0` in a debug build to **stay asleep** on WFI and inspect the state with the debugger.

With `EN_WDT=1`, `ca_os_reset()` has a second path, independent of the core: it arms the IWDG at 1 ms and stops reloading it, then requests the system reset; if that does not happen, the watchdog fires anyway. The CLI command `reboot` uses the IWDG only (`reset` uses the system reset). At restart `ca_wdt_reset_cause()` tells whether the reset came from a watchdog (see §11.10).

> **Open issue — persistent crash log.** Today the dump goes only to UART and disappears on reset. It is planned (TODO in `hard_fault_reset`) a sink that survives the reset — buffered RAM / RTC backup registers / serial EEPROM / SD — to persist CFSR/HFSR + frame + task-id. It depends on the completion of SDIO/FAT support on H/U series.

13.1.3 12.3 Stack overflow and corruption detection: defense levels

Stack overflow is the most common cause of crashes in embedded systems. caOS addresses it with multiple complementary defenses, both **hardware** and **software**, that cover each other:

Level	Mechanism	When detects	Direction
1	**MPU guard** (RO canary band under `stack_end`)	Immediate (MemManage DACCVIOL)	downward

Level	Mechanism	When detects	Direction
2	**Extended guard under** `stack_end` (deep jumps over 32B band)	Immediate (MemManage)	downward
3	**PSP range-check** at context switch (exit **and** entry)	At context switch	both
4	**Predictive watermark** (pattern at init + idle scan)	Warning **before** overflow	growth
5	**Floor check** (8 word at `stack_end`, idle scan)	At next idle tick	upward (cross-task)
6	Canary check + CRC32 digest (idle scan)	At next idle tick	downward

The key difference from a single canary: the PSP range-check also catches corruption of the saved PSP *at a distance* (while the task is not running), which no hardware-based access guard would see. The watermark, finally, warns **before** the overflow becomes a fault (STACK WARNING $> 75\%$ via idle scan).

The asymmetry of the MPU guard

The MPU guard **is not symmetric**, and it's important to state this precisely: it only protects what is **under** the task's `stack_end`. Since stacks are allocated from top to bottom, the first-created tasks — system tasks, `idle` / `stdout` / `cli` — are located **higher** in memory, and are exactly those **exposed** to erroneous writes from subsequently created application tasks. A cross-task write upward does not generate any fault: the MPU does not see it.

On ARMv7-M (F4/F7/H7) there is a second limitation. The MPU region must have size as a power of 2 and natural alignment, so the extended guard cannot cover the entire PSP arena: its depth is the largest aligned block that *ends* exactly at the canary, limited by `DEEP_GUARD_MAX` (8 KB on F4xx/F7xx, 32 KB on H7xx) and still contained in the arena. In practice, it ranges from 32 bytes to several KB, depending on where the canary address falls. On ARMv8-M (H5/U5) this constraint does not exist: base and limit are arbitrary and the guard covers the exact `[arena_base, stack_end)` span.

The two gaps are covered by software mechanisms, not by the MPU: - **upward**: the *floor check* (level 5), linear fixed-cost check on 8 word at `stack_end`, executed by the idle task. It is needed precisely because the watermark is not enough: `calc_stack_watermark` performs a **binary** search and assumes monotonic stack, so a cross-task write in the middle of the intact area either gets skipped or gets mistaken for legitimate use; - **diagnosis**: the panic handler traces back the **owner task** of the hit address (`stack_owner_of()`) instead of attributing every write in the PSP arena to the current task as a false overflow. It distinguishes the **canary** of the victim (under its `stack_end`, where the offset would be an underflow and is not printed) from the **internal offset** `+N` within the stack; only when no task owns the address does the dump fall back to the overflow message.

The floor check, unlike the heap canary, **does not restore** the pattern: at the floor a broken pattern can mean a real overflow, and deleting it would lose the trace.

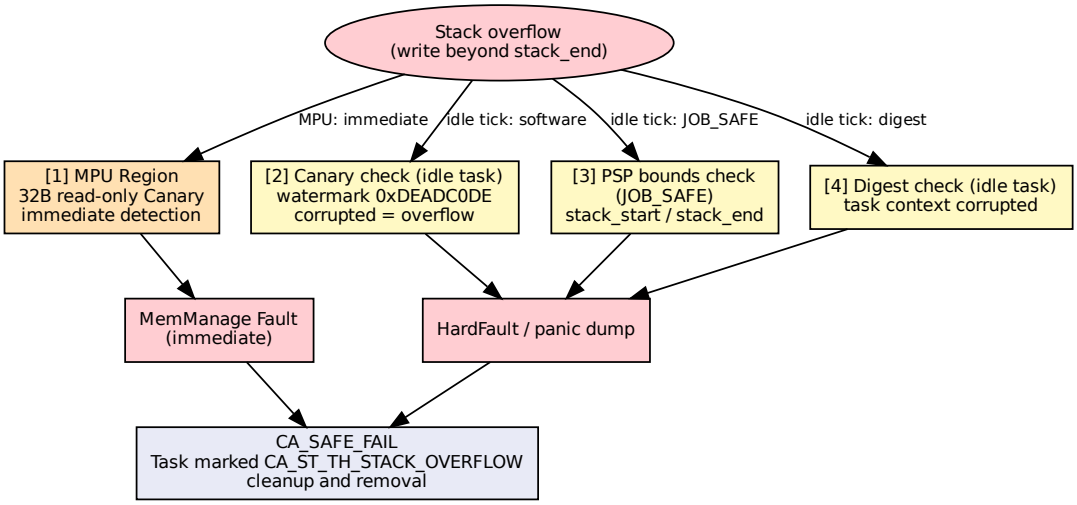

Figure 13.2: Stack MPU protection levels

MPU AP encoding on ARMv8-M (M33). On Cortex-M33 (U5/H5) the encoding of access permissions is **inverted** compared to ARMv7-M: read-write is `AP=1` and read-only is `AP=3` (on M4/M7 `AP=3` is full access). An error in this leaves RO regions *writable* — a real bug fixed in the canary guards and key store.

13.1.4 12.4 Kernel protections: overall framework

The previous sections describe the individual mechanisms. Here is the complete overview of the caOS kernel **safety protections**, from CPU faults to reboot. 1. **Full Cortex-M trap coverage** — dedicated handlers for MemManage / BusFault / UsageFault with decode of *all* CFSR subtypes (§12.2). Enabled by `ca_bus_error_init` (BUSFAULTENA | USGFAULTENA | DIV_0_TRP); MEMFAULTENA from MPU init. 2. **Recovery per-task** — `ca_scheduler_manage_fault()` applies the task policy (remove / restart / emergency) and performs direct context switch to next/idle, without global halt (§12.1). 3. **HardFault escalated de-escalated** — a HardFault `FORCED` from a task, with valid PSP in range, is de-escalated to the same remove-policy instead of killing the RTOS; conservative gate for the rest → reset (§12.2). 4. **MPU stack guard (downward)** — RO canary band under `stack_end`, extended to catch deep jumps that overshoot it; the scheduler suspends/resumes the guard on kernel writes to other tasks' stacks. Covers the exact span on ARMv8-M, limited depth from alignment on ARMv7-M; **does not** protect upward (§12.3). 5. **PSP range-check at context switch** — `stack_end` `psp` `stack_start` verified both on exit and entry; refuses to mount a corrupted saved PSP at distance (§12.3). 6. **Predictive stack watermark** — only the deep part of the stack (from 65% usage down) is filled with pattern at creation and restart; below that threshold `top` prints `Stack= <65%`. STACK WARNING > 75% via idle scan, **before** it becomes a fault (§12.3). 7. **Watchdog per-task on CPU cycles** — `ca_os_thread_set_watchdog(cicli)` accumulates runtime at every context switch; upon budget overrun marks the task `CA_ST_TH_SIG_WDT` ("task watchdog on!"). Captures cumulative CPU overrun. 8. **Stack floor check** — 8 word at `stack_end` checked by idle; intercepts cross-task writes **upward**, which the MPU guard misses and the binary watermark may overshoot (§12.3). 9. **Software canary on heap** — 32-byte pattern `0xAABBCCDD` at extreme, outside the block chain, verified by idle every 100 cycles. Replaces

the two MPU regions at heap boundaries, returning them to the budget: the allocator is next-fit and cannot exceed START/END anyway, while heap overrun *within* the heap — the real case — was not covered by MPU in any way. 10. **MPU on key store** — dedicated MPU region for crypto key store (2048 B), accessible only upon explicit unlock (DACCVIOL otherwise) — see §12.6. 11. **Controlled reboot** — `NVIC_SystemReset()` gated by `PANIC_REBOOT_ON_HARDFAULT` instead of halt (§12.2.1). 12. **Hardware watchdog** — IWDG/WWDG (`wdt.h`, §11.10): resets the system if the software stops reloading it, even with the core stuck; `ca_os_reset()` uses it as a second reset path and `ca_wdt_reset_cause()` reports it at restart. It is global: complementary to, not a replacement for, the per-task watchdog (7).

> On heap canary, the reaction is **message + immediate marker restoration**, deliberately **not** `CA_SAFE_FAIL`: heap corruption is a *global* state, not a task fault that notices it. With policy `RESTART`, the safeguard would trigger an infinite loop that cyclically destroys the idle. All of these protections are exercised on real hardware by **Example 68** (fault test bench): 16 cases that each trigger one of the categories and show their recovery.

Comparison with other embedded RTOSes

The table compares the protections of caOS with those typical of the main RTOSes for Cortex-M. "Optional" indicates a function that is available but not active by default or that requires configuration/additional modules.

Protection	caOS	FreeRTOS	Zephyr	ThreadX	Bare-metal
Dedicated Mem/Bus/Usage handlers with CFSR decode		(HardFault hook only)		opz.	
Per-task recovery after fault (no global halt)			thread abort (userspace)		
HardFault escalated downgraded to per-task policy					
Stack guard via **MPU** (downwards)	exact span on ARMv8-M; limited depth on ARMv7-M	opz. (MPU port)	(`HW_STACK_PROTECTION`)	Modules	
Cross-task write **upwards** detection	SW floor check				
Diagnosis of **owning task** of the hit address					

Protection	caOS	FreeRTOS	Zephyr	ThreadX	Bare-metal
Stack watermark / high-water mark	predictive	(`uxTaskGetStackHighWaterMark`)			
Range-check of saved PSP at context switch					
Per-task watchdog on CPU budget		(global HW WDT only)	opz. (thread analyzer)		
Canary on heap checked periodically	SW		opz. (heap listener)		
MPU on crypto key area			mem domains	Modules	
Controlled reboot on unrecoverable fault	gated	user burden	(`CONFIG_RESET_ON_FATAL`)	Timer	
Restart recovery of failed task					

The distinctive feature of caOS is not the individual mechanism (for example, the stack watermark exists everywhere), but the **per-task recovery**: a fault in a task does not stop the entire system, and depending on the policy the task can be removed, restarted, or pass through an emergency handler. The downgrading of escalated HardFault and the range-check of saved PSP are, as far as we know, specific to caOS.

The limit, stated in full. caOS's MPU guard is *not* stronger than that of other RTOSes in the direction that all cover: it is a downward guard, and on ARMv7-M it covers a depth that depends on the canary alignment, not the entire arena. What caOS adds compared to others is not a better MPU, but **software** defenses that cover what no Cortex-M MPU can see: cross-task write upwards (floor check) and attribution of the hit address to the task that actually owns that memory, instead of the false "overflow of current task".

13.1.5 12.5 CRC32

The `crc32.h` module provides a CRC32 calculation system for thread context integrity verification:

```
// Hardware CRC32 module initialization
void ca_crc32_init(void);
```

Mainly used for: - Verification of thread context integrity - Detection of corruption in context data - Error diagnostics support

The module enables and uses the STM32 microcontroller's hardware CRC32 peripheral to perform efficient calculations.

13.1.6 12.6 Keys Store

The `keys_store.h` module provides an advanced protection system for cryptographic keys using the MPU (Memory Protection Unit) of the microcontroller. Unlike a simple data storage, this module offers a protection mechanism based on dynamic access policies.

System Architecture

The module creates a protected common memory area through a single MPU region that contains all secure keys. This approach optimizes the use of the limited hardware resources of the microcontroller:

- Only one MPU region is used to protect the entire storage area
- All keys share this common area
- Protection is controlled at the common area level, not at the individual key level

Access Modes

Keys can have different access modes:

- `CA_KEYS_STORE_NO_ACCESS`: No access allowed (region disabled)
- `CA_KEYS_STORE_READ_ONLY`: Read-only access allowed
- `CA_KEYS_STORE_READ_WRITE`: Read and write access allowed
- `CA_KEYS_STORE_EXEC_ONLY`: Execute-only access allowed (rarely used)

Typical Usage Sequence

1. **Storage**: Keys are allocated and immediately protected with full access disabled
2. **Temporary Access**: When a key is needed, it is temporarily made accessible (read/write)
3. **Usage**: The key is used for cryptographic operations
4. **Protection**: After use, the key is fully protected again

Main API

```
// System initialization
int ca_keys_store_init(u8 max_keys);

// Allocation of a secure key
void* ca_keys_store_allocate(u32 size);

// Setting the access mode
int ca_keys_store_set_access_mode(void* ptr, ca_keys_store_access_mode_t mode);

// Temporary access (enable/disable)
int ca_keys_store_temp_enable_access(void* ptr, ca_keys_store_access_mode_t mode
    );
int ca_keys_store_temp_disable_access(void* ptr);

// Full protection (no access)
int ca_keys_store_lock_completely(void* ptr);

// Safe copy of data into a protected area
int ca_keys_store_copy(void* dest, const void* src, u32 size);

// Deallocazione
int ca_keys_store_free(void* ptr);
```

Advanced Security

The module implements several security measures:

- **Memory wipe**: Upon deallocation, memory is cleaned with zeros
- **Immediate protection**: Keys are protected immediately after allocation
- **Access control**: Functions verify that operations are permitted
- **Configuration lock**: Possibility to lock MPU configuration to prevent future modifications

This system enables secure handling of cryptographic keys, minimizing the time they are accessible and protecting them from unauthorized access during normal system operation.

13.1.7 12.7 Diagnostica: dump e statistiche

Dump task

```
// Dump of a single task
ca_scheduler_dump_task(index, DUMP_TASK_ALL);

// Dump of all tasks
ca_scheduler_dump_all_tasks(DUMP_TASK_ALL);

// Compact info
ca_scheduler_tasks_info();
```

Selectable flags for the dump:

Flag	Output
DUMP_TASK_HDR	Name, index, state, priority
DUMP_TASK_ADDR	Addresses: TLB, PSP, stack range
DUMP_TASK_REG	Registers R0-R12, LR, PC, xPSR
DUMP_TASK_STACK	Stack usage %, PSP validity
DUMP_TASK_STATS	Running time, sleep, nswitch, fault counters
DUMP_TASK_ALL	All

Compact information

`ca_scheduler_tasks_info()` prints one line per task:

```
task 'idle      ' CPU= 85.3% Stack= 12.5% SW=  84521 SL=      0 Mem=      0
task 'sensore   ' CPU=  8.2% Stack= 45.2% SW=   8420 SL=   4210 Mem=    256
task 'display   ' CPU=  4.1% Stack= 23.8% SW=   4210 SL=   2105 Mem=   1024
```

Canary Check

```
ca_scheduler_check_all_canaries();
```

Output:

```
[0] idle     canary: low:0x1000EFE0 OK
[1] sensore  canary: low:0x1000EBE0 OK
[2] display  canary: low:0x1000E7E0 OK
```

Stdout Statistics

```
u32 queued, dropped;
ca_stdout_stats(&queued, &dropped);
// queued  = lines in the queue
// dropped = lines lost (queue full)
```

Available with `ENABLE_STDOUT 1` in `os_config.h`; with `ENABLE_STDOUT 0` becomes empty macro.

Memory Statistics

```
ca_memory_list();          // List all blocks (used and free)
ca_memory_dump_avail();    // Free blocks only
u32 avail = ca_memory_get_avail_memory();
```

MPU

```
ca_mpu_dump_regions();     // All active MPU regions
```

Section 3: Advanced Concepts

Chapter 14

Thread Pool in caOS

14.1 Thread Pool in caOS

The **thread pool** is a concurrent programming pattern in which a fixed set of threads is pre-allocated at system startup and reused to execute jobs sent dynamically during execution. Instead of creating and destroying a thread for each operation, the workers remain active and sleep waiting for work.

14.1.1 Motivation

In a bare-metal RTOS, every `ca_os_job()` allocates stack and control structure. On MCUs with limited memory, repeating this operation at high frequency causes:

- **heap fragmentation** in CCM (if the stack is released and reallocated)
- **variable task creation latency**
- **bursts of occupancy** when many jobs are created simultaneously

The pool pre-allocates everything at boot and maintains a constant and predictable number of concurrent tasks.

> **Availability**: the pool is enabled with `EN_POOL=1` in `os_config.h` and is operational only on MCUs with `MAX_TASK >= 50` (H5xx, H7xx, U5xx). On smaller platforms the code is excluded at compile time.

14.1.2 Pool Architecture

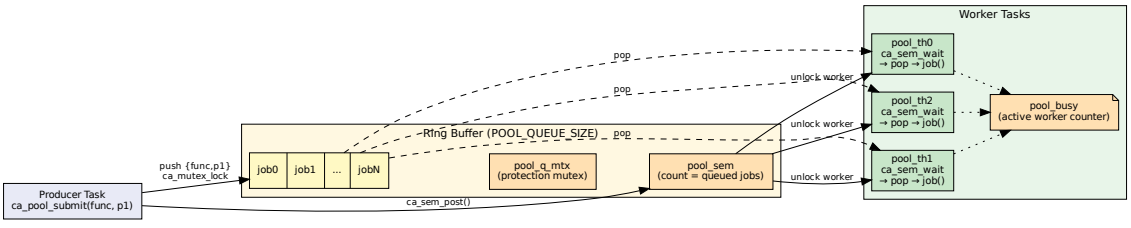

Figure 14.1: caOS Thread Pool Architecture

```
ca_pool_init(n, stack, prio)

                  ca_sem_init(&pool_sem, 0, POOL_QUEUE_SIZE)
                  ca_mutex_init(&pool_q_mtx)

                  pool_th0
                  pool_th1                    loop: ca_sem_wait     pop     job()
        repeat
                  pool_thN

ca_pool_submit(func, arg)

                  push {func, arg} into the ring buffer  (mutex protected)
                  ca_sem_post(&pool_sem)                        wakes a worker
```

The workers never terminate: they execute an infinite loop on `ca_sem_wait()`. The semaphore counts the available jobs; when it is zero, the workers sleep without consuming CPU.

14.1.3 Synchronization mechanism

Counting semaphore

```
ca_sem_init(&pool_sem, 0, POOL_QUEUE_SIZE);
```

- Initial value = **0**: no job available, all workers blocked.
- `ca_pool_submit()` calls `ca_sem_post()` → increments → wakes up **one** worker.
- The worker calls `ca_sem_wait()` → decrements → takes ownership of the job.
- If all workers are busy and a new job arrives, `ca_sem_post()` increments the semaphore above 1: the next worker that becomes free will immediately find work.

Mutex for the ring buffer

```
ca_mutex_init(&pool_q_mtx);
```

The queue is a static ring buffer shared between the caller of `ca_pool_submit()` and the worker threads. The mutex protects push and pop operations from concurrent accesses.

Worker body

```
static u32 pool_worker(void *arg) {
    (void)arg;
    while (1) {
        ca_sem_wait(&pool_sem);          /* sleeps until there is work */
        ca_pool_job_t job = pool_queue_pop();
        pool_busy++;
        job.func(job.arg);               /* runs the job */
        pool_busy--;
    }
    return 0;
}
```

The job receives only its argument. To know which worker runs it, use `ca_os_thid_from_handle(ca_os_self_handle())`, as Example 16 does (`w=5`, `w=6`, `w=7`).

14.1.4 Public API

Initialization

```c
typedef struct {
    u8           n_threads;   /* number of workers (max 99) */
    ca_stack_size_t stack_size;  /* stack of each worker */
    u16          priority;    /* scheduler priority */
} ca_pool_cfg_t;

i32 ca_pool_init(const ca_pool_cfg_t *cfg);
```

Create `n_threads` worker with names `pool_th0 ... pool_thN`. All use the same priority and the same stack size. Returns `0` on success, `-1` if `n_threads == 0` or MAX_TASK exhausted.

Must be called before `ca_os_run()`.

Sending a job

```c
i32 ca_pool_submit(ca_task_fn_t func, void *arg);
```

Return	Meaning
`0`	Job executed (in worker queue or temporary fallback one-shot)
`-1`	Queue full **and** MAX_TASK exhausted: job discarded

The signature of `func` is identical to that of a regular caOS task:

```c
u32 my_job(void *arg);
```

`arg` is the argument passed to `ca_pool_submit()`.

Note: `ca_pool_submit()` is **not safe from ISR** because it uses `ca_mutex_lock()`. Call only from tasks.

Statistics

```c
void ca_pool_stats(u8 *busy, u8 *free_th, u8 *queued);
```

Parameter	Meaning
`busy`	Worker that are executing a job
`free_th`	Worker waiting on the semaphore
`queued`	Job in queue not yet assigned

`busy` is a `volatile u8` counter updated by the worker before and after `job.func()`. It is accurate for display; a delta of ± 1 during a context switch is acceptable.

14.1.5 Configuration in `os_config.h`

```c
/* Enable the pool */
#define EN_POOL         1

/* Depth of the job queue (static ring buffer) */
#define POOL_QUEUE_SIZE 8
```

`POOL_QUEUE_SIZE` determines the maximum number of waiting jobs when all workers are busy. If the queue fills up, `ca_pool_submit()` attempts a fallback with a one-shot thread.

14.1.6 Memory Usage

For a pool of N workers with stack S:

Resource	Size
`ca_thread_context_t` × N	N × 160 bytes (in CCM)
Worker stack	N × S bytes (in CCM)
Queue ring buffer	`POOL_QUEUE_SIZE` `8` bytes (in .bss)
Semaphore	~16 bytes (in .bss)
Mutex	~12 bytes (in .bss)

Example: 3 workers with `STACK_MEDIUM` (512 bytes), `POOL_QUEUE_SIZE=8`:

- Structures: 3 × 160 = 480 bytes in CCM
- Stack: 3 × 512 = 1536 bytes in CCM
- Queue: 8 × 8 = 64 bytes in .bss

Total: approximately 2080 bytes, known and fixed at boot.

14.1.7 Use Cases

Scenario	Pool Useful?	Why
Asynchronous cryptographic (SHA, AES) computing	Yes	Limits concurrent threads, protects the HASH peripheral
Ethernet/CAN packet processing	Yes	Packet bursts, predictable latency
Asynchronous QSPI logging/storage	Yes	Slow operations, does not block the producer
Periodic tasks with fixed frequency	No	Better with a dedicated task using `ca_os_sleep()`
Operations with highly variable stack usage	No	Fixed stack for all jobs is a waste
Fast interrupt response	No	`ca_pool_submit()` is not ISR-safe

14.1.8 Limitations

- **Fixed stack**: all jobs share the same stack size. Size for the most demanding job.
- **Fire-and-forget**: no built-in mechanism to retrieve the job result. If the result is needed, use a global variable, an event (`ca_event_*`) or a task notification (`ca_notify_send`).
- **Single priority**: all workers have the same priority. Urgent jobs and slow jobs compete at the same level.
- **ISR**: `ca_pool_submit()` is not callable from interrupt handlers.

14.1.9 Internal Implementation

The pool is implemented in `caos/src/pool.c`, included at the end of `scheduler.c` with `#include "pool.c"`. This technique allows `pool.c` to access the scheduler's static variables (`g_work_index`, `g_task_array`) without exposing them publicly, maintaining encapsulation.

```
caos/inc/pool.h          API pubblica (ca_pool_init, ca_pool_submit,
    ca_pool_stats)
caos/src/pool.c          Implementazione (inclusa da scheduler.c)
```

No modification to the scheduler core is necessary: workers are normal caOS tasks that never terminate.

Next chapter: Cryptographic Modules in caOS

Chapter 15

Cryptography in caOS

15.1 Chapter 13 - Cryptography in caOS

Cryptography in caOS is organized into **two levels**:

- **Hardware drivers** (`caos/drivers/`): CRC32, HASH, RNG — direct access to STM32 peripherals, protected by mutexes for multithreading.
- **Cryptography** (`caos/crypto/`): AES (driver with HW/SW dispatch), Keys Store, AES Channel Service, Secure Pipe (between tasks and, in link mode, between two boards), key derivation (HMAC / HKDF / PBKDF2 on SHA-256), plus software primitives SHA-256 / SHA-512 / X25519 / Ed25519 / ECDSA P-256 — abstraction that hides key management, IV, wire format, heap, and wipe.

Above these primitives, the network stack builds SSH and the TLS 1.3 server (`caos/net/tls.c`, used by HTTPS): see the HTTPS / TLS 1.3 chapter.

```
Applicazione
           ca_secure_pipe_* / ca_sp_link_* / ca_aes_channel_encrypt / decrypt

caos/crypto/             aes.c, keys_store, aes_channel_service,
   secure_pipe_service,
                         kdf (HMAC/HKDF/PBKDF2), sha256/sha512/x25519/ed25519,
                         ecdsa_p256
           ca_aes_gcm_*, ca_keys_store_*, ca_rng_fill

  dispatch AES                  HW: hw/*/drivers/aes_*.c  (CRYP su H7, AES su
    U5xx con IP)
                           SW: percorso software interno ad aes.c (board senza
    AES HW)

           HASH / RNG / CRC periferici

hw/*/drivers/            implementazioni bare-metal per famiglia
```

> **Note (2026-07-21):** `aes.c`/`aes.h` have been moved from `caos/drivers/` to `caos/crypto/`. The AES driver automatically chooses **hardware or software** based on the peripheral present on the device (detected via CMSIS macros `CRYP_BASE` / `AES_BASE`): where an AES/CRYP IP exists, hardware is used, otherwise a software AES implementation (FIPS-197 + NIST SP 800-38D) internal to the file, at 128 or 256 bits, is used. The public API `ca_aes_*` is identical in both cases.

15.1.1 13.1 Hardware driver overview

Module	Header	Flag	HW Peripheral	Families
CRC32	`crc32.h`	`EN_CRC`	CRC (RCC)	All
HASH (SHA-256)	`hash.h`	`EN_HASH`	HASH	H5xx, H7xx
AES	`aes.h`	`EN_AES`	CRYP / AES **or software**	**All** (HW where present, otherwise SW)
RNG	`rng.h`	`EN_RNG`	RNG	F4xx, F7xx, H5xx, H7xx

For RNG and HASH, on families lacking the peripheral, the functions are **stubs** that return `false`. **AES is an exception**: if the device does not have an AES crypto IP, the driver falls back to a software implementation (128 and 256-bit ECB/CTR/GCM), so `ca_aes_*` works on all families — including Nucleo-U575 and H563, which lack HW AES.

Enablement in `os_config.h`:

```
#define EN_CRC                  1   /* CRC32 hardware */
#define EN_HASH                 1   /* SHA-1 / SHA-256 hardware */
#define EN_AES                  1   /* AES ECB/CBC/CTR/GCM, HW o SW */
#define EN_RNG                  1   /* RNG hardware (True Random Number
    Generator) */
#define EN_KEYS_STORE           1   /* area MPU-protetta per chiavi */
#define EN_AES_CHANNEL_SERVICE  1   /* pipe cifrata applicativa */
```

15.1.2 13.2 CRC32

The CRC32 module uses the microcontroller's hardware CRC peripheral to calculate 32-bit checksums efficiently. It is available on all STM32 families supported by caOS.

Typical uses: buffer integrity verification, packet validation, corruption detection.

API

```
void ca_crc32_init(void);           /* chiamare una volta in ca_os_configure */
u32  ca_crc32_get(u8 *buff, u32 size);   /* protetta da mutex */
```

Typical usage

```
u8 data[256];
u32 crc = ca_crc32_get(data, 256);

data[100] ^= 0xFF;                   /* simula corruzione */
u32 crc2  = ca_crc32_get(data, 256);
if (crc != crc2)
    ca_stdout_put_n("Corruzione rilevata!");
```

`ca_crc32_get()` is internally protected by a mutex: multiple tasks can call it concurrently.

15.1.3 13.3 HASH (SHA-256)

The problem: a single hardware engine, N tasks

The STM32 HASH peripheral is **unique**. The SHA-256 calculation is incremental — the intermediate state (CSR registers) must be preserved between blocks. Two tasks calculating SHA-256 in parallel without protection would corrupt each other's hardware registers.

The solution: context swap

caOS solves the problem with a **cryptographic context swap**: each task possesses a local `ca_hash_ctx_t` structure that contains a copy of the hardware registers (CSR[]). Before using the peripheral, the driver restores the registers from the task's context; after the operation, it saves them again.

```
Task A: update("block1")
         lock mutex HASH
         ripristina registri da ctx_A.csr[]
         elabora "block1" sull'hardware
         salva registri in ctx_A.csr[]
         unlock mutex
  [context switch     Task B]

Task B: update("blockX")
         lock mutex HASH
         ripristina registri da ctx_B.csr[]
         elabora "blockX"
         salva registri in ctx_B.csr[]
         unlock mutex
  [context switch     Task A]

Task A: update("block2")
         ripristina ctx_A.csr[]       riprende esattamente dov'era
         digest A corretto
```

Structure `ca_hash_ctx_t`

```c
typedef enum {
    CA_HASH_ALGO_SHA1   = 0,
    CA_HASH_ALGO_SHA256 = 1,
} ca_hash_algo_t;

#define HASH_SHA1_DIGEST_SIZE    20
#define HASH_SHA256_DIGEST_SIZE  32

typedef struct {
    ca_hash_algo_t algo;
    u32 csr[HASH_MAX_CSR];   /* copia registri HW (H5=103 CSR, H7=54 CSR) */
    u32 cr_save;
    u32 csr_count;
    bool started;
} ca_hash_ctx_t;
```

API

```c
bool ca_hash_init(void);   /* una volta in ca_os_configure */

/* One-shot */
bool ca_hash_compute(ca_hash_algo_t algo,
                     const u8 *data, u32 len,
                     u8 *digest, u32 *digest_len);

/* Incrementale con context swap */
bool ca_hash_ctx_init(ca_hash_ctx_t *ctx, ca_hash_algo_t algo);
bool ca_hash_ctx_update(ca_hash_ctx_t *ctx, const u8 *data, u32 len);
bool ca_hash_ctx_final(ca_hash_ctx_t *ctx, u8 *digest, u32 *digest_len);
```

One-shot

```
u8 digest[HASH_SHA256_DIGEST_SIZE];
u32 digest_len;
ca_hash_compute(CA_HASH_ALGO_SHA256, data, data_len, digest, &digest_len);
```

Incremental (block data)

```
ca_hash_ctx_t ctx;   /* LOCALE al task     non condivisa */
u8 digest[HASH_SHA256_DIGEST_SIZE];
u32 digest_len;

ca_hash_ctx_init(&ctx, CA_HASH_ALGO_SHA256);
ca_hash_ctx_update(&ctx, header,  header_len);
ca_hash_ctx_update(&ctx, payload, payload_len);
ca_hash_ctx_update(&ctx, trailer, trailer_len);
ca_hash_ctx_final(&ctx, digest, &digest_len);
/* digest = SHA-256(header || payload || trailer) */
```

Two tasks SHA-256 in parallel

```
static u32 task_hash_channel_a(void *arg) {
    (void)arg;
    ca_hash_ctx_t ctx;
    u8 digest[HASH_SHA256_DIGEST_SIZE]; u32 digest_len;
    while (1) {
        ca_hash_ctx_init(&ctx, CA_HASH_ALGO_SHA256);
        ca_hash_ctx_update(&ctx, (const u8*)"CanalA-block1", 13);
        ca_os_sleep(10);   /* Task B pu  usare l'HW HASH qui */
        ca_hash_ctx_update(&ctx, (const u8*)"CanalA-block2", 13);
        ca_hash_ctx_update(&ctx, (const u8*)"CanalA-block3", 13);
        ca_hash_ctx_final(&ctx, digest, &digest_len);
        ca_stdout_printf_n("[A] %02X..%02X", digest[0], digest[31]);
        ca_os_sleep(200);
    }
    return 0;
}

static u32 task_hash_channel_b(void *arg) {
    (void)arg;
    ca_hash_ctx_t ctx;
    u8 digest[HASH_SHA256_DIGEST_SIZE]; u32 digest_len;
    while (1) {
        ca_hash_ctx_init(&ctx, CA_HASH_ALGO_SHA256);
        ca_hash_ctx_update(&ctx, (const u8*)"CanalB-X", 8);
        ca_os_sleep(15);
        ca_hash_ctx_update(&ctx, (const u8*)"CanalB-Y", 8);
        ca_hash_ctx_final(&ctx, digest, &digest_len);
        ca_stdout_printf_n("[B] %02X..%02X", digest[0], digest[31]);
        ca_os_sleep(200);
    }
    return 0;
}
```

The two digests are **independent and correct** despite having shared the same physical peripheral.

> **Rule:** `ca_hash_ctx_t` must never be shared between tasks. The physical peripheral is shared; the context is private.

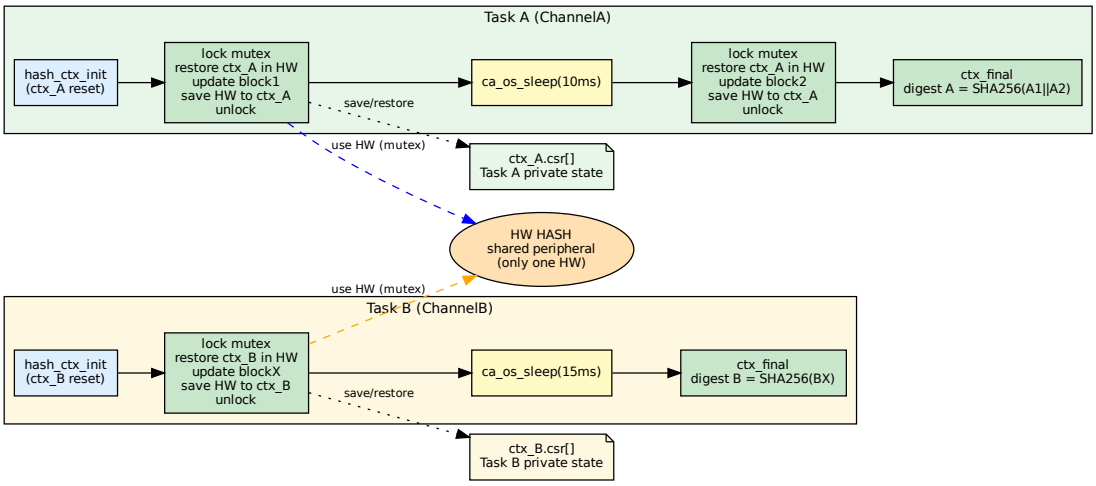

Figure 15.1: Timeline context swap HASH multithread

15.1.4 13.4 AES

Automatic hardware / software dispatch

The AES peripheral is not uniform across the STM32 family: the **CRYP** block (AES+GCM) exists on H753, the **AES** IP on some U5 variants (U585/U5A5...), while Nucleo-U575 and H563 have no AES accelerator at all. To ensure `ca_aes_*` everywhere, the driver chooses the path only once in `ca_aes_init()`:

```
#if defined(CRYP_BASE) || defined(AES_BASE)
    aes_hw_ready = true;    /* IP crypto presente     hardware */
#else
    aes_hw_ready = false;   /* nessun HW     AES software interno */
#endif
```

Detection uses the **device** CMSIS macros (`CRYP_BASE`, `AES_BASE`), not `MCU`/`MCU_ID` (which do not reliably discriminate families in the preprocessor). The software path is a pure AES (FIPS-197) with GCM/GHASH over GF(2^128) (NIST SP 800-38D), verified against NIST vectors (McGrew/Viega) — CLI command `aes_nist test` (example 26). It covers ECB, CTR, and GCM at **128 and 256 bits**: 256 for SSH and crypto services, 128 for TLS 1.3 (`TLS_AES_128_GCM_SHA256` is the mandatory suite). The number of rounds (10 or 14) is fixed when the key is expanded, the first time the context is used. AES-192 is not supported in software. The public API is identical in both paths.

The problem: key and IV to be preserved per session

The AES peripheral contains the loaded key, the initialization vector (IV), and the GCM state. Two tasks with different keys sharing the peripheral without protection would find the other's key loaded. In CTR/GCM mode, the internal counter advances with every encrypted block: an interruption produces corrupted ciphertext without any visible error.

Context swap AES: state in `ca_aes_ctx_t`

```c
typedef struct {
    ca_aes_mode_t    mode;       /* ECB / CBC / CTR / GCM */
    ca_aes_keysize_t keysize;    /* 128 / 192 / 256 bit */
    u32 key[8];                  /* chiave (fino a 256 bit = 8 word) */
    u32 iv[4];                   /* IV corrente (aggiornato dopo ogni blocco CTR
   /GCM) */
    bool configured;
} ca_aes_ctx_t;

#define AES_GCM_TAG_SIZE  16
```

Before each encrypt/decrypt operation, the driver: acquires the CRYP mutex → loads `ctx.key` and `ctx.iv` → performs the operation → updates `ctx.iv` → releases the mutex.

Operating modes

Mode	Constant	IV	Authentication	Typical use
ECB	`CA_AES_MODE_ECB`	No	No	Independent single blocks
CBC	`CA_AES_MODE_CBC`	Yes	No	Chaining streams
CTR	`CA_AES_MODE_CTR`	Yes	No	High-speed streams
GCM	`CA_AES_MODE_GCM`	Yes	Yes (16B tag)	Authenticated protocols

API

```c
bool ca_aes_init(void);   /* una volta in ca_os_configure */

bool ca_aes_ctx_setup(ca_aes_ctx_t *ctx, ca_aes_mode_t mode,
                      ca_aes_keysize_t keysize,
                      const u8 *key, const u8 *iv);

/* Solo un IV nuovo: chiave e key schedule SW restano (niente ri-espansione).
 * Per una sessione che tiene il contesto per molti messaggi. */
bool ca_aes_ctx_set_iv(ca_aes_ctx_t *ctx, const u8 *iv);

bool ca_aes_encrypt(ca_aes_ctx_t *ctx, const u8 *in, u8 *out, u32 len);
bool ca_aes_decrypt(ca_aes_ctx_t *ctx, const u8 *in, u8 *out, u32 len);

bool ca_aes_gcm_encrypt(ca_aes_ctx_t *ctx,
                        const u8 *aad, u32 aad_len,
                        const u8 *in, u8 *out, u32 len,
                        u8 tag[AES_GCM_TAG_SIZE]);

bool ca_aes_gcm_decrypt(ca_aes_ctx_t *ctx,
                        const u8 *aad, u32 aad_len,
                        const u8 *in, u8 *out, u32 len,
                        const u8 tag[AES_GCM_TAG_SIZE]);
```

AES-256 ECB — basic usage

```c
ca_aes_ctx_t ctx;
u8 key[32], plain[16] = "Hello AES World!", cipher[16], decrypted[16];

ca_rng_fill(key, 32);
ca_aes_ctx_setup(&ctx, CA_AES_MODE_ECB, CA_AES_KEY_256, key, NULL);
ca_aes_encrypt(&ctx, plain, cipher, 16);
ca_aes_decrypt(&ctx, cipher, decrypted, 16);
```

AES-256 GCM — authenticated encryption

GCM authenticates both the ciphertext and the AAD (*Additional Authenticated Data*) left in plaintext. The tag (16 bytes) binds key + IV + AAD + ciphertext: any modification is detected during decryption.

```
ca_aes_ctx_t ctx;
u8 key[32], iv[16];
u8 aad[16]   = "header-in-chiaro";
u8 plain[32] = "payload segreto!!!";
u8 cipher[32], decrypted[32], tag[AES_GCM_TAG_SIZE];

ca_rng_fill(key, 32); ca_rng_fill(iv, 16);
ca_aes_ctx_setup(&ctx, CA_AES_MODE_GCM, CA_AES_KEY_256, key, iv);

ca_aes_gcm_encrypt(&ctx, aad, 16, plain, cipher, 32, tag);

if (ca_aes_gcm_decrypt(&ctx, aad, 16, cipher, decrypted, 32, tag))
    ca_stdout_put_n("GCM OK     dati autentici");
else
    ca_stdout_put_n("GCM FAIL     dati manomessi!");
```

> **Rule:** `ca_aes_ctx_t` must never be shared between tasks. The physical CRYP peripheral is shared and protected by an internal mutex.

HASH vs AES context swap comparison

	HASH	AES
Saved state	CSR[] (up to 103 regs.)	key[8] + iv[4] (12 words)
Atomic operation	one block (update)	entire encrypt/decrypt call
Interruptible calculation between blocks	Yes	No (ECB/CBC); Yes (CTR/GCM)
Parallel sessions	unlimited	unlimited

15.1.5 13.5 RNG

The RNG module uses the STM32 hardware True Random Number Generator peripheral to generate random numbers based on thermal noise. It is not a PRNG: every value is unpredictable and non-reproducible.

Availability: F4xx, F7xx, H5xx, H7xx. On F1xx, the functions are stubs (`false`).

API

```
bool ca_rng_init(void);
bool ca_rng_get(u32 *val);          /* singolo u32, blocking, mutex */
bool ca_rng_fill(u8 *buf, u32 len); /* buffer di byte casuali */
```

Typical usage

```
u32 random_val;
ca_rng_get(&random_val);

u8 aes_key[32], aes_iv[16];
ca_rng_fill(aes_key, 32);
ca_rng_fill(aes_iv, 16);
```

15.1.6 13.6 Initialization in `ca_os_configure()`

Cryptographic modules are initialized using `EVAL_*` macros. Recommended order: CRC → HASH → AES → RNG (no dependencies between them):

```
void ca_os_configure(void) {
    EVAL_CRC(  ca_crc32_init(); )
    EVAL_HASH( ca_hash_init();  )
    EVAL_AES(  ca_aes_init();   )
    EVAL_RNG(  ca_rng_init();   )
    /* ... */
    EVAL_STDOUT( ca_stdout_init(); ca_stdout_set_sender(STDOUT);
    ca_stdout_create_thread(); )
}
```

If a module is disabled (`EN_xxx 0`), the `EVAL_xxx(...)` macro expands to nothing.

15.1.7 13.7 Pattern: Key Derivation

A common pattern is to derive a cryptographic key by combining RNG, HASH, and AES:

```
IV_SECRET (16 B, RNG) + KEY_SECRET (32 B, RNG)

                        Concatenazione 48 B     SHA-256     Chiave derivata 32 B
```

```
u8 iv_secret[16], key_secret[32];
u8 hash_input[48], digest[32]; u32 digest_len;

ca_rng_fill(iv_secret, 16);
ca_rng_fill(key_secret, 32);
ca_memcpy(hash_input,      iv_secret,  16);
ca_memcpy(hash_input + 16, key_secret, 32);
ca_hash_compute(CA_HASH_ALGO_SHA256, hash_input, 48, digest, &digest_len);
/* digest = chiave derivata (32 byte per AES-256) */
```

For the secure storage of the derived key, see the **Keys Store** module (§13.9).

Standard functions: HMAC, HKDF, PBKDF2 (`kdf.h`)

As of 10/15/2026, derivation has its own standard functions, in `caos/crypto/kdf.{h,c}`, built on the **software** SHA-256: they yield the same result on every family, with or without the HASH accelerator. They are enabled with `EN_SHA256`; known-answer tests with `EN_SHA256_TEST`.

Function	Standard	Purpose
`ca_hmac_sha256` (+ `_init/_update/_final`)	RFC 2104 / FIPS 198-1	Keyed MAC, the building block for the other two
`ca_hkdf_sha256(salt, ikm, info, out, n)`	RFC 5869	from key material to independent keys (one per use, with different `info`)
`ca_pbkdf2_sha256(pwd, salt, iter, out, n)`	RFC 8018	from a **password** to a key, intentionally slow

```
u8 master[32], k12[32], k21[32];
ca_pbkdf2_sha256((const u8 *)pwd, ca_strlen(pwd), (const u8 *)name, ca_strlen(
    name),
                 100000U, master, 32U);
ca_hkdf_sha256(NULL, 0U, master, 32U, (const u8 *)"link 1->2", 9U, k12, 32U);
ca_hkdf_sha256(NULL, 0U, master, 32U, (const u8 *)"link 2->1", 9U, k21, 32U);
ca_memzero(master, sizeof(master));
```

- Each intermediate buffer (HMAC pads, PRK, U blocks) is zeroed before exiting.
- PBKDF2 prepares the password HMAC pads **once** and copies the context at each round, instead of re-hashing them 2 times per iteration.
- **Measured cost** (`sha256 kdf [N]` of ex66): ~22 µs per iteration on H753 → 100000 iterations = 2.25 s; F767 and H563 about double. One derivation per boot, after the password: every attempt by an attacker costs the same time.
- `ca_kdf_selftest()`: RFC 4231 #1/#2/#6, RFC 5869 #1/#3, RFC 7914 c=1 and a c=4096 compared with `hashlib`. 7/7 on H753.

The "SHA-256 of a concatenation" scheme above remains valid for simple cases (used by `keystore_service`); to derive **multiple keys** from the same secret or start from a **password**, HKDF and PBKDF2 are used.

15.1.8 13.8 Crypto Infrastructure (`caos/crypto/`)

Application services in `caos/crypto/` build an abstraction layer on top of hardware drivers that hides key management, IVs, wire format, heap, and wiping.

```
caos/crypto/
          inc/
                aes.h                       driver AES, dispatch HW/SW
                keys_store.h                area MPU-protetta per chiavi
                aes_channel_service.h       canale cifrato sincrono  r e d black
                secure_pipe_service.h       pipe fra task + modalit  link fra
    board
                keystore_service.h          chiave divisa in flash
                kdf.h                       HMAC / HKDF / PBKDF2 (SHA-256)
                sha256.h sha512.h x25519.h ed25519.h ecdsa_p256.h
          src/
              aes.c  keys_store.c  aes_channel_service.c  secure_pipe_service.c
              keystore_service.c  kdf.c
              sha256.c  sha512.c  x25519.c  ed25519.c  ecdsa_p256.c
```

Dependencies

```
Driver HW (caos/drivers/)          caos/crypto/

  aes.h  (EN_AES)                                  aes_channel_service.h
  rng.h  (EN_RNG)                                  aes_channel_service.h
  hash.h (EN_HASH)                                 (keystore_service     futuro)
  mpu.h                                            keys_store.h
  memory.h                                         aes_channel_service.h
  sync.h (ca_mutex_t)                                 aes_channel_service.h
```

15.1.9 13.9 Keys Store (`keys_store.h`)

Problem

Cryptographic keys in RAM are vulnerable: a buggy task, a buffer overflow, or access via debugger can read arbitrary memory areas. On Cortex-M, the **MPU** allows marking regions as inaccessible until they are explicitly opened.

Design

`keys_store` manages **a single contiguous area** of 2048 bytes protected by a single MPU region. The protection granularity is the entire region (not the individual key).

- Keys are allocated sequentially (**bump allocator**) and never move. Each allocation is rounded to **multiples of 4 bytes**: a slot can also contain a structure with `u32` fields, for example, the link mode AES session context (§13.10).
- **First-fit allocation**: a new key goes into the first free interval large enough among those already allocated, starting from the beginning of the area. `ca_keys_store_free` zeroes the key and its space immediately becomes reusable, even in the middle of the area. Until 10/15/2026, the area was a bump allocator and `free` only freed the table entry: every allocate/free cycle consumed the area forever. Harmless with a few 32-byte keys, fatal for a link that changes passwords (app_3 keeps two sets of keys and frees the *lower* one, contexts of ~300 bytes).

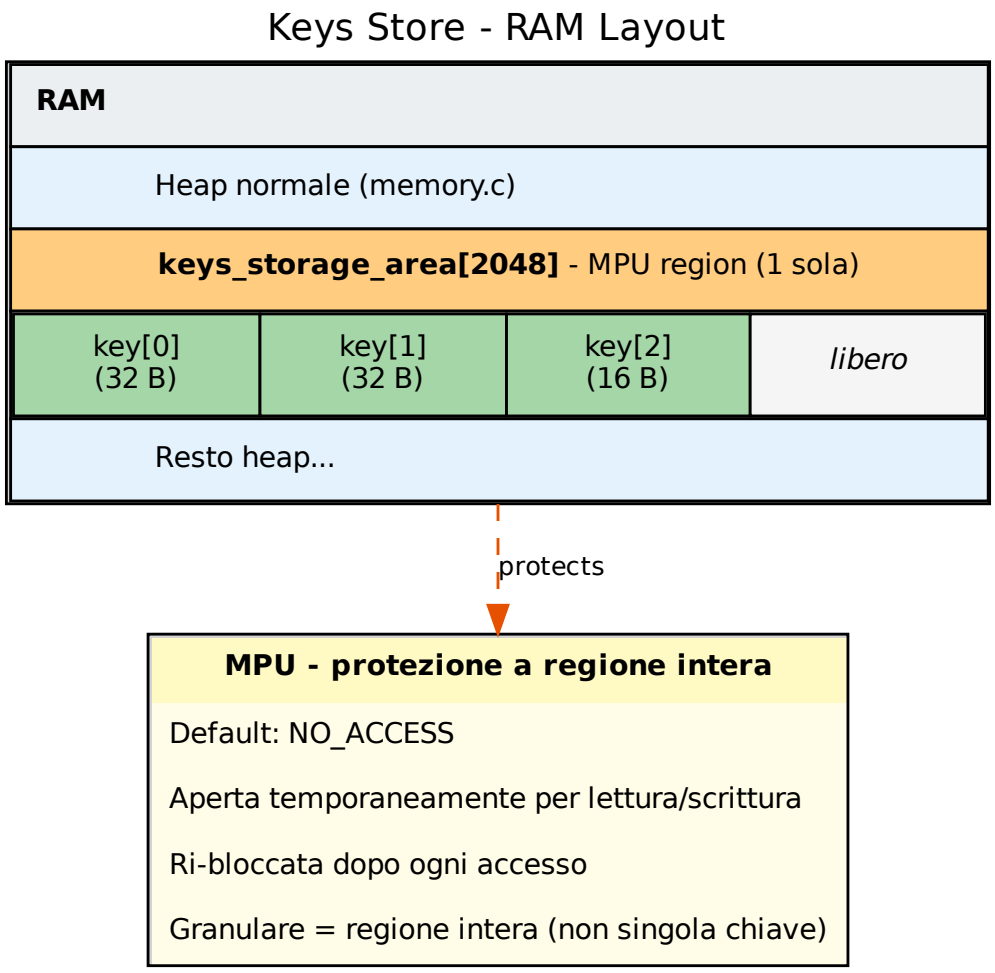

Figure 15.2: Layout RAM keys_store

Key lifecycle

```
ca_keys_store_allocate(32)
      ptr nell'area protetta
ca_keys_store_temp_enable_access(ptr, READ_WRITE)
ca_keys_store_copy(ptr, raw_key, 32)
ca_keys_store_lock_completely(ptr)              MPU: NO_ACCESS
  [chiave inaccessibile finch  non serve]
ca_keys_store_temp_enable_access(ptr, READ_ONLY)
  [leggi, usa, azzera dallo stack]
ca_keys_store_lock_completely(ptr)              ri-proteggi
```

Access modes

```
typedef enum {
    CA_KEYS_STORE_NO_ACCESS  = 0,
```

```
    CA_KEYS_STORE_READ_ONLY  = 1,
    CA_KEYS_STORE_READ_WRITE = 2,
    CA_KEYS_STORE_EXEC_ONLY  = 3,
} ca_keys_store_access_mode_t;
```

API

```
int  ca_keys_store_init(u8 max_keys);
void *ca_keys_store_allocate(u32 size);
int  ca_keys_store_free(void *ptr);
int  ca_keys_store_temp_enable_access(void *ptr, ca_keys_store_access_mode_t
    mode);
int  ca_keys_store_lock_completely(void *ptr);
int  ca_keys_store_copy(void *dest, const void *src, u32 size);
bool ca_keys_store_is_key_expired(void *ptr);
int  ca_keys_store_set_expiry(u8 key_idx, u32 start, u32 stop);
```

Packed date

```
/* 2026-03-15     0x001A030F */
#define KSTORE_DATE_PACK(y, m, d)  (((u32)(y) << 16) | ((u32)(m) << 8) | (u32)(d
    ))

ca_keys_store_set_expiry(0,
    KSTORE_DATE_PACK(26, 1, 1),
    KSTORE_DATE_PACK(26, 12, 31));
```

If the RTC is disabled and the expiration is configured, `is_key_expired()` returns `true` for security reasons (key not usable without a time reference).

Tamper (`EN_TAMP`, paid version). On U575 and H563, with `EN_TAMP = 1`, the `keys_store` area resides in the **secret area** (SRAM2) that caOS reserves at startup (§10.2): a tamper on the B1 button clears the keys in hardware, before any code runs. Elsewhere, or without `EN_TAMP`, it remains a static array in the main SRAM. The MPU region is the same: the start of SRAM2 is 64 KB aligned. See Backup SRAM and tamper.

15.1.10 13.10 AES Channel Service (`aes_channel_service.h`)

Problem

Using `ca_aes_gcm_encrypt/decrypt` directly requires the application to handle: IV generation, wire format, temporary access to the key in the keys_store, output buffer allocation, wipe after use, thread safety — at least 10 lines of boilerplate for every encrypt/decrypt point.

`aes_channel_service` encapsulates all this complexity:

```
ca_aes_channel_encrypt(&ch, plain, plen, &out, &out_len);
ca_aes_channel_decrypt(&ch, cipher, clen, &out, &out_len);
```

Red/black terminology

Side	Content	Direction
Red	plaintext	→ encrypt → black

Side	Content	Direction
Black	ciphertext	→ decrypt → red

The terminology is borrowed from military cryptography (TEMPEST, NATO SDIP-27).

Wire format

```
     nonce          orig_len          ciphertext (paddato)          GCM tag
    12 byte          2 byte           ceil(plain_len, 16) B          16 byte

overhead fisso = AES_CH_OVERHEAD = 30 byte
```

- **nonce**: 12 random bytes from HW RNG, freshness for each message
- **orig_len**: original length of the plaintext (big-endian, 2 bytes)
- **ciphertext**: always a multiple of 16 bytes (plaintext padded with zeros)
- **tag**: 16 bytes GCM — end-to-end authentication

The header `[nonce|orig_len]` (14 bytes) is the GCM AAD (as of 10/15/2026, `AES_CH_HDR_SIZE`). Previously, GCM ran with an empty AAD: `orig_len` traveled outside the tag, and a value lowered by an attacker would **truncate the plaintext under a valid tag**, without an error. The AAD is copied into an aligned buffer because the H7 CRYP reads it in 32-bit words.

This is a format change: a ciphertext produced previously (including encrypted files from `fat_service`) can no longer be decrypted. There is no fallback to the old format: that would be the vulnerability itself. Verified with ex46/ex47 on H753 (CRYP), F767, and H563 (software GCM).

The GCM nonce passed to the H7 CRYP peripheral is `[nonce:12][0x00000002:4]`: the final 4 bytes are the initial counter required by the GCM specification (RFC 5116 §3) for the Init phase of the H753 CRYP peripheral.

Note: padding and H7 CRYP The STM32H7 CRYP peripheral has an asymmetry in the GHASH calculation for partial blocks in GCM: in encrypt, GHASH covers the ciphertext with non-zero keystream bytes; in decrypt, it covers the ciphertext padded with zeros — the two GHASH values diverge → tag mismatch. The `NPBLB` field of the CR should correct this, but it proved unreliable on the H753 CRYP.

Solution: always pad the plaintext to a multiple of 16 before encrypting. `orig_len` in the wire allows the receiver to extract the actual bytes.

Structure `ca_aes_channel_t`

```
typedef void (*ca_aes_iv_gen_cb_t)(u8 iv[AES_CH_IV_SIZE], void *user);
typedef bool (*ca_aes_key_ratchet_cb_t)(u8 *key, u32 key_len, void *user);

typedef struct {
    ca_aes_mode_t            mode;
    ca_aes_keysize_t         keysize;
    void                    *ks_handle;   /* ptr keys_store */
    ca_aes_iv_gen_cb_t       iv_gen_cb;   /* NULL     ca_rng_fill() automatico
   */
    ca_aes_key_ratchet_cb_t  ratchet_cb;  /* NULL     rotate disabilitato */
```

```
    void                    *cb_user;
    ca_aes_ctx_t            *red_ctx;     /* heap */
    ca_aes_ctx_t            *black_ctx;   /* heap */
    ca_mutex_t                  mutex;
} ca_aes_channel_t;
```

Generatore di callback IV

```
/* Default (NULL): usa HW RNG */

/* Deterministico per test */
static void test_iv_gen(u8 iv[12], void *user) {
    u32 *counter = (u32 *)user;
    ca_memzero(iv, 12);
    ca_memcpy(iv, counter, 4);
    (*counter)++;
}
```

Using a deterministic IV is only safe for testing. In production, always use NULL (HW RNG).

Callback key ratchet

Updates the key in-place: it receives the current key and must overwrite it with the new one.

```
static bool sha256_ratchet(u8 *key, u32 key_len, void *user) {
    u32 session_id = *(u32 *)user;
    u8 input[36], digest[32]; u32 digest_len;

    ca_memcpy(input,      key,         key_len);
    ca_memcpy(input + 32, &session_id, 4);
    ca_hash_compute(CA_HASH_ALGO_SHA256, input, 36, digest, &digest_len);
    ca_memcpy(key, digest, key_len);
    ca_memzero(input, sizeof(input));
    return true;
}
```

Complete API

```
i32  ca_aes_channel_init(ca_aes_channel_t *ch,
                         ca_aes_mode_t mode, ca_aes_keysize_t keysize,
                         void *ks_handle,
                         ca_aes_iv_gen_cb_t iv_cb,
                         ca_aes_key_ratchet_cb_t ratchet_cb,
                         void *cb_user);

/*  R e d Black : alloca *out su heap */
i32  ca_aes_channel_encrypt(ca_aes_channel_t *ch,
                            const u8 *plain, u32 plain_len,
                            u8 **out, u32 *out_len);

/*  B l a c k Red : alloca *out su heap; -1 se tag mismatch */
i32  ca_aes_channel_decrypt(ca_aes_channel_t *ch,
                            const u8 *cipher, u32 cipher_len,
                            u8 **out, u32 *out_len);

void ca_aes_channel_free(void *p);      /* wipe + free     OBBLIGATORIO */
i32  ca_aes_channel_rotate(ca_aes_channel_t *ch);
void ca_aes_channel_deinit(ca_aes_channel_t *ch);
```

Thread safety

Level	Protection	Granularity
AES Driver	Internal `aes_mutex`	Single HW operation
Channel service	`ch->mutex`	load_key → setup_ctx → encrypt/decrypt

Heap management and wipe

```
/* CORRETTO */
u8 *out; u32 out_len;
ca_aes_channel_encrypt(&ch, plain, plen, &out, &out_len);
/* ... usa out ... */
ca_aes_channel_free(out);           /* wipe + free */

/* SBAGLIATO */
ca_memory_free(out, NULL, false);   /* non azzera il ciphertext */
```

Wiping is mandatory: it prevents ciphertext or plaintext from remaining readable in "free" heap areas that other tasks might subsequently allocate.

Complete typical usage

```
/* In ca_os_configure() */
ca_aes_init();
ca_rng_init();
ca_keys_store_init(4);

/* Carica chiave */
void *key_ptr = ca_keys_store_allocate(32);
ca_keys_store_temp_enable_access(key_ptr, CA_KEYS_STORE_READ_WRITE);
ca_keys_store_copy(key_ptr, my_key_32bytes, 32);
ca_keys_store_lock_completely(key_ptr);

/* Init canale */
static ca_aes_channel_t ch;
ca_aes_channel_init(&ch, CA_AES_MODE_GCM, CA_AES_KEY_256,
                    key_ptr, NULL, NULL, NULL);

/* Encrypt (task mittente) */
u8 *enc; u32 enc_len;
if (ca_aes_channel_encrypt(&ch, plain, plen, &enc, &enc_len) == 0) {
    send_to_transport(enc, enc_len);
    ca_aes_channel_free(enc);
}

/* Decrypt (task ricevente) */
u8 *dec; u32 dec_len;
u8 rx[MAX_RX]; u32 rx_len = recv_from_transport(rx, sizeof(rx));
if (ca_aes_channel_decrypt(&ch, rx, rx_len, &dec, &dec_len) == 0) {
    process_plaintext(dec, dec_len);
    ca_aes_channel_free(dec);
} else {
    /* tag mismatch: messaggio corrotto o manomesso */
}

/* Deinit */
ca_aes_channel_deinit(&ch);
ca_keys_store_free(key_ptr);
```

Secure pipe (`secure_pipe_service.h`)

The channel encrypts one message at a time, but the transport remains the caller's responsibility: code, packet struct, and heap buffer properties (who frees them, even when sending fails). The **secure pipe** closes the loop between two tasks: a shared AES channel + one heap queue per direction, with encrypted and plaintext buffers never leaving the service. It is enabled with the same flag `EN_AES_CHANNEL_SERVICE`.

```
static ca_secure_pipe_t pipe;                    /* deve partire azzerata */
ca_secure_pipe_init(&pipe, CA_AES_MODE_GCM, CA_AES_KEY_256, key_ptr, 4);

/* capo A */
ca_secure_pipe_send(&pipe, CA_SECURE_PIPE_A, msg, len, 2000);

/* capo B */
u8 buf[64]; u32 n;
if (ca_secure_pipe_recv(&pipe, CA_SECURE_PIPE_B, buf, sizeof(buf), &n, 5000)
        == CA_SECURE_PIPE_OK)
    process_plaintext(buf, n);

ca_secure_pipe_deinit(&pipe);
```

Code	Meaning
`CA_SECURE_PIPE_OK`	message sent / received
`CA_SECURE_PIPE_ERR`	arguments, pipe not ready, heap full, encryption failed
`CA_SECURE_PIPE_TIMEOUT`	queue full (send) or empty (recv) until timeout
`CA_SECURE_PIPE_DECRYPT`	invalid GCM tag: message discarded
`CA_SECURE_PIPE_SIZE`	message larger than buffer: discarded, `*out_len` = size

- `send` encrypts and queues towards the **other** end; `recv` decrypts and **copies** into the caller's buffer, then zeroes and frees internal buffers.
- Maximum message `CA_SECURE_PIPE_MAX_MSG` = 65535 bytes (16-bit length in the channel wire format).
- `deinit` flushes queues with wipe, but must be called **while the pipe is stopped**: a task still inside `send`/`recv` will wait again on the destroyed queue. Examples: ex46 (fixed pipe) and ex47 (pipe recreated at every `start`, closed by Bob).

Secure pipe in link mode (`ca_sp_link_*`)

The pipe connects two tasks on the **same** board. **Link mode** connects two **boards**: it seals and opens **buffers**, and the application handles transport (UDP in `workspace/app_3`). Since the service does not touch the network, the two ends can be tested on a single board (ex97). Requires `EN_AES_CHANNEL_SERVICE` + `EN_SHA256`.

Keys

```
password + nome del link (8..16 caratteri, uguali sulle due board)
          PBKDF2-HMAC-SHA256(password, nome, 100000)      master
               HKDF(master, "caos-sp-link 1->2")      K12
               HKDF(master, "caos-sp-link 2->1")      K21
```

Role 1 encrypts with K12 and decrypts with K21, role 2 does the opposite (no reflection). In `keys_store`, K12/K21 and the two **AES session contexts** remain; password, name, and master are zeroed out.

Handshake (at every startup, peer restart, rekey)

```
HELLO = [tipo][ruolo][iv:12][nonce|eco cifrati:32][tag:16]     62 byte
  tipo 1 = apre, tipo 3 = risposta, che ripete il nonce a cui risponde
sessione: S12 = HKDF(K12, n1|n2)   S21 = HKDF(K21, n1|n2)
```

- New session keys for every handshake: the data counter restarts from 1 without reusing a GCM nonce, and a registered session is not valid for the next one.
- A response is **never responded to** (otherwise the two boards would respond to each other infinitely: found in app_3, ~4000 handshakes in 4 s).
- The initiator only accepts the response with the **echo of its current nonce**: a response to an old HELLO, queued while the peer was waiting for the password, does not pair with the new one (without the echo, the two boards ended up with different keys).
- If they start at the same time, the role is decided: 2 responds, 1 waits.

Data

```
[tipo=2][contatore:8][len:2][cifrato, padding a 16][tag:16]   overhead     42
    byte
```

- GCM Nonce = `0000|contatore`; AAD = header + caller's AAD (in app_3: IP and UDP ports), therefore length and stream are authenticated.
- Anti-replay with a window of 64, updated only after a valid tag; an incorrect tag clears the output buffer.
- The **session AES context** is prepared once per session in the `keys_store` slot; for each message, only the nonce changes (`ca_aes_ctx_set_iv`), without re-expanding the key. Overwritten upon rekey, cleared and freed upon deinit.
- Suggested rekey (`ca_sp_link_need_rekey`) after 1 h or 2^20 messages.

```c
ca_sp_link_init(&l, role, password, name);        /* secondi: PBKDF2 */
ca_sp_link_hello(&l, false, out, cap, &n);        /* apre: spedire al peer */
rc = ca_sp_link_accept(&l, in, len);              /* OK | REPLY | REPLAY |
    DECRYPT */
if (rc == CA_SECURE_PIPE_REPLY) ca_sp_link_hello(&l, true, out, cap, &n);
ca_sp_link_seal(&l, aad, alen, plain, len, out, cap, &n);
ca_sp_link_open(&l, aad, alen, in, len, out, cap, &n);   /* REPLAY se ripetuto
    */
ca_sp_link_deinit(&l);
```

Code	Meaning (in addition to pipe codes)
`CA_SECURE_PIPE_REPLY`	`accept`: peer opened, respond with `hello(reply = true)`
`CA_SECURE_PIPE_REPLAY`	counter already seen or out of window; HELLO response exceeded
`CA_SECURE_PIPE_NOT_UP`	no session: handshake first

Verified: ex97 13/13 on H753 (CRYP), F767 and H563 (software GCM); in app_3 between H753 and H563, encrypted UDP in both directions with no failed tags, peer reboot with new handshake.

[1] `keys_store` works on all families with Cortex-M MPU (M3+).
[2] Now works everywhere: `ca_aes_gcm_*` falls back to the software path where HW AES is missing.
[3] H563 does not have AES/SAES → software. Other H5 variants with AES would use the HW. U575 does not have AES → software; U585/U5A5 (AES IP) → hardware, auto-detected via `AES_BASE`.
Excluded by choice: no hardware RNG and too little RAM for the TLS that uses it. The H563 PKA is not used: it is in limited mode, it only knows how to verify (RM0481 §36.3).

15.1.13 13.13 Keystore Service (`keystore_service.h`)

Problem

`keys_store` protects keys in RAM but does not solve the **provisioning** problem: how to securely bring keys onto the device? Writing them to flash in cleartext exposes them to anyone with

physical access or access via a debugger.

`keystore_service` solves this: keys are pre-provisioned in flash **encrypted with AES-256-GCM** and are decrypted and loaded into `keys_store` only at runtime, providing the second half of the secret.

Split-key security model

The decryption secret is built from **three components**:

Component	Where it resides	Who knows it
`IV` (16 B)	Flash (cleartext header)	anyone who reads the flash
`p1` (16 B)	Flash (cleartext header)	anyone who reads the flash
`p2` (16 B)	Provided at runtime	only those who need to unlock

The decryption key is derived with:

```
decrypt_key = SHA256( SHA256( ... SHA256(IV || p1 || p2) ... ) )
                                                  n_evolve volte
```

`IV` and `p1` in flash are inherently useless without `p2`. `n_evolve` makes brute-forcing `p2` computationally expensive (key stretching).

Flash block layout

Keystore Service - FLASH block layout

base_addr	HEADER - cleartext (AAD per GCM) - 54 byte
+0	size (u32, 4 B) - dimensione totale blocco
+4	IV[16] (16 B) - sale per KDF
+20	n_evolve (u32, 4 B) - iterazioni SHA256
+24	p1[16] (16 B) - prima meta segreto (in flash)
+40	n_key (u16, 2 B) - numero di chiavi
+42	gcm_nonce[12] (12 B) - nonce AES-GCM
+54	**PAYLOAD - AES-256-GCM cifrato - ceil(n_key*48, 16) B**
key[0]	ca_flash_key_entry_t - 48 byte
key[1]	ca_flash_key_entry_t - 48 byte
...	...
-16	**TAG GCM (16 B) - autentica header + payload**

detail

input KDF

ca_flash_key_entry_t - 48 byte	
+0 (2 B)	key_id (u16)
+2 (6 B)	label[6]
+8 (32 B)	**key[32] - chiave AES-256**
+40 (4 B)	start (KSTORE_DATE_PACK)
+44 (4 B)	stop (KSTORE_DATE_PACK)

KDF - chiave di decifratura

decrypt_key =

SHA256^n_evolve(IV || p1 || p2)

p1: da flash (header)

p2: fornito a runtime (segreto)

Figure 15.3: Flash block layout keystore_service

GCM authenticates both the encrypted payload and the plaintext header (AAD): any modification to the header or the payload is detected during decryption.

Data structures

```
/* Singola entry chiave     48 byte */
typedef struct {
    u16 key_id;
    u8  label[KSTORE_SVC_LABEL_SIZE];   /* 6 byte */
    u8  key[KSTORE_SVC_KEY_SIZE];       /* 32 byte */
    u32 start;      /* KSTORE_DATE_PACK validity start (0 = no limit) */
    u32 stop;       /* KSTORE_DATE_PACK validity stop  (0 = no limit) */
} ca_flash_key_entry_t;
```

```

/* Header del blocco flash     cleartext, AAD per GCM     54 byte */
typedef struct {
    u32 size;
    u8  IV[16];
    u32 n_evolve;
    u8  p1[16];
    u16 n_key;
    u8  gcm_nonce[12];
} ca_flash_key_block_hdr_t;
```

API

```
/* Legge e valida l'header dal blocco flash a base_addr.
 * Ritorna 0 se header valido, -1 altrimenti. */
int ca_keystore_service_init(u32 base_addr);

/* Fornisce p2 (16 byte), deriva la chiave, decifra il payload,
 * carica le chiavi in keys_store.
 * Ritorna 0 se successo, -1 se p2 errato o flash corrotta.
 * In caso di errore chiama automaticamente ca_keystore_service_lock(). */
int ca_keystore_service_unlock(const u8 *p2);

/* Wipe di tutte le chiavi caricate in keys_store     stato INACTIVE. */
void ca_keystore_service_lock(void);

/* Ritorna true se le chiavi sono caricate (stato ACTIVE). */
bool ca_keystore_service_is_active(void);
```

State machine

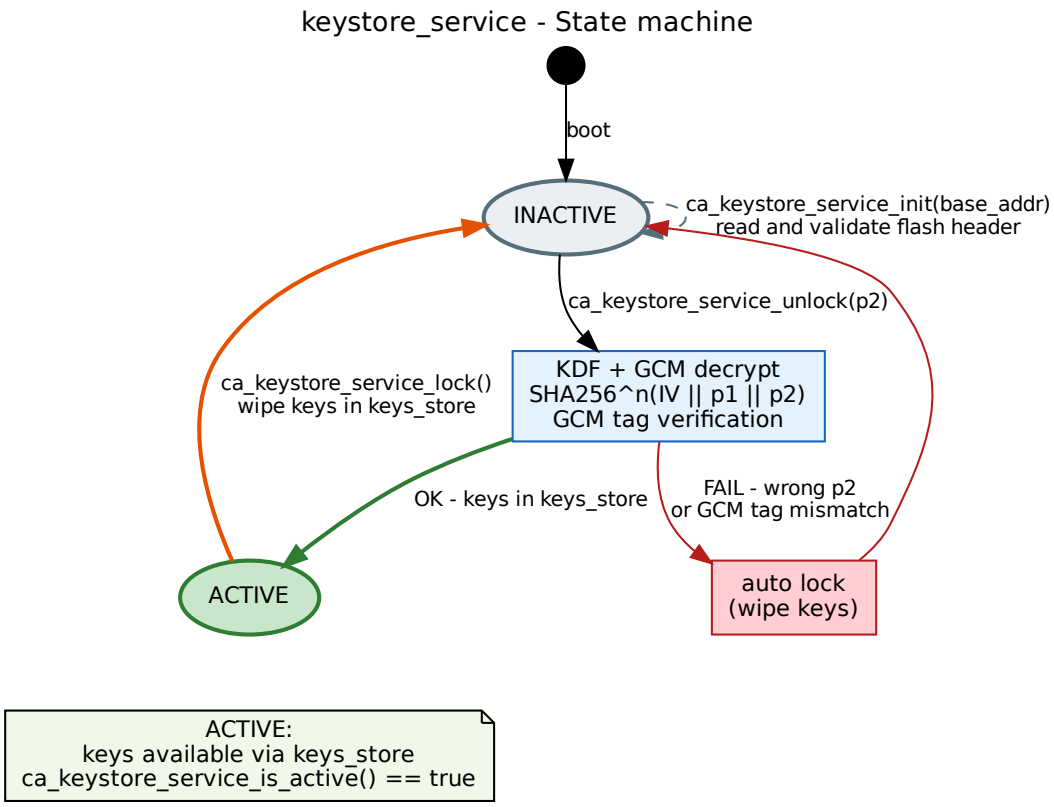

Figure 15.4: State machine keystore_service

Any error in `unlock` (incorrect p2, corrupted flash, GCM tag mismatch, allocation failed) calls `lock()` automatically: keys are never partially loaded.

Internal unlock sequence

```
ca_keystore_service_unlock(p2)

        derive_key(hdr.IV, hdr.p1, p2, hdr.n_evolve, decrypt_key)
               SHA256^n_evolve(IV || p1 || p2)     32 byte

        ca_aes_ctx_setup(ctx, GCM, 256, decrypt_key, hdr.gcm_nonce)
        ca_memzero(decrypt_key)                 wipe immediato

        ca_aes_gcm_decrypt(ctx,
           AAD=hdr, payload_enc, payload_dec, tag)
               tag mismatch?     lock() + return -1

        per ogni ca_flash_key_entry_t in payload_dec:
      ptr = ca_keys_store_allocate(32)
      ca_keys_store_copy(ptr, entry.key, 32)
      ca_keys_store_lock_completely(ptr)
      [imposta scadenza se entry.start/stop != 0]
```

```
        s_key_ptrs[i] = ptr

          ca_memory_free(payload_dec, wipe=true)
          s_state = KSS_ACTIVE
```

Typical usage

```
/* 1. In ca_os_configure(): init FLASH keystore */
if (ca_keystore_service_init(FLASH_KEYSTORE_BASE) != 0) {
    /* flash non provisionata o header corrotto */
    error_handler();
}

/* 2. Al login dell'utente / dopo ricezione p2 da canale sicuro */
u8 p2[16];
receive_p2_from_secure_channel(p2);     /* es. via UART cifrata, NFC, ecc. */

if (ca_keystore_service_unlock(p2) != 0) {
    ca_stdout_put_n("Unlock fallito     p2 errato o flash corrotta");
    return;
}
ca_memzero(p2, sizeof(p2));             /* wipe p2 dallo stack */

/* 3. Le chiavi sono ora in keys_store, accessibili via ptr */
/* ... usa le chiavi con aes_channel_service o direttamente ... */

/* 4. Al logout o fine sessione */
ca_keystore_service_lock();
```

Note: key provisioning in flash

The flash block must be written during production/provisioning with an external tool that knows `IV`, `p1`, `p2` and the keys to be protected. The device never writes the block itself — it only receives `p2` at runtime.

15.1.14 13.14 ECDSA P-256 (`ecdsa_p256.h`)

Why

The TLS 1.3 (HTTPS) server signs the exchange with its certificate key, and browsers do not accept Ed25519 certificates: **ECDSA on P-256** (`ecdsa_secp256r1_sha256`) is required. None of our boards do this in hardware. The H563 has a PKA, but the H523/562/563 series uses it in **limited mode**: only signature verification (RM0481 §36.3). A server must sign, so ECDSA is software on all MCUs, and it is the same code everywhere.

Formats

Data	Bytes	Format
private key	32	integer `d` in [1, n-1], big-endian
public key	64	`X` `Y` (without the `0x04` prefix of the SEC1 form)
signature	64	raw `r` `s` (TLS wants it in DER: conversion is done by `tls.c`)

Deterministic Nonce (RFC 6979)

The `k` value of each signature does not come from the RNG but from HMAC-SHA256 on the private key and message hash. A weak or repeated RNG cannot leak the key (with ECDSA, two signatures with the same `k` reveal it), and the signature is verifiable against published vectors.

Implementation

- 8 32-bit limbs, a single Montgomery multiplier (CIOS) for the `p` field and for the `n` order; inverses using Fermat's Little Theorem.
- Points in projective coordinates with the **complete** addition formulas by Renes-Costello-Batina (2016): a single formula for addition, doubling, and point at infinity, without special cases.
- Signing (secret data `k`): "always add and select with a mask", without branches or memory accesses that depend on `k`.
- Verification (public data): Shamir's trick `u1G + u2Q`, variable time. Rejects `r/s` outside [1, n-1] and a public key that does not lie on the curve.

API

```
bool ca_ecdsa_p256_public_from_private(u8 *public_key, const u8 *private_key);
bool ca_ecdsa_p256_keygen(u8 *public_key, u8 *private_key);       /* RNG */
bool ca_ecdsa_p256_sign_hash(u8 *signature, const u8 *hash, const u8 *
    private_key);
bool ca_ecdsa_p256_sign(u8 *signature, const u8 *message, u32 len, const u8 *
    private_key);
bool ca_ecdsa_p256_verify_hash(const u8 *signature, const u8 *hash, const u8 *
    public_key);
bool ca_ecdsa_p256_verify(const u8 *signature, const u8 *message, u32 len, const
     u8 *public_key);
```

Flag: `EN_ECDSA_P256` (requires `EN_SHA256`), `EN_ECDSA_P256_TEST` for self-test, `EN_CLI_ECDSA_P256` for the `p256 test | keygen` command. The self-test is in example 66.

Measured timings (23/10/2026)

MCU	Signature	Verification
H753	17 ms	13 ms
F767	36 ms	29 ms
H563 (250 MHz)	43 ms	36–41 ms
U575	67 ms	132 ms
F446	70 ms	140 ms

On U575 and F446, verification is slower than signing, unlike the others: not yet investigated. For a TLS server, only the signature counts (one per handshake).

15.1.15 13.15 Crypto module status summary

Module	Status	Notes
CRC32/HASH/RNG Driver	**HW Tested**	All families

Module	Status	Notes
AES (HW CRYP)	**HW Tested**	H753 via CRYP
AES (software)	**HW Tested**	U575+F407: ECB/CTR/GCM 256; NIST vectors 4/4 (`aes_nist test`), ex26 aes/aes_gcm PASS. AES-128 (23/10): 184/184 on PC against `cryptography`, in use in TLS on H563/F767/U575
AES-128 on CRYP	**HW Tested**	H753, via TLS 1.3 (ex45/ex80, 23/10)
AES (HW AES U5xx)	**Code**	`aes_u5xx.c` driver for U585/U5A5; not tested (U575 board = SW)
`keys_store`	**HW Tested**	MPU region, expiration, max 20 keys
`aes_channel_service`	**HW Tested**	GCM-256, IV from HW RNG, 16B padding
`keystore_service`	**HW Tested**	KDF SHA256ˆn, AES-GCM, key split p1/p2
`kdf` HMAC/HKDF/PBKDF2	**HW Tested**	7/7 RFC vectors on H753 (ex66 `sha256 kdf`); PBKDF2 100000 it = 2.25 s
`aes_channel_service` AAD header	**HW Tested**	ex46/ex47 on H753, F767, H563 (15/10)
`secure_pipe` link	**HW Tested**	ex97 13/13 on H753, F767, H563; app_3 between H753 and H563
`keys_store` space recovery	**HW Tested**	ex46/47/97 on H753 and H563 after `free` fix
ECDSA P-256	**HW Tested**	RFC 6979 A.2.5 + negative cases, ex66 10/10 on the 5 Nucleo boards (23/10)

Chapter 16

caOS Network Stack: Low Level

16.1 Chapter 14 - caOS Network Stack: Low Level

This section describes the physical and transport layers of the caOS network stack: zero-copy ETH driver, DMA-safe buffer pool, MPU configuration, initialization sequence and link control.

16.1.1 14.0 Zero-copy Architecture

The caOS ETH driver uses a **DMA-safe buffer pool** (NCacheable) to eliminate copies between CPU and DMA in the RX/TX hot path:

```
[ DMA ETH ]          [ Pool NCacheable ]          [ CPU / task_net ]
```

No `memcpy`: the DMA writes directly to the pool, the processor reads directly from the pool. The only necessary condition is that the pool be in an **NCacheable** region (MPU) to avoid inconsistency between CPU D-cache and DMA.

Buffer pool — `ca_net_buf_t`

```c
/* caos/net/inc/net_buf.h */
#define NET_BUF_SIZE       2048U   /* total structure size */
#define NET_BUF_HDR_SIZE     64U   /* metadata header */
#define NET_BUF_DATA_SIZE  1984U   /* data area (2048 - 64) */
#define NET_BUF_HEADROOM    128U   /* prepend room for protocol headers */
#define NET_BUF_COUNT        64U   /* number of buffers in the pool */
#define NET_BUF_INVALID  0xFFFFU   /* sentinel index "no buffer" */

/* RX parse cache -- filled step by step by the L2->L3->L4 pipeline */
typedef struct {
    u16    l3_off;    /* L3 header offset from frame start */
    u16    l4_off;    /* L4 header offset from frame start; 0 if absent */
    ca_ipv4_t src_ip;    /* source IPv4 (spa for ARP) */
    ca_ipv4_t dst_ip;    /* destination IPv4 (tpa for ARP) */
    u16    src_port;  /* source UDP/TCP port */
    u16    dst_port;  /* destination UDP/TCP port */
    u16    vlan_id;   /* 802.1Q VID (0 = untagged) */
    u8     vlan_pcp;  /* 802.1Q PCP */
    u8     ip_proto;  /* IP_PROTO_ICMP/UDP/TCP; 0 if not IP */
} ca_net_buf_rx_t;                                          /* 20 byte */

typedef struct {
    u16                next;       /* next buffer index (chain) */
    u16                data_off;   /* offset payload in data[] */
    u16                data_len;   /* valid data length */
```

```
    u8                flags;      /* NET_BUF_F_IN_USE, NET_BUF_F_TX */
    u8                proto;      /* NET_PROTO_ARP/IP4/NONE */
    u32               timestamp;  /* ca_os_tick() at reception */
    ca_net_buf_rx_t   meta_rx;    /* cache parse RX */
    u8                data[NET_BUF_DATA_SIZE];  /* 1984 byte DMA-safe */
} ca_net_buf_t;                                              /* 2048 byte */
```

`data_off = NET_BUF_HEADROOM = 128` leaves room for header prepend (e.g. adding IP/UDP before the payload without reallocation). DMA descriptors point to `b->data + b->data_off`.

Buffer pool API

Function	Description
`ca_net_buf_pool_init()`	Initialize pool in D2 SRAM1 NCacheable; call before `ca_eth_init()`
`ca_net_buf_alloc()`	Allocate a buffer; returns `NET_BUF_INVALID` if pool is exhausted
`ca_net_buf_free(idx)`	Free a buffer; DO NOT call if driver owns it
`ca_net_buf_ptr(idx)`	Pointer to `ca_net_buf_t` from index
`ca_net_buf_free_count()`	Available buffers in pool

ETH zero-copy API

```
/* Transmission -- no copy */
i32 ca_eth_send(u16 buf_idx);
/* CA_ETH_SEND_OK (0):          the driver owns buf_idx (deferred free)
   CA_ETH_SEND_ERR_LINK (-102): link down (state seen by the last
                                ca_eth_link_poll(), DOWN until the first poll)
   CA_ETH_SEND_ERR_TX   (-101): TX ring full or MAC not initialized
   In EVERY case the driver owns buf_idx: the caller never frees it
   (freeing it on error was a double free: the driver already gave it back) */

/* Reception -- zero-copy swap */
bool ca_eth_recv(u16 *out_idx, u16 new_idx);
/* true:  *out_idx holds the frame (to process and then free)
          new_idx is now in DMA (do not touch)
   false: new_idx not consumed -> ca_net_buf_free(new_idx) */

/* Buffers held by the driver (for a correct leak check) */
u16 ca_eth_pool_held_count(void);
/* Typical steady-state value: 4 (fixed RX) + 0-4 (deferred TX) */
```

16.1.2 14.1 MPU Configuration — NCacheable Regions

```
/* MPU region 3: pool D2 SRAM1 -- configurata in ca_eth_hw_init() */
MPU->RNR  = 3U;
MPU->RBAR = 0x30000000U;                        /* base pool */
MPU->RASR = MPU_RASR_ENABLE_Msk
          | (16U << MPU_RASR_SIZE_Pos)          /* 128 KB */
          | (3U  << MPU_RASR_AP_Pos)            /* RW/RW */
          | (1U  << MPU_RASR_TEX_Pos)           /* TEX=001 */
          | MPU_RASR_S_Msk;                     /* Shareable */
/* C=0, B=0 -> Non-cacheable */

/* MPU region 4: .eth_dma D2 SRAM3 */
MPU->RNR  = 4U;
MPU->RBAR = (u32)tx_desc;                       /* base .eth_dma */
```

```
MPU->RASR = MPU_RASR_ENABLE_Msk
          | (14U << MPU_RASR_SIZE_Pos)          /* 32 KB */
          | (3U  << MPU_RASR_AP_Pos)
          | (1U  << MPU_RASR_TEX_Pos)
          | MPU_RASR_S_Msk;
```

IMPRECISERR: if `.eth_dma` is in Write-back cacheable region, the CPU write buffer may delay the write of the OWN bit to the physical RAM. The DMA reads the old value -> asynchronous bus fault (CFSR bit 10). The MPU NCacheable resolves the issue at the root.

16.1.3 14.2 Network stack modules

Module	File	EN_ flag	Description
ETH driver	`caos/drivers/src/eth.c` + hw/	`EN_ETH`	DMA TX/RX, IRQ, buffer pool
Net proto	`caos/net/src/net_proto.c`	`EN_NET`	pure decoder/builder (ARP/IP/ICMP/TCP/UDP)
ARP service	`caos/net/src/arp_service.c`	`EN_ARP_SERVICE`	ARP cache, GARP, MAC resolution
Route service	`caos/net/src/route_service.c`	`EN_ROUTE_SERVICE`	route table + longest-prefix match
DHCP service	`caos/net/src/dhcp_service.c`	`EN_DHCP_SERVICE`	DORA client, lease renewal
NTP service	`caos/net/src/ntp_service.c`	`EN_NTP_SERVICE`	NTP client with automatic polling
DNS service	`caos/net/src/dns_service.c`	`EN_DNS_SERVICE`	DNS client with cache
mDNS service	`caos/net/src/mdns_service.c`	`EN_MDNS_SERVICE`	mDNS .local responder
Syslog svc	`caos/net/src/syslog_service.c`	`EN_SYSLOG_SERVICE`	remote UDP logging on port 514
TCP service	`caos/net/src/tcp_service.c`	`EN_TCP_SERVICE`	PCB, RTO timer, listen/connect
UDP server	`caos/net/src/udp_server.c`	`EN_UDP_SERVER`	multi-client with worker task
UDP client	`caos/net/src/udp_client.c`	`EN_UDP_CLIENT`	async or blocking send/recv
IP defrag	`caos/net/src/ip_defrag.c`	`EN_IP_DEFRAG`	fragment reassembly RFC 791
TFTP service	`caos/net/src/tftp_service.c`	`EN_TFTP_SERVICE`	TFTP client RFC 1350 GET/PUT, OTA
HTTP service	`caos/net/src/http_service.c`	`EN_HTTP_SERVICE`	HTTP/1.1 server with route table
MQTT service	`caos/net/src/mqtt_service.c`	`EN_MQTT_SERVICE`	MQTT 3.1.1 QoS 0 client

Module	File	EN_ flag	Description
Modbus svc	caos/net/src/modbus_service.c	EN_MODBUS_SERVICE	Modbus/TCP client
iperf svc	caos/net/src/iperf_service.c	EN_IPERF_SERVICE	TCP throughput measurement
Packet tracer	caos/net/src/packet_tracer_service.c	EN_PACKET_TRACER	bare-metal tcpdump

Basic enable in `os_config.h`:

```
#define EN_ETH    1   /* driver Ethernet HW */
#define EN_NET    1   /* stack net_proto */
```

`EN_NET` requires **at least one L2 interface**: ETH (`EN_ETH=1`) or USB-NCM (`EN_USB && EN_USB_NCM`). If neither is active, `EN_NET` is forced to 0 (and with it all sub-protocols and services).

16.1.4 14.2.1 Interface abstraction — `ca_net_iface_t`

The `net.c` core does not communicate directly with the driver: it uses an **abstract interface** (`ca_net_iface_t`, function pointer structure). This way the same IP stack runs interchangeably on **Ethernet** or on **USB-NCM** (USB Ethernet), and in the future on WiFi/PPP, changing only the registered interface.

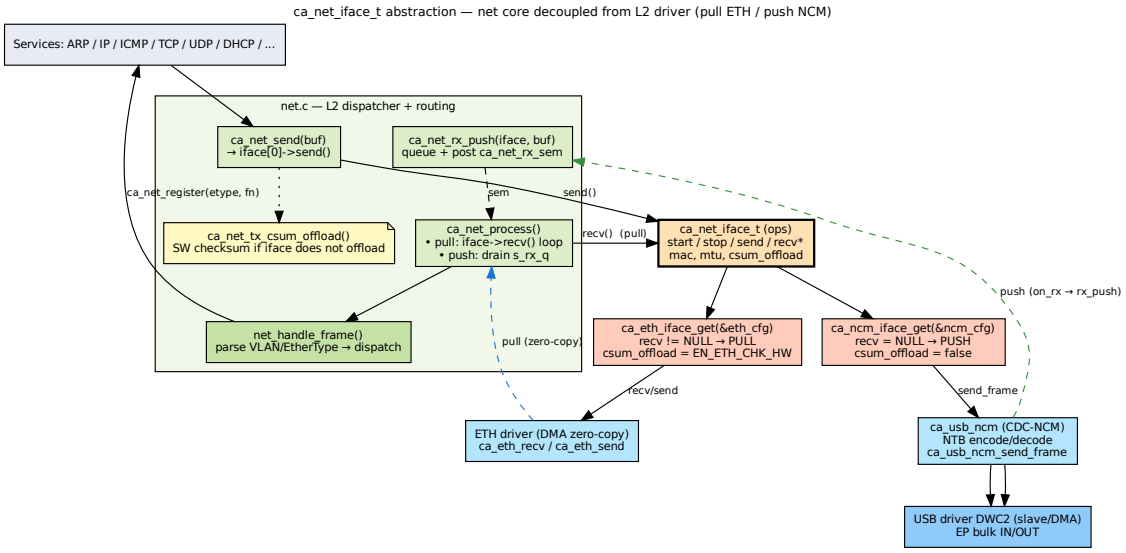

Figure 16.1: net_iface

Source: `doc/diagrams/net_iface_arch.dot` *(regenerated from* `make diagrams`*).*

```
/* caos/net/inc/net_iface.h */
struct ca_net_iface {
    cstr   name;              /* "eth0", "usb0" -- diagnostics */
    u8     id;                /* assigned by ca_net_register_iface */
```

```
    ca_mac_t mac;                /* L2 MAC of the interface */
    u16   mtu;                /* MTU L2 (payload max) */
    bool  up;                 /* state managed by the core via start/stop */
    bool  csum_offload;       /* true = HW calcola checksum IP/L4 (ETH DMA);
                                 false = the SW computes them (NCM) */
    void *priv;               /* ctx driver (ca_eth_cfg_t*, ctx NCM) */
    bool (*start)(ca_net_iface_t *self);
    bool (*stop) (ca_net_iface_t *self);
    bool (*send) (ca_net_iface_t *self, u16 buf_idx);
    bool (*recv) (ca_net_iface_t *self, u16 *out_idx, u16 new_idx); /* opz. */
};
```

Hybrid RX model — pull / push

The abstraction supports **two RX models** to cover drivers with different characteristics without rewriting the core:

Model	`ops.recv`	Who delivers the frames	Used by
pull (zero-copy)	!= NULL	`ca_net_process()` calls `recv()` in loop	ETH (DMA)
push	NULL	the driver calls `ca_net_rx_push()`	USB-NCM

`ca_net_process()` for each iface with `recv` executes a zero-copy pull-loop; then drains the push queue (`ca_net_rx_push`). The two paths converge in the same L2 parser (`net_handle_frame`).

Adapter

Two factories wrap the concrete drivers in a `ca_net_iface_t`:

```
/* ETH: pull zero-copy, checksum HW (caos/net/inc/eth_iface.h) */
ca_net_iface_t *ca_eth_iface_get(ca_eth_cfg_t *cfg);   /* csum_offload =
    EN_ETH_CHK_HW */

/* USB-NCM: push, checksum SW (caos/net/inc/ncm_iface.h) */
ca_net_iface_t *ca_ncm_iface_get(ca_usb_ncm_cfg_t *cfg); /* csum_offload = false
    */
```

Per-interface Checksum

`net_proto` builders leave the IP/ICMP/TCP/UDP checksum fields to 0 **only if the TX interface does HW offload** (`ca_net_tx_csum_offload()`). ETH delegates to the MAC, which calculates them and **inserts** them by overwriting the field: CIC=11 in the TX descriptor, valid because the MTL is in store-and-forward (TSF). The NCM, which lacks offload, has the software calculate the checksums. The choice is runtime, per-interface:

```
if (!ca_net_tx_csum_offload())
    ip4->cksum = ca_htons(ca_net_cksum((const u8 *)ip4, 20U));
```

> The check is **at 13 call-sites**, at runtime. `EN_ETH_CHK_HW` no longer has (a) `EVAL_` macro: the old `EVAL_NO_ETH_CHK_HW` was generated by `caos_model.py` in the generic form (`__VA_ARGS__` dry). A previous version contained the runtime test written by hand, and a regen of the config silently reverted it to the generic form: since then the SW checksum has always been calculated — wasted work on ETH — and with `EN_ETH_CHK_HW=0` it is **never** calculated **by anyone**. Having no users left, it was removed from the model (03/10) because nobody should put the test back in.

API interface

```
bool ca_net_init(ca_net_iface_t *iface);          /* registra iface default + start */
bool ca_net_register_iface(ca_net_iface_t *iface);/* additional iface (multi-iface) */
bool ca_net_rx_push(ca_net_iface_t *iface, u16 buf_idx); /* RX push (driver -> core) */
bool ca_net_tx_csum_offload(void);                /* true if the TX iface does HW offload */
```

16.1.5 14.3 Initialization Sequence

```
/* ca_os_configure() -- hardware init and core services */
eth_gpio_init();

ca_eth_cfg_t eth_cfg = { .link_cb = on_link_change, /* ... */ };
ca_net_init(ca_eth_iface_get(&eth_cfg));   /* ETH; per USB-NCM: ca_ncm_iface_get(&ncm) */

ca_ipv4_t zero = { .addr = 0U };
ca_arp_service_init(s_mac, zero);
ca_dhcp_service_init(s_mac, on_dhcp_bound, on_dhcp_expire);
/* other services: ca_ntp_service_init(), ca_dns_service_init(), ... */

/* ca_os_main() -- avvio task */
ca_arp_service_start();
ca_dhcp_service_start();
ca_tcp_service_start();
ca_os_job("net",     CA_TH_LEVEL2, task_net,     NULL, STACK_SMALL, CA_JOB_STD, CA_FAULT_RESTART_THREAD);
ca_os_run(true);
```

task_net — type structure

```
static u32 task_net(void *arg)
{
    ca_net_proto_init(&net_cfg);
    ca_net_proto_bind_udp(DHCP_CLIENT_PORT, dhcp_udp_handler);
    /* bind other services: ca_ntp_service_bind(), ca_dns_service_bind(), ... */

    ca_eth_link_poll();
    ca_os_delay_ms(200U);
    ca_dhcp_service_net_ready();   /* unblocks the DHCP task */

    while (1) {
        ca_sem_wait(&ca_net_rx_sem);
        ca_net_process();
    }
    return 0U;
}
```

Callback DHCP bound

```
static void on_dhcp_bound(ca_ipv4_t ip, ca_ipv4_t mask, ca_ipv4_t gw, ca_ipv4_t dns)
{
    (void)mask; (void)dns;
    ca_net_proto_set_local_ip(ip);
```

```
    ca_arp_service_update_local_ip(ip);
    ca_arp_send_garp();
    /* notify the application services: */
    /* ca_http_update_local_ip(ip); */
    /* ca_iperf_update_local_ip(ip); */
    /* ca_sem_post(&s_dhcp_sem); */
}
```

16.1.6 14.4 Configuration — `ca_net_cfg_t`

All configuration is collected in `caos/net/inc/net_cfg.h`.

Attention to types `ca_ipv4_t` and `ca_mac_t`: always use `.v = {}` for initialization:

```
ca_net_cfg_t net_cfg = {
    .ip   = { .v = { 192U, 168U, 10U, 33U } },
    .mask = { .v = { 255U, 255U, 255U,  0U } },
    .mac  = { .v = { 0x02U, 0x00U, 0x00U, 0x00U, 0x00U, 0x33U } },
    .arp  = { .renew_ms = 30000U },
    .icmp = { .echo_reply = true },
#if EN_NET_DHCP
    .dhcp = { .timeout_ms = 5000U, .on_bound = my_dhcp_callback },
#endif
#if EN_NET_NTP
    .ntp  = { .server_ip = { .v = {192U,168U,10U,1U} }, .poll_ms = 64000U },
#endif
#if EN_NET_SYSLOG
    .syslog = { .server_ip = { .v = {192U,168U,10U,200U} },
                .facility = SYSLOG_FAC_LOCAL0 },
#endif
#if EN_NET_DNS
    .dns  = { .server_ip = { .v = {8U,8U,8U,8U} } },

    .mdns = { .hostname = "caos-board" },
#endif
};

ca_net_proto_init(&net_cfg);
```

16.1.7 14.5 Link control

Software to bring down and restore the Ethernet link, with optional PHY nRST pin control:

```
/* Takes the link down: disables the RCC clock, stops the ETH DMA */
void ca_net_link_down(void);

/* Restores the link: re-enables the RCC clock, restarts the ETH DMA */
void ca_net_link_up(void);

/* Configures the PHY nRST GPIO (optional) */
void ca_net_set_phy_nrst(u8 port, u8 pin);
```

`port = 0xFF` means "not wired" (no GPIO control). The structure `ca_net_cfg_t` also exposes `mtu`, `phy_nrst_port`, `phy_nrst_pin` for static configuration.

16.1.8 14.6 Source files

File	Role
caos/net/inc/net_buf.h	ca_net_buf_t, constants pool
caos/net/src/net_buf.c	ca_net_buf_pool_init, alloc, free, ptr, free_count
caos/net/src/net.c	ca_net_init, ca_net_process, ca_net_send, ca_net_stats

Chapter 17

caOS Network Stack: net_proto

17.1 Chapter 14 - caOS Network Stack: net_proto (pure decoder/builder)

`net_proto` is the bare-metal frame decoding and building layer of caOS. All functions are **pure** (no side effects, no global state), **zero-copy** (pointers to original raw buffer), and identical on PC and MCU.

17.1.1 14.7 Overview

```
Applicazione / task caOS
  (ARP cache, timer DHCP/DNS, state machine)
-------------------------------------------------
net_proto  -- decoder/builder puri
  L2: Ethernet, VLAN 802.1Q, ARP
  L3: IPv4, ICMP echo
  L4: UDP, TCP
  App: DHCP, NTP, Syslog, DNS, mDNS
-------------------------------------------------
net.c / net_buf.c -- dispatcher RX, buffer pool
-------------------------------------------------
Driver ETH bare-metal (CMSIS)
```

Fundamental properties: - **Pure functions**: no side effects, no global state - **Zero-copy**: output pointers directly into the original raw buffer - Return `false` on malformed input leaving `*out` unchanged - Identical on PC (test) and MCU (production)

17.1.2 14.8 Decoding pipeline

Each received frame goes through a pipeline of pure functions:

```
raw frame (u8 *, len)
  +-- ca_net_proto_l2()    -> const ca_l2_frame_t *   (filtro MAC, VLAN strip)
       +-- EtherType ARP   -> ca_net_proto_arp()        -> const ca_arp_frame_t
    *
       +-- EtherType IPv4  -> ca_net_proto_ip4()        -> const ca_ip4_frame_t
    *
                              +-- proto UDP  -> ca_net_proto_udp()        ->
    const ca_udp_frame_t *
                              +-- proto ICMP -> ca_net_proto_icmp_echo()  ->
    const ca_icmp_echo_t *
```

```
                                +-- proto TCP  -> ca_net_proto_tcp()        ->
    const ca_tcp_frame_t *
```

Complete example — UDP reception:

```
const ca_l2_frame_t  *l2;
const ca_ip4_frame_t *ip4;
const ca_udp_frame_t *udp;

ca_l2_result_t r = ca_net_proto_l2(frame, len, local_mac, &l2);
if (r == CA_L2_DROP) return;

if (ca_ntohs(l2->ethertype) != ETH_P_IP) return;
if (!ca_net_proto_ip4(l2, len, &ip4)) return;
if (!ca_net_proto_udp(ip4, &udp)) return;

const u8 *payload     = CA_UDP_PAYLOAD(udp);
u16       payload_len = (u16)(ca_ntohs(udp->length) - 8U);
process_udp(ca_ntohs(udp->src_port), ca_ntohs(udp->dst_port),
            payload, payload_len);
```

17.1.3 14.9 L2 — Ethernet and VLAN 802.1Q

Wire-format

```
/** Ethernet II header -- 14 byte (IEEE 802.3) */
typedef struct {
    ca_mac_t  dst;       /* destination MAC */
    ca_mac_t  src;       /* source MAC */
    u16    ethertype; /* ETH_P_IP / ETH_P_ARP / ETH_P_VLAN (big-endian) */
} __attribute__((packed)) ca_l2_frame_t;

/** 802.1Q VLAN header -- 18 byte */
typedef struct {
    ca_mac_t  dst;
    ca_mac_t  src;
    u16    tpid;      /* 0x8100 big-endian */
    u16    tci;       /* PCP[15:13]|DEI[12]|VID[11:0] big-endian */
    u16    ethertype; /* inner EtherType big-endian */
} __attribute__((packed)) ca_l2_vlan_frame_t;
```

Decoder

```
ca_l2_result_t ca_net_proto_l2(const u8 *frame, u16 len,
                               ca_mac_t local_mac,
                               const ca_l2_frame_t **out);
```

Result	Condition
`CA_L2_ACCEPT_UNICAST`	`dst == local_mac`
`CA_L2_ACCEPT_BROADCAST`	`dst == FF:FF:FF:FF:FF:FF`
`CA_L2_ACCEPT_MULTICAST`	first byte dst I/G bit == 1
`CA_L2_DROP`	frame not for us or too short

`local_mac = {0}` enables promiscuous mode.

VLAN 802.1Q: if `ca_ntohs((*out)->ethertype) == ETH_P_VLAN` the pointer is cast to `const ca_l2_vlan_frame_t *`. Read `VID` and `PCP` with the macros:

```
u16 vid = CA_VLAN_VID(vl2->tci);   /* 0-4094 */
u8  pcp = CA_VLAN_PCP(vl2->tci);   /* 0-7    */
```

Payload Navigation Macros

```
CA_L2_PAYLOAD(l2)        /* first byte after Ethernet header (14 bytes) */
CA_L2_VLAN_PAYLOAD(l2v)  /* first byte after 802.1Q header  (18 bytes) */
CA_IP4_PAYLOAD(ip4)      /* first byte after IPv4 header (IHL-aware)   */
CA_UDP_PAYLOAD(udp)      /* first byte after UDP header     ( 8 bytes) */
```

17.1.4 14.10 Proto — ARP

Wire-format

```
/** ARP per IPv4/Ethernet -- 28 byte (RFC 826) */
typedef struct {
    u16    htype;  /* ARP_HTYPE_ETH = 1 (big-endian) */
    u16    ptype;  /* ARP_PTYPE_IP = 0x0800 (big-endian) */
    u8     hlen;   /* 6 */
    u8     plen;   /* 4 */
    u16    oper;   /* ARP_OP_REQUEST=1 / ARP_OP_REPLY=2 (big-endian) */
    ca_mac_t  sha;    /* sender hardware address */
    ca_ipv4_t spa;    /* sender protocol address */
    ca_mac_t  tha;    /* target hardware address */
    ca_ipv4_t tpa;    /* target protocol address */
} __attribute__((packed)) ca_arp_frame_t;
```

Decoder

```
bool ca_net_proto_arp(const ca_l2_frame_t *l2, u16 len,
                      const ca_arp_frame_t **out);
```

Returns `false` if `htype != Ethernet`, `ptype != IPv4`, `hlen != 6`, `plen != 4` or frame too short.

ARP Reply Builder

```
u16 ca_net_proto_arp_build_reply(const ca_arp_frame_t *req,
                                 ca_mac_t  local_mac,
                                 ca_ipv4_t local_ip,
                                 u8    *out_frame);  /* buffer >= 42 byte */
```

Returns 42 (14 Ethernet + 28 ARP) or 0 if `req->oper != ARP_OP_REQUEST`.

GARP Builder

```
u16 ca_net_proto_arp_build_garp(ca_mac_t  local_mac,
                                ca_ipv4_t local_ip,
                                u8    *out_frame);  /* buffer >= 60 byte */
```

Builds an ARP REQUEST with `spa == tpa == local_ip` (Gratuitous ARP, RFC 5227). Resulting frame: 60 bytes. Pure function (stateless).

Typical flow

```
RX frame -> ca_net_proto_l2() -> ca_net_proto_arp()
  oper == ARP_OP_REQUEST && tpa == local_ip ?
    -> ca_net_proto_arp_build_reply()
    -> ca_net_send()
```

17.1.5 14.11 Proto — IPv4

Wire-format

```
/** IPv4 header -- 20 byte minimo (RFC 791) */
typedef struct {
    u8      ver_ihl;     /* version[7:4]=4 | IHL[3:0] in word a 32-bit */
    u8      dscp_ecn;
    u16     total_len;   /* total length incl. header (big-endian) */
    u16     id;
    u16     flags_frag;  /* flags[15:13] | fragment offset[12:0] (big-endian) */
    u8      ttl;
    u8      proto;       /* IP_PROTO_ICMP=1 / TCP=6 / UDP=17 */
    u16     cksum;       /* header checksum (big-endian) */
    ca_ipv4_t src;
    ca_ipv4_t dst;
} __attribute__((packed)) ca_ip4_frame_t;
```

Decoder

```
bool ca_net_proto_ip4(const ca_l2_frame_t *l2, u16 len,
                      const ca_ip4_frame_t **out);
```

Verification: version == 4, IHL >= 20, `total_len <= payload_len`, header checksum RFC 1071.

Internet checksum

```
u16 ca_net_cksum(const u8 *buf, u16 len);
```

Implementation of RFC 1071. Returns 0 if the data is correct (RX verification).

> **TX Note**: `ca_net_cksum()` returns the checksum in host format (little-endian on ARM). For TX, **always** assign with `ca_htons()`:
>
> ```
> ip4->cksum = ca_htons(ca_net_cksum((const u8 *)ip4, 20U));
> ```

17.1.6 14.12 Proto — UDP

Wire-format

```
/** UDP header -- 8 byte (RFC 768) */
typedef struct {
    u16     src_port;  /* (big-endian) */
    u16     dst_port;  /* (big-endian) */
    u16     length;    /* header + data (big-endian) */
    u16     checksum;  /* 0 = absent (RFC 768) */
} __attribute__((packed)) ca_udp_frame_t;
```

Decoder

```
bool ca_net_proto_udp(const ca_ip4_frame_t *ip4,
                      const ca_udp_frame_t **out);
```

Check `proto == IP_PROTO_UDP`, `udp_len >= 8`, `udp_len <= ip4_payload_len`. The UDP checksum is optional (RFC 768): if 0 it is accepted without verification.

17.1.7 14.13 Proto — ICMP

Wire-format

```
/** ICMP echo request/reply -- 8 byte (RFC 792) */
typedef struct {
    u8     type;      /* 8 = echo request, 0 = echo reply */
    u8     code;      /* 0 */
    u16    checksum;  /* (big-endian) */
    u16    id;        /* identifier (big-endian) */
    u16    seq;       /* sequence number (big-endian) */
} __attribute__((packed)) ca_icmp_echo_t;
```

Decoder

```
bool ca_net_proto_icmp_echo(const ca_ip4_frame_t *ip4,
                            const ca_icmp_echo_t **out);
```

Accept only `type == 8` (request) or `type == 0` (reply).

Builder Echo Reply

```
u16 ca_net_proto_icmp_build_echo_reply(
    const ca_l2_frame_t  *req_l2,
    const ca_ip4_frame_t *req_ip4,
    const ca_icmp_echo_t *req_icmp,
    ca_mac_t  local_mac,
    ca_ipv4_t local_ip,
    u8    *out_frame,
    u16    out_max);
```

Produce complete Ethernet+IPv4+ICMP frame with IPv4 and ICMP checksums.

17.1.8 14.14 Proto — TCP (wire-format and builder)

Wire-format

```
typedef struct {
    u16 src_port;
    u16 dst_port;
    u32 seq;
    u32 ack_seq;
    u8  data_off;   /* [7:4] = header len in parole a 32-bit */
    u8  flags;      /* TCP_FLAG_* */
    u16 window;
    u16 checksum;
    u16 urg_ptr;
} __attribute__((packed)) ca_tcp_frame_t;

#define TCP_FLAG_FIN  0x01U
#define TCP_FLAG_SYN  0x02U
#define TCP_FLAG_RST  0x04U
#define TCP_FLAG_PSH  0x08U
#define TCP_FLAG_ACK  0x10U

#define CA_TCP_HDR_LEN(tcp)   ((u16)(((tcp)->data_off >> 4U) << 2U))
#define CA_TCP_PAYLOAD(tcp)   ((u8*)(tcp) + CA_TCP_HDR_LEN(tcp))
#define TCP_MSS_DEFAULT       1460U
```

Decoder

```
bool ca_net_proto_tcp(const ca_ip4_frame_t *ip4,
                      const ca_tcp_frame_t **out);
```

Builder TCP (`net_proto_tcp.c`)

All builders produce a complete Ethernet+IPv4+TCP frame with pseudo-header checksum RFC 793. They return the frame length or 0.

```
/* SYN con opzione MSS (header TCP 24 byte) */
u16 ca_net_proto_tcp_build_syn(ca_mac_t dst_mac, ca_ipv4_t dst_ip,
                               ca_mac_t src_mac, ca_ipv4_t src_ip,
                               u16 src_port, u16 dst_port,
                               u32 seq, u16 mss,
                               u8 *out_frame, u16 out_max);

/* ACK puro (header 20 byte) */
u16 ca_net_proto_tcp_build_ack(ca_mac_t dst_mac, ca_ipv4_t dst_ip,
                               ca_mac_t src_mac, ca_ipv4_t src_ip,
                               u16 src_port, u16 dst_port,
                               u32 seq, u32 ack_seq, u16 window,
                               u8 *out_frame, u16 out_max);

/* PSH+ACK with data (20-byte header + payload) */
u16 ca_net_proto_tcp_build_data(ca_mac_t dst_mac, ca_ipv4_t dst_ip,
                                ca_mac_t src_mac, ca_ipv4_t src_ip,
                                u16 src_port, u16 dst_port,
                                u32 seq, u32 ack_seq, u16 window,
                                const u8 *data, u16 data_len,
                                u8 *out_frame, u16 out_max);

/* FIN+ACK (header 20 byte) */
u16 ca_net_proto_tcp_build_fin(ca_mac_t dst_mac, ca_ipv4_t dst_ip,
                               ca_mac_t src_mac, ca_ipv4_t src_ip,
                               u16 src_port, u16 dst_port,
                               u32 seq, u32 ack_seq, u16 window,
                               u8 *out_frame, u16 out_max);

/* RST (header 20 byte, ack=0) */
u16 ca_net_proto_tcp_build_rst(ca_mac_t dst_mac, ca_ipv4_t dst_ip,
                               ca_mac_t src_mac, ca_ipv4_t src_ip,
                               u16 src_port, u16 dst_port,
                               u32 seq,
                               u8 *out_frame, u16 out_max);

/* SYN+ACK with MSS option -- server reply to client SYN (24-byte header) */
u16 ca_net_proto_tcp_build_synack(ca_mac_t dst_mac, ca_ipv4_t dst_ip,
                                  ca_mac_t src_mac, ca_ipv4_t src_ip,
                                  u16 src_port, u16 dst_port,
                                  u32 seq, u32 ack_seq, u16 mss,
                                  u8 *out_frame, u16 out_max);
```

17.1.9 14.15 Proto — DHCP (pure functions)

This section describes the **pure** DHCP decoding/construction functions. The complete service with DORA state machine, tasks and callbacks is in section §14.17 DHCP Service.

Constants

```
#define DHCP_SERVER_PORT   67U
#define DHCP_CLIENT_PORT   68U
#define DHCP_MSG_DISCOVER  1U
#define DHCP_MSG_OFFER     2U
#define DHCP_MSG_REQUEST   3U
#define DHCP_MSG_ACK       5U
```

Builder Discover

```
u16 ca_net_proto_dhcp_build_discover(ca_mac_t local_mac, u32 xid,
                                     u8 *out_frame, u16 out_max);
```

Produce a **286 byte** frame: Ethernet(14)+IP(20)+UDP(8)+BOOTP(244).

Offer/ACK Parser

```
bool ca_net_proto_dhcp_parse_offer(const ca_udp_frame_t *udp,
                                   ca_dhcp_offer_t *out);
```

```
typedef struct {
    ca_ipv4_t offered_ip;   /* yiaddr -- offered IP */
    ca_ipv4_t server_ip;    /* siaddr -- DHCP server IP */
    ca_ipv4_t subnet_mask;  /* option 1 */
    ca_ipv4_t gateway;      /* option 3 (first router) */
    ca_ipv4_t dns;          /* option 6 (first DNS) */
    u32    lease_time;   /* option 51, seconds */
    u8     msg_type;     /* DHCP_MSG_OFFER o DHCP_MSG_ACK */
} ca_dhcp_offer_t;
```

17.1.10 14.16 Proto — NTP, Syslog, DNS, mDNS (Pure Functions)

NTP (RFC 5905)

```
#define NTP_PORT         123U
#define NTP_EPOCH_DELTA  2208988800UL  /* NTP epoch (1900) a UNIX (1970) */

u16 ca_net_proto_ntp_build_request(ca_mac_t server_mac, ca_ipv4_t server_ip,
                                   ca_mac_t local_mac,  ca_ipv4_t local_ip,
                                   u8 *out_frame, u16 out_max);
/* Produce 90 byte: ETH(14)+IP(20)+UDP(8)+NTP(48) */

bool ca_net_proto_ntp_parse_response(const ca_udp_frame_t *udp,
                                     ca_ntp_pkt_t *out);
```

Syslog (RFC 3164)

```
#define SYSLOG_PORT       514U
#define SYSLOG_FAC_LOCAL0 16U
#define SYSLOG_SEV_INFO   6U

u16 ca_net_proto_syslog_build(ca_mac_t server_mac, ca_ipv4_t server_ip,
                              ca_mac_t local_mac,  ca_ipv4_t local_ip,
                              u8 facility, u8 severity,
                              const char *msg,
                              u8 *out_frame, u16 out_max);
```

The `PRI` field = `facility * 8 + severity`. UDP payload: `<PRI>message`.

Severity	Value
SYSLOG_SEV_EMERG	0
SYSLOG_SEV_ERR	3
SYSLOG_SEV_WARN	4
SYSLOG_SEV_INFO	6
SYSLOG_SEV_DEBUG	7

DNS (RFC 1035)

```
#define DNS_PORT     53U
#define DNS_TYPE_A   1U    /* record A -- IPv4 */
#define DNS_CLASS_IN 1U

u16 ca_net_proto_dns_build_query(ca_mac_t server_mac, ca_ipv4_t server_ip,
                                 ca_mac_t local_mac,  ca_ipv4_t local_ip,
                                 u16 id, const char *hostname,
                                 u8 *out_frame, u16 out_max);

bool ca_net_proto_dns_parse_response(const ca_udp_frame_t *udp,
                                     ca_dns_response_t *out);
```

The parser handles DNS **pointer compression** (0xC0xx) and the wrapping of multi-level labels (e.g. "pool.ntp.org" -> \x04pool\x03ntp\x03org\x00).

mDNS (RFC 6762)

```
#define MDNS_PORT    5353U
#define MDNS_TTL     120U

u16 ca_net_proto_mdns_build_announce(ca_mac_t local_mac, ca_ipv4_t local_ip,
                                     const char *hostname,
                                     u8 *out_frame, u16 out_max);

bool ca_net_proto_mdns_parse_query(const ca_udp_frame_t *udp,
                                   const char *our_hostname,
                                   bool *is_for_us);
```

Typical flow:

```
Boot:
  ca_net_proto_mdns_build_announce(...) -> ca_net_send()

RX su porta UDP 5353 (multicast 01:00:5E:00:00:FB):
  ca_net_proto_mdns_parse_query(&udp, "caos-board", &is_for_us)
  is_for_us == true?
    -> ca_net_proto_mdns_build_announce(...) -> ca_net_send()
```

17.1.11 14.17 Route lookup — ca_net_resolve_mac

All services use ca_net_resolve_mac (with routing) instead of ca_arp_resolve (without):

```
bool ca_net_resolve_mac(ca_ipv4_t dst, ca_mac_t *mac_out, u32 timeout_ms);
/* equivale a: ca_arp_resolve(ca_route_lookup(dst), mac_out, timeout_ms) */
```

ca_route_lookup(dst) executes in order: 1. On-link: if (dst & local_mask) == (local_ip & local_mask) -> returns dst 2. Longest prefix match: scans route table, selects longest match 3. Default gateway: if configured -> returns default_gw 4. Fallback: returns dst (ARP will likely fail)

When EN_ROUTE_SERVICE=0, ca_net_resolve_mac is a direct alias of ca_arp_resolve (fallback without overhead).

Chapter 18

caOS Network Stack: Network Services

This chapter describes network services with dedicated tasks and state machines: ARP, Route, DHCP, NTP, DNS, mDNS, Syslog, TCP, UDP, IP defrag, TFTP, Packet Tracer, HTTP, MQTT, Modbus/TCP, iperf.

18.1 ARP Service (`EN_ARP_SERVICE`)

The ARP service manages a local **IP-MAC mapping cache** and provides **blocking** resolution with fast-path: if the MAC is already in cache, the function returns immediately.

The ARP task runs at **CA_TH_LEVEL0** (maximum priority).

18.1.1 Architecture

```
Caller (qualsiasi task)
  ca_arp_resolve(ip, mac_out, timeout_ms)
    +-- ca_arp_avail(ip) == true  -> MAC immediato  (fast path)
    +-- cache miss                -> post s_request_sem
                                     wait s_done_sem (con timeout)

ARP task (CA_TH_LEVEL0)
  wait s_request_sem
  loop retry:
    build ARP REQUEST -> broadcast FF:FF:FF:FF:FF:FF
    wait s_reply_sem (ARP_RETRY_MS)
  post s_done_sem

net task
  every ARP frame received -> ca_arp_set(spa, sha)
  se ip == pending -> post s_reply_sem
```

18.1.2 API

Function	Description
`ca_arp_service_init(local_mac, local_ip)`	Init cache; call in `ca_os_configure()`
`ca_arp_service_start()`	Create ARP task (CA_TH_LEVEL0); call in `ca_os_main()`

Function	Description
`ca_arp_service_update_local_ip(local_ip)`	Update local IP after DHCP bind (without reinit)
`ca_arp_resolve(ip, mac_out, timeout_ms)`	Blocking resolution; fast-path on cache hit
`ca_arp_avail(ip)`	Non-blocking cache lookup (only valid non-expired entries)
`ca_arp_find(ip, mac_out)`	Cache lookup without TTL check
`ca_arp_set(ip, mac)`	Insert/update entry; called by net task and DHCP
`ca_arp_send_garp()`	Send Gratuitous ARP (GARP) with configured local MAC/IP
`ca_arp_dump()`	Print cache to stdout
`ca_arp_flush()`	Invalidate all entries

18.1.3 Parameters `os_config.h`

Parameter	Default	Meaning
`ARP_CACHE_SIZE`	8	Maximum entries in cache
`ARP_RETRY_N`	3	Attempts before failure
`ARP_RETRY_MS`	500	Timeout for single response
`ARP_ENTRY_TTL_MS`	60000	Entry expiration (1 min)

`timeout_ms` in `ca_arp_resolve` must be `>= ARP_RETRY_N x ARP_RETRY_MS` (default: 1500 ms).

18.1.4 Typical pattern

```c
/* ca_os_configure() */
ca_arp_service_init(local_mac, local_ip);

/* ca_os_main() */
ca_arp_service_start();

/* after DHCP bound */
ca_arp_service_update_local_ip(new_ip);
ca_arp_send_garp();    /* announce the new IP on the LAN */

/* MAC resolution before sending UDP */
ca_mac_t server_mac;
if (!ca_arp_resolve(server_ip, &server_mac, 1500U)) {
    /* server not reachable */
}
```

> **DO NOT call `ca_arp_service_init()` from `on_dhcp_bound`:** reinitialize internal semaphores while the ARP task is running -> SAFEGUARD overflow. Always use `ca_arp_service_update_local_ip()`.

18.2 Route Service (`EN_ROUTE_SERVICE`)

`route_service` maintains a static route table with **longest prefix match** and a default gateway. It resolves routing towards different subnets.

18.2.1 Configuration

```
/* os_config.h */
#define EN_ROUTE_SERVICE  1
#ifndef NET_ROUTE_MAX
#define NET_ROUTE_MAX  8U   /* max entries in the table */
#endif
```

18.2.2 Public API

```
/* Initialization -- called automatically by ca_net_proto_init() */
void ca_route_init(ca_ipv4_t local_ip, ca_ipv4_t local_mask);

/* Updates the local IP/mask at runtime (e.g. after DHCP bind) */
void ca_route_update_local(ca_ipv4_t local_ip, ca_ipv4_t local_mask);

/* Sets/replaces the default gateway */
bool ca_route_set_gw(ca_ipv4_t gw);

/* Adds a route: dst/prefix_len via gw */
bool ca_route_add(ca_ipv4_t dst, u8 prefix_len, ca_ipv4_t gw);

/* Removes a route by index */
bool ca_route_del(u8 idx);

/* Empties the table (the default gateway stays) */
void ca_route_flush(void);
```

18.2.3 Integration with DHCP

The DHCP service automatically updates the route service after binding: the DHCP default gateway becomes operational without manual actions.

18.2.4 Static configuration (without DHCP)

```
void ca_os_main(void) {
    /* ca_route_init() already called by ca_net_proto_init() with ip+mask */
    ca_ipv4_t gw = { .v = { 192U, 168U, 10U, 1U } };
    ca_route_set_gw(gw);
    /* optional additional routes: */
    ca_ipv4_t dst = { .v = { 10U, 0U, 0U, 0U } };
    ca_ipv4_t via = { .v = { 192U, 168U, 10U, 254U } };
    ca_route_add(dst, 8U, via);   /* 10.0.0.0/8 via 192.168.10.254 */
    ca_os_run(true);
}
```

18.2.5 CLI

```
route info                          -- mostra local, default gw e tabella rotte
route gw <ip>                       -- sets/replaces the default gateway
route add <ip/prefix> gw <ip>       -- adds a route
route del <n>                       -- removes the route at index n
route flush                         -- svuota la tabella (default gw invariato)
```

18.3 DHCP Service (`EN_DHCP_SERVICE`)

`ca_dhcp_service` manages the entire life cycle of the DHCP lease: acquisition (DORA), unicast renewal (RENEWING), broadcast rebinding (REBINDING) and reacquisition at expiration.

Enable: `EN_DHCP_SERVICE 1` (requires `EN_NET=1` and `EN_NET_DHCP=1`).

18.3.1 Configurable parameters

Macro	Default	Meaning
`DHCP_DISCOVER_RETRY_N`	3	DISCOVER attempts before backoff
`DHCP_OFFER_TIMEOUT_MS`	4000	WAIT for OFFER per attempt (ms)
`DHCP_REQUEST_TIMEOUT_MS`	4000	WAIT for ACK after REQUEST (ms)
`DHCP_BIND_TIMEOUT_MS`	60000	Maximum `ca_dhcp_service_bind()` timeout

18.3.2 State machine

```
INIT -> DISCOVERING
  send DISCOVER (broadcast, xid)
  timedwait OFFER_TIMEOUT (retry -> backoff -> xid++)
REQUESTING
  send REQUEST (broadcast, ciaddr=0, opt50+opt54)
  timedwait REQUEST_TIMEOUT (NAK/timeout -> DISCOVERING)
BOUND
  apply_lease(): calcola T1, T2, lease_deadline
  fire on_bound(ip, mask, gw, dns)
  timedwait ms_until(T1) (interrompibile da force-renew)
RENEWING (unicast al server, finche' T2 non scade)
  REQUEST unicast: ciaddr=ip
  ACK -> apply_lease() -> BOUND | timeout -> REBINDING
REBINDING (broadcast, finche' lease non scade)
  REQUEST broadcast: ciaddr=ip
  ACK -> BOUND | lease scaduta -> on_expire() -> DISCOVERING
```

18.3.3 Public API

```
/* Inizializza strutture e semafori. Chiamare in ca_os_configure(). */
void ca_dhcp_service_init(ca_mac_t             local_mac,
                          ca_dhcp_bound_cb_t   on_bound,
                          ca_dhcp_expire_cb_t  on_expire);

/* Creates the DHCP task (LEVEL1). Call in ca_os_main(). */
void ca_dhcp_service_start(void);

/* Unblocks the DHCP task -- port 68 ready.
 * Call from task_net AFTER ca_net_proto_bind_udp(68, ...). */
void ca_dhcp_service_net_ready(void);

/* RX handler: call from task_net for every UDP frame on port 68. */
void ca_dhcp_service_rx_handler(const ca_udp_frame_t *udp, u16 len);

/* Blocks until BOUND or timeout. Do NOT call from task_net (deadlock). */
bool ca_dhcp_service_bind(void);

/* Checks the BOUND state without blocking. */
static inline bool ca_dhcp_service_bound(void);

/* Forces an early renew. */
```

```
void ca_dhcp_service_renew(void);

/* Parameters of the current lease (valid only if bound()==true). */
ca_ipv4_t ca_dhcp_service_get_ip(void);
ca_ipv4_t ca_dhcp_service_get_mask(void);
ca_ipv4_t ca_dhcp_service_get_gw(void);
ca_ipv4_t ca_dhcp_service_get_dns(void);
```

18.3.4 Callbacks

```
typedef void (*ca_dhcp_bound_cb_t)(ca_ipv4_t ip, ca_ipv4_t mask,
                                   ca_ipv4_t gw,  ca_ipv4_t dns);
typedef void (*ca_dhcp_expire_cb_t)(void);
```

18.3.5 Adapter dhcp_udp_handler

```
static void dhcp_udp_handler(u16 buf_idx)
{
    ca_net_buf_t *b  = ca_net_buf_ptr(buf_idx);
    u8 *frame        = b->data + b->data_off;
    u16 l4_off       = b->meta.rx.l4_off;
    const ca_udp_frame_t *udp = (const ca_udp_frame_t *)(frame + l4_off);
    ca_dhcp_service_rx_handler(udp, (u16)(b->data_len - l4_off));
    ca_net_buf_free(buf_idx);
}
```

18.3.6 Critical Warnings

Deadlock: do not call `ca_dhcp_service_bind()` from task_net: the net task is blocked and OFFER/ACK frames are never processed.

`on_dhcp_bound` **must explicitly update:** - `ca_net_proto_set_local_ip(ip)` – for ICMP/ARP reply with correct IP - `ca_udp_server_set_local_ip(ip)` – for UDP replies with valid `src_ip` - `ca_arp_service_update_local_ip(ip)` – updates local_ip in the ARP service

18.4 NTP Service (EN_NTP_SERVICE)

NTP client (RFC 5905) with automatic polling and multi-server fallback.

18.4.1 API

Function	Description
`ca_ntp_service_init(server_ip, local_mac, on_sync, on_fail)`	Init; in `ca_os_configure()`
`ca_ntp_service_start()`	Create NTP task (CA_TH_LEVEL3)
`ca_ntp_service_bind()`	Register port 123 in UDP dispatcher
`ca_ntp_service_net_ready()`	Signal stack ready (post-DHCP)
`ca_ntp_service_rx_handler(udp, len)`	RX handler for port 123
`ca_ntp_service_synced()`	`true` if at least one sync has occurred
`ca_ntp_service_get_unix_time()`	Unix timestamp of last sync
`ca_ntp_service_set_server(server_ip)`	Update primary server
`ca_ntp_service_sync_now()`	Force immediate sync cycle

18.4.2 Parameters `os_config.h`

Parameter	Default	Meaning
`NTP_SERVER_N`	3	Configurable servers (multi-server fallback)
`NTP_RETRY_N`	3	Attempts per server before `on_fail`
`NTP_RESPONSE_TIMEOUT_MS`	5000	Timeout for single response
`NTP_POLL_MS`	64000	Normal polling interval (~1 min)

18.4.3 Typical pattern

```
/* ca_os_configure() */
ca_ntp_service_init(gw_ip, local_mac, on_ntp_sync, NULL);
/* ca_os_main() */
ca_ntp_service_start();
/* task_net, after a valid IP */
ca_ntp_service_bind();
ca_ntp_service_net_ready();
/* callback */
static void on_ntp_sync(u32 unix_time) {
    ca_rtc_from_net(unix_time);
}
```

`ca_rtc_from_net()` converts the unix time (UTC, since 1970) to the RTC format and writes it to the hardware RTC; the opposite is `ca_rtc_to_net()`, which reads the RTC and returns the unix time. Valid range 2000-2099, that of the RTC.

18.5 Syslog Service (`EN_SYSLOG_SERVICE`)

Syslog client (RFC 3164) with message queue. `ca_syslog_send` is non-blocking and safe from any task.

18.5.1 API

Function	Description
`ca_syslog_service_init(server_ip, local_mac, facility)`	Init; in `ca_os_configure()`
`ca_syslog_service_start()`	Create syslog task (CA_TH_LEVEL4)
`ca_syslog_service_net_ready()`	Signal stack ready
`ca_syslog_service_set_server(server_ip)`	Update server IP at runtime
`ca_syslog_send(severity, msg)`	Queue message – fire-and-forget
`ca_syslog_dropped()`	Messages discarded due to full queue

18.5.2 Parameters `os_config.h`

Parameter	Default	Meaning
`SYSLOG_QUEUE_SIZE`	8	Message queue depth
`SYSLOG_MSG_MAX`	128	Maximum message length (bytes)

18.5.3 Typical pattern

```
ca_syslog_service_init(server_ip, local_mac, SYSLOG_FAC_LOCAL0);
ca_syslog_service_start();
/* task_net, after a valid IP */
ca_syslog_service_net_ready();
/* qualsiasi task */
ca_syslog_send(SYSLOG_SEV_INFO,  "system started");
ca_syslog_send(SYSLOG_SEV_ERR,   "sensor timeout");
```

18.6 DNS Service (EN_DNS_SERVICE)

Blocking DNS client (RFC 1035) with concurrent slots.

18.6.1 API

Function	Description
`ca_dns_service_init(server_ip, local_mac)`	Init; in `ca_os_configure()`
`ca_dns_service_start()`	Create DNS task (CA_TH_LEVEL3)
`ca_dns_service_bind()`	Register port 53 in UDP dispatcher
`ca_dns_service_net_ready()`	Signal stack ready
`ca_dns_service_set_server(server_ip)`	Update DNS server
`ca_dns_resolve(hostname, &out, timeout_ms)`	Blocking resolution

18.6.2 os_config.h Parameters

Parameter	Default	Meaning
`DNS_PENDING_MAX`	4	Concurrent resolution slots
`DNS_RESPONSE_TIMEOUT_MS`	3000	Timeout for single response
`DNS_RETRY_N`	2	Attempts before failure

18.6.3 Typical Pattern

```
ca_ipv4_t ip;
if (ca_dns_resolve("pool.ntp.org", &ip, 10000U)) {
    ca_ntp_service_set_server(ip);
}
```

18.7 mDNS Service (EN_MDNS_SERVICE)

mDNS responder (RFC 6762) without a DNS server. The device responds to multicast queries on `224.0.0.251:5353` for `hostname.local`.

18.7.1 API

Function	Description
`ca_mdns_service_init(local_mac, hostname)`	Init; in `ca_os_configure()`
`ca_mdns_service_start()`	Create mDNS responder task (CA_TH_LEVEL3)

Function	Description
`ca_mdns_service_bind()`	Register port 5353 in the UDP dispatcher
`ca_mdns_service_net_ready(local_ip)`	Signal stack ready + send announce
`ca_mdns_service_rx_handler(udp, len)`	RX handler for port 5353

18.7.2 Embedded network scenario without router

```
[PC 192.168.10.1] -- gateway + DNS esterno
      |
   [Switch]
      +-- caos-board1  192.168.10.10
      +-- caos-board2  192.168.10.11

Risoluzione locale:
  caos-board1 -> "caos-board2.local" -> mDNS query multicast
  caos-board2 -> answers with its own IP
```

At the startup of each device: 1. Gratuitous ARP -> everyone learns MAC/IP 2. mDNS announce -> everyone learns hostname.local

18.8 TCP Service (`EN_TCP_SERVICE`)

`ca_tcp_service` implements a bare-metal TCP stack with a pool of concurrent connections, retransmission timers, and a complete state machine. It supports both **active open** (client) and **passive open** (server).

18.8.1 Configuration

```
#define EN_TCP_SERVICE   1
#define TCP_MAX_CONN          8U     /* connessioni dati concorrenti */
#define TCP_MAX_INFLIGHT      16U    /* segmenti TX in-volo per connessione */
#define TCP_RX_RING_DEPTH     8U     /* buffer RX per connessione */
#define TCP_MAX_LISTEN        2U     /* slot listen concorrenti */
#define TCP_RTO_INITIAL_MS    1000U
#define TCP_RTO_MAX_MS        16000U
#define TCP_CONNECT_TIMEOUT_MS  5000U
```

`TCP_RX_RING_DEPTH` is the **ceiling** for connection, not a reserve: the actual space is decided at runtime by `rx_quota()`, which divides the pool among active connections keeping 4 reserve buffers (the sum cannot exceed the pool by design — ex85). Default 8 since 10/05, measured on ex44/H563 Release in reception: 4 → 59.7 Mbps, **8 → 93.9**, 16 → 94.7. The ring contains indices, not buffers: increasing it costs 2 bytes per slot.

18.8.2 State machine

```
CLOSED -> (ca_tcp_connect) -> SYN_SENT
  SYN+ACK ricevuto -> ACK inviato -> ESTABLISHED
  ca_tcp_close() -> FIN_WAIT_1 -> FIN_WAIT_2 -> TIME_WAIT(4s) -> CLOSED

Passive open:
  ca_tcp_listen() -> attende SYN -> SYN_RECEIVED -> ESTABLISHED
  peer chiude (on_rx, callback):   ESTABLISHED -> LAST_ACK -> CLOSED
  peer chiude (ca_tcp_recv):       ESTABLISHED -> CLOSE_WAIT
      ca_tcp_recv() drena i segmenti arrivati prima del FIN, poi false (fine
    flusso)
      ca_tcp_close() del proprietario -> LAST_ACK -> CLOSED
      TCP_CLOSE_WAIT_MS (10 s) senza close -> il FIN lo manda lo stack
```

Half-close (from 10/02/2026). A reader connection no longer loses bytes that arrived with or before the peer's FIN: it remains in CLOSE_WAIT until the owner has read them and calls `ca_tcp_close()`. In CLOSE_WAIT, `ca_tcp_send()` is still allowed (RFC 793) and `ca_tcp_accept()` also returns a connection that is already half-closed, because its data is still to be read. Previously, the board would respond with FIN+ACK immediately and, upon the final ACK, would discard the queue ("DISCARDING n queued rx segment(s)").

18.8.3 Public API — client

```
/* Avvia il timer task TCP (CA_TH_LEVEL3, 100ms tick). */
void ca_tcp_service_start(void);

/* Active open. Ritorna handle 1-based oppure 0 su errore. */
u8 ca_tcp_connect(const ca_tcp_connect_cfg_t *cfg);

/* Invia dati su ESTABLISHED. Segmenta in chunk MSS. */
bool ca_tcp_send(u8 handle, const u8 *data, u16 len);

/* Ricezione bloccante (solo se on_rx==NULL).
 * Consegna UN segmento per chiamata: i byte oltre buf_len vengono SCARTATI. */
bool ca_tcp_recv(u8 handle, u8 *buf, u16 buf_len,
                 u16 *out_len, u32 timeout_ms);

/* Graceful close (FIN). */
void ca_tcp_close(u8 handle);

bool ca_tcp_is_connected(u8 handle);
```

18.8.4 Configuration structure — client

```
typedef struct {
    ca_ipv4_t         remote_ip;
    u16               remote_port;
    ca_ipv4_t         local_ip;
    ca_mac_t          local_mac;
    u32               arp_timeout_ms;      /* 0 -> TCP_ARP_TIMEOUT_MS */
    u32               connect_timeout_ms;  /* 0 -> TCP_CONNECT_TIMEOUT_MS */
    ca_tcp_rx_t       on_rx;               /* NULL = blocking ca_tcp_recv() */
    ca_tcp_conn_t     on_connected;        /* NULL = ca_tcp_connect() bloccante */
    ca_tcp_close_t    on_closed;
} ca_tcp_connect_cfg_t;
```

18.8.5 Public API — server

```
u8   ca_tcp_listen(const ca_tcp_listen_cfg_t *cfg);
void ca_tcp_unlisten(u8 listen_handle);
u8   ca_tcp_accept(u8 listen_handle, u32 timeout_ms);
```

18.8.6 Configuration structure — server

```
typedef struct {
    u16               local_port;
    ca_ipv4_t         local_ip;    /* l'IP della board: obbligatorio, vedi
    Avvertenze */
    ca_mac_t          local_mac;
    ca_tcp_conn_t     on_accept;   /* NULL = blocking ca_tcp_accept() */
    ca_tcp_rx_t       on_rx;       /* NULL = blocking ca_tcp_recv() */
    ca_tcp_close_t    on_closed;
```

```
} ca_tcp_listen_cfg_t;
```

18.8.7 CLI

```
tcp list          -- handle, stato, porte, IP remoto
tcp info <h>      -- dettaglio PCB: seq, ack, window, MSS, inflight, rx_ring
tcp slist         -- slot listen attivi
tcp buf           -- pool liberi/held/leak (diagnosi perdite buffer)
```

18.8.8 Warnings

Buffer pool: 4 conn x 4 inflight = 16 store buffers in the worst-case. Pool 64 buffers; leave at least 20 buffers free for RX and other services.

`ca_tcp_recv()` **from task_net**: deadlock. Use only from separate application tasks or the callback mode (`on_rx`).

`ca_tcp_recv()` **delivers one segment at a time and truncates**: if the segment is longer than `buf_len`, the rest is lost. Anyone reading in small pieces (for example, the 5-byte header of a TLS record) must read an entire segment into a `TCP_MSS_DEFAULT`-byte support buffer and consume it from there, as `https_service` does.

`local_ip` **of the listener**: must be set with the board's IP (`ca_net_proto_get_local_ip()` or the one provided by DHCP). With 0.0.0.0, the SYN is accepted but the SYN-ACK is not sent, and connections remain in `SYN_RECEIVED` (found on 10/23/2026 with `https_service`). For this reason, services open the listener after the DHCP bind.

RST on a server connection (fixed on 10/23/2026): the branch handling an RST was incrementing `conn_sem` without a ceiling, but that semaphore is only consumed by a blocking `ca_tcp_connect()`. On an accepted connection, no one was consuming it: on the second RST on the same reused slot, it would overflow, triggering a safeguard in the `net` task while holding the TCP mutex, and from there, every task restart would hang on the same mutex. Now the post has a ceiling. TLS clients often close with an RST: with HTTPS, it happened on the third request.

18.9 UDP Server (`EN_UDP_SERVER`)

The UDP Server service manages multi-client UDP connections, assigning each `src_ip:src_port` combination to a dedicated slot with worker task.

18.9.1 API

Function	Description
`ca_udp_server_start(&cfg)`	Init structures, spawn workers; in `ca_os_main()`
`ca_udp_server_bind()`	Register UDP port in dispatcher; from net task
`ca_udp_server_send(client_id, payload, len)`	Send reply to client
`ca_udp_server_disconnect(client_id)`	Force disconnection
`ca_udp_server_set_local_ip(ip)`	Update local IP (after DHCP bound)

18.9.2 Configuration Structure

```
typedef struct {
    u16                 port;
    u8                  max_clients;        /* <= UDPSRV_MAX_CLIENTS */
    u32                 client_timeout_ms;
```

```
    ca_mac_t              local_mac;
    ca_ipv4_t             local_ip;
    ca_udp_srv_rx_t    on_rx;             /* obbligatorio */
    ca_udp_srv_event_t on_connect;        /* NULL ok */
    ca_udp_srv_event_t on_disconnect;     /* NULL ok */
} ca_udp_server_cfg_t;
```

Parameter `os_config.h`: `UDPSRV_MAX_CLIENTS` (default 4).

18.10 UDP Client (EN_UDP_CLIENT)

Two modes: **async** (`on_rx != NULL`, called in the net task) and **blocking** (`on_rx == NULL`, `ca_udp_client_recv()` unblocks the task).

18.10.1 API

Function	Description
`ca_udp_client_connect(&cfg)`	Resolves server MAC, binds port; returns handle or 0
`ca_udp_client_send(handle, payload, len)`	Sends UDP datagram
`ca_udp_client_recv(handle, buf, len, &out_len, timeout)`	Blocking RX
`ca_udp_client_disconnect(handle)`	Closes connection
`ca_udp_client_refresh_mac(handle, arp_timeout_ms)`	Renews MAC via ARP

Parameter `os_config.h`: `UDPCLI_MAX_HANDLES` (default 4).

18.11 IP Defrag Service (EN_IP_DEFRAG)

Transparent IP fragment reassembly (RFC 791) for the upper stack.

18.11.1 Configuration parameters

Define	Default	Description
`IP_DEFRAG_MAX_SESSIONS`	4	Parallel reassembly sessions
`IP_DEFRAG_TIMEOUT_MS`	15000	ms before an incomplete session is discarded
`IP_DEFRAG_MAX_PAYLOAD`	1480	Maximum reassemblable payload (bytes, excluding IP header)

Heap allocated at init: `IP_DEFRAG_MAX_SESSIONS x IP_DEFRAG_MAX_PAYLOAD` bytes (default 4 x 1480 = 5920 B).

18.11.2 Operational flow

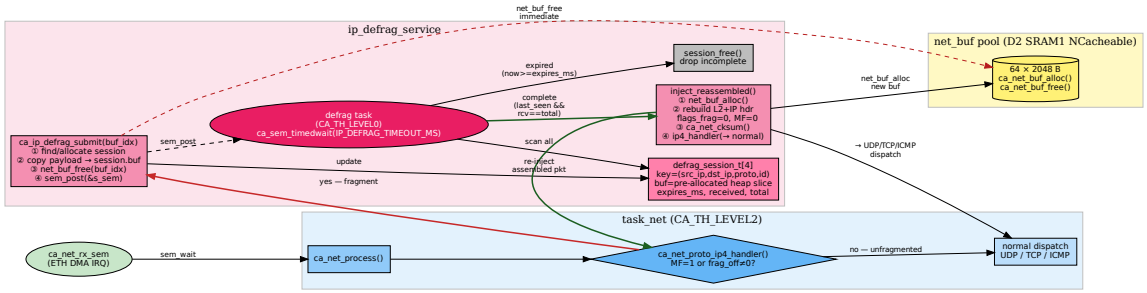

Figure 18.1: IP Defrag flow

18.11.3 Initialization

```
/* ca_os_configure() */
EVAL_IP_DEFRAG(
    if (!ca_ip_defrag_init(IP_DEFRAG_MAX_PAYLOAD))
        CA_SAFE_FAIL("ca_ip_defrag_init");
)
/* ca_os_main() */
EVAL_IP_DEFRAG(ca_ip_defrag_service_start();)
```

18.11.4 Public API

Function	Called by	Description
`ca_ip_defrag_init(max_payload)`	`ca_os_configure()`	allocates heap + initializes sessions
`ca_ip_defrag_service_start()`	`ca_os_main()`	creates task `defrag`
`ca_ip_defrag_submit(buf_idx)`	`ca_net_proto_ip4_handler()`	receives a fragment (internal use)

Usage example: Example 48.

18.12 TFTP Service (`EN_TFTP_SERVICE`)

TFTP (RFC 1350) over UDP. As a client it supports GET (download from server) and PUT (upload to server); as a server it receives **one file pushed by a client** (WRQ), one per call. Main use case: firmware update (the `workspace/app_2` bootloader receives its images this way). One transfer at a time.

18.12.1 Configuration parameters

Define	Default	Description
`EN_TFTP_SERVICE`	`1`	Enables the TFTP service

Define	Default	Description
TFTP_BLOCK_TIMEOUT_MS	5000	Timeout per block (ms)
TFTP_RETRY_N	3	Retries per block before failure
EN_CLI_TFTP	1	Enables tftp CLI commands

18.12.2 Public API

Function	Description
ca_tftp_service_init(mac)	Initializes service and registers CLI
ca_tftp_get(cfg, on_block, arg)	Downloads file from server (blocking)
ca_tftp_put(cfg, data, len)	Uploads buffer to server (blocking)
ca_tftp_receive(cfg, on_wrq, on_block, arg, wait_ms)	Waits for a WRQ and receives that file (blocking, server side)

18.12.3 on_block Callbacks

```
typedef bool (*ca_tftp_rx_block_t)(u16 block_num,
                                   const u8 *data, u16 len,
                                   void *arg);
```

Returning false aborts the transfer.

18.12.4 Server side: ca_tftp_receive

```
typedef u16 (*ca_tftp_wrq_t)(const char *filename, ca_ipv4_t client, void *arg);

ca_tftp_srv_cfg_t cfg = { .local_mac = mac };      /* port 0 = 69 */
bool ok = ca_tftp_receive(&cfg, on_wrq, on_block, &ctx, CA_WAIT_FOREVER);
```

- The port is listened to **only while a task waits** in ca_tftp_receive(); a WRQ arriving outside that window, or during a transfer, gets no answer and the client times out. One waiting task at a time. RRQ is not served.
- The listener runs in the net task and does not block: it records the WRQ (name, IP, port, MAC from the frame, so no ARP) and wakes the waiting task, which runs the transfer.
- on_wrq decides before block 0 is acknowledged: it returns 0 to accept or a TFTP_ERR_* code to refuse (the client gets an ERROR). It may take its time, for instance to erase the destination flash.
- Blocks reach on_block as with ca_tftp_get(): the same receive loop serves both.

From the PC the file is pushed with the tools/caos_tftp package (standard library, no sudo: port 69 is the board's):

```
python3 tools/caos_tftp put <board-ip> <file> [--name NAME]
```

18.12.5 CLI

```
tftp get <ip> <filename>    -- downloads a file from the TFTP server
tftp put <ip> <filename>    -- uploads a file to the TFTP server
tftp recv [sec]             -- receives ONE file pushed by a client (default 30
   s), data discarded
tftp info                   -- shows the service state
```

Usage example: Example 49.

18.13 Packet Tracer Service (`EN_PACKET_TRACER`)

Lightweight bare-metal tcpdump. Captures metadata of every RX/TX frame without copying the payload. A dedicated task formats and sends on configurable output channel (UART, USB CDC, ITM).

18.13.1 Architecture

```
net_proto.c:
  ARP/IP/UDP/TCP handler -> ca_pktrace_push_rx()    ring[8]
net.c:
  ca_net_send           -> ca_pktrace_push_tx() ---> pktrace_task
                                                       filter_pass()
                                                       s_out(msg)
```

Every entry in the ring is a 20-byte snapshot of `ca_net_buf_rx_t`: **zero-copy of the payload**.

18.13.2 Configuration

```
#define EN_PACKET_TRACER        1
#define PACKET_TRACER_RING_SIZE 8U
#define EN_CLI_TRACE            1
```

18.13.3 API

```
void ca_pktrace_start(void);
void ca_pktrace_set_sender(sender fn);
void ca_pktrace_enable(bool en);
void ca_pktrace_filter_src(ca_ipv4_t ip);
void ca_pktrace_filter_dst(ca_ipv4_t ip);
```

18.13.4 CLI

Command	Description
`trace on`	Enable frame capture
`trace off`	Disable capture
`trace filter src <ip>`	Only frames with src IP = `<ip>`
`trace filter dst <ip>`	Only frames with dst IP = `<ip>`
`trace filter clear`	Remove all filters

18.13.5 Output format

```
[RX] ARP  192.168.10.1 -> 192.168.10.158 len=60
[TX] ARP  192.168.10.158 -> 192.168.10.1 len=42
[RX] ICMP 192.168.10.1 -> 192.168.10.158 len=98
[RX] UDP  192.168.10.1:67 -> 255.255.255.255:68 len=342
[RX] TCP  192.168.10.1:48282 -> 192.168.10.158:80 len=74
```

The tracer uses its own `sender` – **not** `ca_stdout_printf_n` – to avoid conflicts with CLI capture and audit_log.

Resource	Value
RAM ring	8 x 20 B = 160 B

Resource	Value
Overhead per frame (push)	~12 instructions
Overhead when disabled	1 test on `s_enabled` -> zero

18.14 HTTP Service

`ca_http_service` implements a sequential bare-metal HTTP/1.1 server on `ca_tcp_service`. It supports GET, POST, HEAD, OPTIONS with a static route table defined by the application.

The same routes can also be served via **HTTPS** on port 443: the parser, the route table, and the response builder are the same; only the transport changes (TLS 1.3 instead of the TCP socket). See HTTPS and TLS 1.3.

File: `caos/net/src/http_service.c` / `caos/net/inc/http_service.h`

Dependencies: `EN_ETH 1`, `EN_NET 1`, `EN_ARP_SERVICE 1`, `EN_TCP_SERVICE 1`.

18.14.1 Configuration `os_config.h`

```
#define EN_HTTP_SERVICE     1    /* richiede EN_NET=1 + EN_TCP_SERVICE=1 */

/* Dimensioni buffer -- critiche per browser reali */
#ifndef HTTP_REQ_BUF_SIZE
#define HTTP_REQ_BUF_SIZE   2048U   /* default 512 insufficiente per Chrome */
#endif
#ifndef HTTP_RESP_BUF_SIZE
#define HTTP_RESP_BUF_SIZE  4096U   /* default 1024 -- aumentare per CLI verbose
    */
#endif
#ifndef HTTP_URI_MAX
#define HTTP_URI_MAX        128U
#endif
#ifndef HTTP_QUERY_MAX
#define HTTP_QUERY_MAX      128U
#endif
#ifndef HTTP_DEFAULT_PORT
#define HTTP_DEFAULT_PORT   80U
#endif
#ifndef HTTP_RECV_TIMEOUT_MS
#define HTTP_RECV_TIMEOUT_MS  1500U
#endif
```

> **Note**: the default values (512/1024) are sufficient only for `curl` with minimal headers. Modern browsers (Chrome, Firefox) send ~610 bytes of headers in POST requests. With `HTTP_REQ_BUF_SIZE=512` the body falls into the headers -> 400 Bad Request. **Always** set >= 2048 in `os_config.h`.

18.14.2 Architecture

```
ca_http_service_start(routes, count, port)
        |
        +-- task "http" (CA_TH_LEVEL6)
                |
                +-- ca_tcp_listen(port)
                +-- loop: accept -> ca_http_serve_connection(io TCP) -> close
```

The task handles one connection at a time (sequential). The connection is closed after sending the response.

Abstract transport (23/10/2026)

`ca_http_serve_connection()` reads the request, passes it to the route table, and writes the response through a **transport** (`ca_http_io_t`), without knowing what lies underneath. Task `http` passes it the TCP socket; task `https` a TLS session. Each service has its own buffers (`ca_http_conn_t`), so the two tasks never share them.

```
typedef struct {
    bool  (*send)(void *io, const u8 *data, u16 len);           /* true = tutto scritto */
    i32   (*recv)(void *io, u8 *buf, u16 len, u32 timeout_ms);  /* >0 byte, 0 timeout, <0 chiuso */
    void   *io;
} ca_http_io_t;

typedef struct {
    u8                rx[HTTP_REQ_BUF_SIZE];
    u8                tx[HTTP_RESP_BUF_SIZE];
    ca_http_response_t resp;
} ca_http_conn_t;

void ca_http_serve_connection(ca_http_conn_t *c, const ca_http_io_t *io);
```

The transport is not closed by `ca_http_serve_connection()`: closing it (TCP FIN, `close_notify` TLS) is up to the caller. `ca_http_conn_t` and the `io` descriptor must be in **static** memory, never on the task stack: in chunked mode, a handler can pass the response to another task (the `/cli` route in example 80).

18.14.3 Data structures

HTTP Methods (bitmask)

Macro	Value
`HTTP_METHOD_GET`	`0x01`
`HTTP_METHOD_POST`	`0x02`
`HTTP_METHOD_HEAD`	`0x04`
`HTTP_METHOD_OPTIONS`	`0x08`

`ca_http_request_t`

Field	Type	Description
`method`	`u8`	received method bitmask
`uri`	`char[]`	path, e.g., “/status”
`query`	`char[]`	query string after `?`, e.g., “state=on”
`body`	`const u8 *`	POST body (pointer in the rx buffer)
`body_len`	`u16`	body length

ca_http_response_t

```
typedef struct {
    u8  *buf;           /* buffer output (fornito dal service) */
    u16  size;          /* dimensione buffer */
    u16  len;           /* byte scritti finora */
    u16  cl_pos;        /* offset placeholder Content-Length */
    u16  hdr_end;       /* offset inizio body (dopo \r\n\r\n) */
    bool head_only;     /* true se metodo HEAD */
    bool chunked;       /* risposta a chunk (ca_http_resp_begin_chunked) */
    const ca_http_io_t *io;  /* trasporto su cui vanno i chunk */
    bool failed;        /* un invio    fallito: la risposta    abbandonata */
} ca_http_response_t;
```

Route table

```
typedef void (*ca_http_handler_fn)(const ca_http_request_t *req,
                                   ca_http_response_t      *resp);

typedef struct {
    const char        *uri;      /* es. "/status" -- confronto esatto */
    u8                 methods;  /* bitmask HTTP_METHOD_* accettati */
    ca_http_handler_fn handler;
} ca_http_route_t;
```

18.14.4 Public API

```
/* Avvia il task HTTP e registra CLI.
 * routes/count: tabella route -- il puntatore deve restare valido.
 * port: 0 -> usa HTTP_DEFAULT_PORT (80). */
void ca_http_service_start(const ca_http_route_t *routes, u8 count, u16 port);

/* Aggiorna local IP dopo DHCP bind. */
void ca_http_update_local_ip(ca_ipv4_t ip);

/* Costruisce header HTTP + Content-Type. Chiamare prima del body. */
void ca_http_resp_begin(ca_http_response_t *r, u16 status,
                        const char *content_type);

/* Aggiunge dati al body (no-op se head_only). */
void ca_http_resp_write(ca_http_response_t *r, const char *s, u16 len);
void ca_http_resp_puts(ca_http_response_t *r, const char *s);
void ca_http_resp_puti(ca_http_response_t *r, u32 v);

/* Risposte di errore pre-costruite. */
void ca_http_resp_not_found(ca_http_response_t *r);    /* 404 */
void ca_http_resp_bad_request(ca_http_response_t *r);  /* 400 */
```

18.14.5 DHCP Integration

```
static void on_dhcp_bound(ca_ipv4_t ip, ca_ipv4_t mask, ca_ipv4_t gw, ca_ipv4_t
    dns)
{
    (void)mask; (void)gw; (void)dns;
    ca_net_proto_set_local_ip(ip);
```

```
    ca_arp_service_update_local_ip(ip);
    ca_arp_send_garp();
    ca_http_update_local_ip(ip);   /* notifica l'IP al servizio HTTP */
}
```

18.14.6 Usage patterns

```
/* Route table (flash) */
static const ca_http_route_t routes[] = {
    { "/",       HTTP_METHOD_GET | HTTP_METHOD_HEAD, handler_root   },
    { "/status", HTTP_METHOD_GET | HTTP_METHOD_HEAD, handler_status },
    { "/cli",    HTTP_METHOD_POST,                   handler_cli    },
};

/* Handler di esempio */
static void handler_status(const ca_http_request_t *req,
                           ca_http_response_t      *resp)
{
    (void)req;
    ca_http_resp_begin(resp, 200U, "application/json");
    ca_http_resp_puts(resp, "{\"ip\":\"");
    /* ... */
    ca_http_resp_puts(resp, "\"}");
}

/* Avvio (da on_dhcp_bound o ca_os_main) */
ca_http_update_local_ip(ip);
ca_http_service_start(routes, 3U, 0U);   /* porta 80 */
```

18.14.7 CLI Capture Integration

With `EN_CLI_CAPTURE 1`, every CLI command is reachable via HTTP:

```
static void handler_cli(const ca_http_request_t *req,
                        ca_http_response_t *resp)
{
    char cmd[128];
    extract_cmd(req->body, req->body_len, cmd, sizeof(cmd));
    ca_http_resp_begin(resp, 200U, "text/plain");
    if (!ca_cli_exec_capture(cmd, g_buf, sizeof(g_buf), 1500U))
        ca_http_resp_puts(resp, "timeout");
    else
        ca_http_resp_puts(resp, g_buf);
}
```

`ca_cli_exec_capture` redirects stdout to a buffer for the duration of the command.

18.14.8 Implementation details

Content-Length in the response

`ca_http_resp_begin` writes a 10-space placeholder. Upon completion of the body construction, `ca_http_serve_connection` patches the actual value in place:

```
/* In ca_http_resp_begin() */
resp_append(r, "Content-Length: ", 16U);
r->cl_pos = r->len;
resp_append(r, "          ", 10U);  /* placeholder 10 spazi */
r->hdr_end = r->len + 4U;

/* In ca_http_serve_connection() dopo route_and_respond() */
u16 body_len = rp->len - rp->hdr_end;
ca_memcpy(rp->buf + rp->cl_pos, itoa_left(body_len, 10), 10U);
```

Multi-segment reception

If a browser splits the request into multiple TCP segments, `ca_http_serve_connection` accumulates the data with a loop before calling `parse_request`:

```
for (;;) {
    body_off = cerca_rnrn(rx_buf, rx_len);
    if (body_off > 0 || rx_len >= HTTP_REQ_BUF_SIZE) break;
    u16 more = io_read(io, rx_buf + rx_len, HTTP_REQ_BUF_SIZE - rx_len);
    if (more == 0) break;
    rx_len += more;
}
```

Waiting for the body: only if announced

After the headers, the server waits for the body **only if `Content-Length` is greater than zero**, and in that case, it reads until the body is complete. Until 10/23/2026 it always waited, even for a GET without a body: every request cost the entire `HTTP_RECV_TIMEOUT_MS`. Measured on example 45: a GET went from 1.5 s to 0.8 ms.

18.14.9 CLI: `http` command

With `EN_CLI_HTTP 1`:

```
http            -> stato, porta, numero route, IP locale
http info       -> uguale
http routes     -> URI + bitmask metodi per ogni route
```

Example:

```
c.a.O.S. > http info
HTTP  : running
port  : 80
routes: 3
IP    : 192.168.10.158

c.a.O.S. > http routes
  [0] /         methods=0x0D
  [1] /status   methods=0x0D
  [2] /cli      methods=0x02
```

18.14.10 Warnings

`HTTP_REQ_BUF_SIZE`: set >= 2048. Real browsers send ~610 bytes of headers in POST requests -> 400 Bad Request with buffers that are too small.

`HTTP_RESP_BUF_SIZE`: set >= 4096 for verbose CLI responses (output of `top`, `help`, `tcp list` can exceed 1 kB).

Simultaneous connections: the server is sequential. The TCP accept queue handles multiple browser connections without dropping them, but serves them one at a time.

OPTIONS: handled automatically by the router with the `Allow:` header generated from the method bitmask of the corresponding route.

URI not found: -> `404`. Method not allowed: -> `405` with `Allow:`.

See **Example 45** for a complete application (HTTP and HTTPS over Ethernet) and **Example 80** for the same application over USB-NCM.

18.15 MQTT Service

`mqtt_service` implements an MQTT 3.1.1 client over TCP for caOS. Fully callback-driven: no internal MQTT task, everything is processed by `on_tcp_rx()` within the net task context.

File: `caos/net/src/mqtt_service.c` / `caos/net/inc/mqtt_service.h`

Dependencies: `EN_ETH 1`, `EN_NET 1`, `EN_TCP_SERVICE 1`, `EN_ARP_SERVICE 1`.

18.15.1 Features

Property	Value
MQTT Version	3.1.1
Supported QoS	0 (fire-and-forget)
TX Packets	CONNECT, PUBLISH, SUBSCRIBE, PINGREQ, DISCONNECT
RX Packets	CONNACK, PUBLISH, SUBACK, PINGRESP
Dedicated Task	none – callback-driven in net task
Concurrent Connections	1 (single internal state)

18.15.2 Configuration `os_config.h`

Define	Default	Description
`EN_MQTT_SERVICE`	`1`	enables the service
`MQTT_RX_BUF_SIZE`	`256`	max RX payload in bytes
`MQTT_KEEPALIVE_SEC`	`60`	keepalive advertised to broker
`EN_CLI_MQTT`	`1`	`mqtt` command from CLI

18.15.3 Architecture

```
ca_mqtt_service_init()   <- sets up state, registers callbacks
ca_mqtt_service_net_ready() <- apre connessione TCP (asincrona)

TCP ESTABLISHED -> on_tcp_connected() -> MQTT CONNECT inviato
CONNACK OK      -> on_connected() dell'applicazione
PUBLISH RX      -> on_message(topic, tlen, payload, plen)
TCP chiuso      -> on_disconnected() dell'applicazione
```

RX Parser a stati

```
state 0 -> waiting for fixed header (1 byte: packet type)
state 1 -> decodes remaining length (1-4 bytes, 7-bit varlen encoding)
state 2 -> accumulating payload in rx_buf up to rem_len bytes
           -> process_packet()
```

Packets with payload > `MQTT_RX_BUF_SIZE` are silently discarded. The parser correctly handles TCP fragmentation.

18.15.4 Public API

```
void ca_mqtt_service_init(ca_ipv4_t broker_ip, u16 broker_port,
                          ca_ipv4_t local_ip,  ca_mac_t local_mac,
                          const char *client_id,
                          ca_mqtt_connected_cb_t    on_connected,
                          ca_mqtt_message_cb_t      on_message,
                          ca_mqtt_disconnected_cb_t on_disconnected);

bool ca_mqtt_service_net_ready(void);   /* starts TCP connect */
bool ca_mqtt_publish(const char *topic, const u8 *payload, u16 len);
bool ca_mqtt_subscribe(const char *topic);
void ca_mqtt_ping(void);
bool ca_mqtt_is_connected(void);
void ca_mqtt_disconnect(void);
```

Callbacks

```
typedef void (*ca_mqtt_connected_cb_t)(void);

typedef void (*ca_mqtt_message_cb_t)(const char *topic,  u16 topic_len,
                                     const char *payload, u16 payload_len);

typedef void (*ca_mqtt_disconnected_cb_t)(void);
```

> **Warning**: `topic` and `payload` point to `rx_buf` inside the service. They are valid **only for the duration of the callback**. Copy the data if necessary after the return.

18.15.5 Initialization

```
/* ca_os_configure() -- before the network is available */
ca_mqtt_service_init(broker_ip, 1883,
                     local_ip, local_mac,
                     "my-client",
                     on_mqtt_connected,
                     on_mqtt_message,
                     on_mqtt_disconnected);
```

After the DHCP bind, notify the service:

```
static void on_dhcp_bound(ca_ipv4_t ip, ...)
{
    ca_net_proto_set_local_ip(ip);
    ca_arp_service_update_local_ip(ip);
    ca_mqtt_service_net_ready();   /* starts the connection to the broker */
}
```

18.15.6 Pattern — periodic publish + reconnect

```
static u32 task_mqtt(void *arg)
{
    (void)a; (void)b;
    ca_sem_wait(&s_dhcp_sem);

    ca_ipv4_t broker_ip = s_gw;          /* DHCP gateway = broker */
    ca_mqtt_service_init(broker_ip, 1883, s_ip, s_mac,
                         "caos-h753",
                         on_connected, on_message, on_disconnected);
    ca_mqtt_service_net_ready();

    u32 last_pub = 0, last_ping = 0, last_reconnect = 0;

    while (1) {
        u32 now = ca_os_tick_ms();

        if (!ca_mqtt_is_connected()) {
            if ((now - last_reconnect) >= MQTT_RECONNECT_MS) {
                last_reconnect = now;
                ca_mqtt_service_init(broker_ip, 1883, s_ip, s_mac,
                                     "caos-h753",
                                     on_connected, on_message, on_disconnected);
                ca_mqtt_service_net_ready();
            }
            ca_os_delay_ms(500U);
            continue;
        }

        if ((now - last_pub) >= PUB_PERIOD_MS) {
            last_pub = now;
            char payload[64];
            ca_snprintf(payload, sizeof(payload), "{\"up\":%u}", now / 1000U);
            ca_mqtt_publish("caos/status", (const u8 *)payload,
                            (u16)ca_strlen(payload));
        }
        if ((now - last_ping) >= PING_PERIOD_MS) {
            last_ping = now;
            ca_mqtt_ping();
        }
        ca_os_delay_ms(500U);
    }
    return 0U;
}
```

Broker IP from DHCP gateway

The recommended pattern is to use the DHCP gateway as the broker address. Remove the hardcoded PC IP from the firmware.

```
static void on_dhcp_bound(ca_ipv4_t ip, ca_ipv4_t mask, ca_ipv4_t gw, ca_ipv4_t
    dns)
{
    (void)mask; (void)dns;
    s_ip = ip;
    s_gw = gw;                    /* broker = gateway */
    ca_net_proto_set_local_ip(ip);
    ca_arp_service_update_local_ip(ip);
    ca_arp_send_garp();
    ca_sem_post(&s_dhcp_sem);
}
```

18.15.7 CLI: command `mqtt`

With `EN_CLI_MQTT 1`:

```
mqtt                          -> connection state, broker IP
mqtt pub <topic> <payload> -> pubblica
mqtt sub <topic>           -> sottoscrive
mqtt ping                  -> PINGREQ manuale
mqtt disconnect            -> chiude connessione
```

18.15.8 Warnings

Single internal state: `ca_mqtt_service_init` clears the state including `tcp_handle`. Do not do it while a connection is active: use `ca_mqtt_disconnect()` first.

`ca_mqtt_ping()` **is application responsibility**: the service does not send automatic keepalives. The task must call `ca_mqtt_ping()` every `< MQTT_KEEPALIVE_SEC` seconds to prevent the broker from closing the session.

`ca_mqtt_subscribe()` **inside** `on_connected`: correct and recommended pattern.

TX packets as single buffer: each `ca_mqtt_publish` / `ca_mqtt_subscribe` builds the complete packet in a local buffer (128 bytes) and calls `ca_tcp_send` only once. Respects the `TCP_MAX_INFLIGHT =4` limit.

See **Example 41** for a complete application.

18.16 Modbus/TCP Service

`modbus_service` implements a Modbus/TCP client for caOS. Blocking API with timeout: the calling task blocks until the response arrives or the timeout expires.

File: `caos/net/src/modbus_service.c` / `caos/net/inc/modbus_service.h`

Dependencies: `EN_ETH 1`, `EN_NET 1`, `EN_TCP_SERVICE 1`.

18.16.1 `os_config.h` Configuration

Define	Default	Description
`EN_MODBUS_SERVICE`	`1`	enables the service
`MODBUS_TIMEOUT_MS`	`1000`	response timeout (ms)
`MODBUS_RX_BUF_SIZE`	`270`	RX buffer in bytes (>= max expected PDU)
`EN_CLI_MODBUS`	`1`	`modbus` command from CLI

18.16.2 Architecture

```
applicazione
    | ca_modbus_read_holding_regs() / write_single_reg() / ...
    v
modbus_service.c   -- MBAP framing, RX state machine, serializzazione tx_mtx
    | ca_tcp_send() / callbacks on_rx / on_connected / on_closed
    v
tcp_service.c      -- PCB, retransmit, finestra
    |
    v
rete fisica
```

MBAP Framing

Every request/response is encapsulated in an ADU (Application Data Unit):

```
+--------+--------+--------+--------+--------+--------+--------+--------+---
| TID(H) | TID(L) |  0x00  |  0x00  | Len(H) | Len(L) | UnitID |  FC    | data...
+--------+--------+--------+--------+--------+--------+--------+--------+---
 <---------------- MBAP header (6 byte) ----------------> <---- PDU ---->
```

`Len` = `1 (UnitID) + len(PDU)`. The RX parser uses two states: - **state 0**: accumulates 6 bytes of header, extracts `rx_pdu_len` - **state 1**: accumulates exactly `rx_pdu_len` bytes in the buffer, sets `rx_sem`

Supported function codes

FC	Name	Description
`0x01`	Read Coils	reads N coils (max 2000)
`0x03`	Read Holding Registers	reads N 16-bit registers (max 125)
`0x06`	Write Single Register	writes a register
`0x10`	Write Multiple Registers	writes N registers (max 123)

18.16.3 Initialization

```c
/* ca_os_configure() */
ca_modbus_service_init(server_ip, server_port, local_ip, mac, unit_id);
```

Parameter	Type	Description
`server_ip`	`ca_ipv4_t`	Modbus server (PLC/RTU gateway) IP
`server_port`	`u16`	TCP port, normally 502
`local_ip`	`ca_ipv4_t`	Local IP (0.0.0.0 before DHCP)
`local_mac`	`ca_mac_t`	Local MAC
`unit_id`	`u8`	Modbus Unit ID (slave address)

After DHCP bind:

```c
static void on_dhcp_bound(ca_ipv4_t ip, ...)
{
    ca_net_proto_set_local_ip(ip);
    ca_modbus_service_init(server_ip, 502U, ip, mac, unit_id);
    ca_modbus_service_net_ready();   /* opens a TCP connection to the server */
}
```

18.16.4 Public API

```c
/* Starts a TCP connection to the server (asynchronous via callback) */
bool ca_modbus_service_net_ready(void);

/* Connection state */
bool ca_modbus_is_connected(void);

/* Closes the connection */
void ca_modbus_disconnect(void);
```

```

/* FC01 -- Read Coils */
bool ca_modbus_read_coils(u16 addr, u16 count, u8 *out);

/* FC03 -- Read Holding Registers */
bool ca_modbus_read_holding_regs(u16 addr, u16 count, u16 *out);

/* FC06 -- Write Single Register */
bool ca_modbus_write_single_reg(u16 addr, u16 value);

/* FC16 -- Write Multiple Registers */
bool ca_modbus_write_multiple_regs(u16 addr, const u16 *values, u16 count);
```

All blocking functions are serialized by `tx_mtx`.

18.16.5 Usage patterns

```
static u32 task_modbus(void *arg)
{
    (void)a; (void)b;
    ca_sem_wait(&s_dhcp_sem);

    ca_ipv4_t server = s_gw;
    ca_modbus_service_init(server, 502U, s_ip, s_mac, 1U);
    ca_modbus_service_net_ready();

    u32 last_poll = 0U;
    u32 last_reconnect = ca_os_tick_ms();

    while (1) {
        u32 now = ca_os_tick_ms();

        if (!ca_modbus_is_connected()) {
            if ((now - last_reconnect) >= 5000U) {
                last_reconnect = now;
                ca_modbus_service_init(server, 502U, s_ip, s_mac, 1U);
                ca_modbus_service_net_ready();
            }
            ca_os_delay_ms(500U);
            continue;
        }

        if ((now - last_poll) >= 3000U) {
            last_poll = now;
            u16 regs[4];
            if (ca_modbus_read_holding_regs(0U, 4U, regs))
                ca_stdout_printf_n("reg[0]=%u", (u32)regs[0]);
            ca_modbus_write_single_reg(4U, 1234U);
        }
        ca_os_delay_ms(200U);
    }
    return 0U;
}
```

18.16.6 CLI: command `modbus`

With `EN_CLI_MODBUS 1`:

```
modbus                      -> connection state, server IP, unit id
modbus read <addr> <count> -> FC03 Read Holding Registers
```

```
modbus write <addr> <val>  -> FC06 Write Single Register
modbus coils <addr> <cnt>  -> FC01 Read Coils
```

18.16.7 Warnings

`ca_modbus_service_init` **closes the previous connection** (if active) before resetting the state, avoiding zombie PCBs in the TCP service.

Serialized concurrent accesses: `tx_mtx` ensures that the automatic task and CLI do not overlap. The response waiting occurs with the mutex acquired but with the task in SLEEP state.

Stale callback management: each TCP callback verifies that `handle == s.tcp_handle` before acting. Prevents events from a already closed connection from corrupting the state of the new one.

```
static void on_tcp_closed(u8 handle)
{
    if (handle != s.tcp_handle) return;   /* ignora TIME_WAIT stantio */
    s.tcp_up = false;
    ca_sem_post(&s.rx_sem);              /* unblocks the waiting transact() */
}
```

See **Example 43** for a complete application.

18.17 iperf Service

`iperf_service` measures the TCP throughput between the board and a network peer compatible with iperf2 (default port 5001).

Supports two modes: - **client**: the board opens the connection and transmits bulk data - **server**: the board accepts the connection and measures received data

File: `caos/net/src/iperf_service.c` / `caos/net/inc/iperf_service.h`

Dependencies: `EN_ETH 1`, `EN_NET 1`, `EN_ARP_SERVICE 1`, `EN_TCP_SERVICE 1`.

18.17.1 `os_config.h` Configuration

Define	Default	Description
`EN_IPERF_SERVICE`	`1`	enables the service
`EN_CLI_IPERF`	`1`	`iperf` command from CLI
`NET_BUF_COUNT`	—	required; 64 recommended (128 KB NET_SRAM1)

18.17.2 Architettura

```
CLI / applicazione
    | ca_sem_post(&s.sem)   <- non bloccante: iperf_task esegue in background
    v
iperf_task (CA_TH_LEVEL3)
    | ca_iperf_client()  o  ca_iperf_server()
    v
iperf_service.c  -- TX/RX loop, misura bytes/ms/bps
    | ca_tcp_connect / listen / accept / send / recv / close
    v
tcp_service.c    -- PCB, retransmit, window
```

Client Mode — `ca_iperf_client()`

```
ca_tcp_connect(remote_ip, port)       <- SYN -> attende ESTABLISHED
loop finche' (now - t0) < duration_ms:
    ca_tcp_wait_writable(h, 200 ms)   <- yields the CPU if the window is full
    ca_tcp_send(h, buf, 1460 B)       <- segmento a MSS
ca_tcp_close(h)                       <- FIN + drain
-> RESULT: bytes_total / duration_ms / bps
```

The fixed chunk of 1460 bytes corresponds to the standard Ethernet MSS (MTU 1500 - 20 IP - 20 TCP).

Server Mode — `ca_iperf_server()`

```
ca_tcp_listen(port)                   <- apre slot passivo
ca_tcp_accept(lh, idle_timeout_ms)    <- BLOCKED: waits for SYN from the PC
ca_tcp_unlisten(lh)                   <- libera slot ascolto
loop:
    ca_tcp_recv(h, buf, 1460, &got, idle_ms)
    received += got
    [break if got == 0 or timeout]   <- FIN/RST from the PC
ca_tcp_close(h)
-> RESULT: bytes_total / duration_ms / bps
```

18.17.3 Initialization

```c
/* ca_os_main() -- after ca_tcp_service_start() */
{
    ca_ipv4_t zero = { .addr = 0U };
    ca_iperf_service_start(zero, s_mac);
}

/* update the IP at DHCP bind */
static void on_dhcp_bound(ca_ipv4_t ip, ...)
{
    ca_net_proto_set_local_ip(ip);
    ca_arp_service_update_local_ip(ip);
    ca_iperf_update_local_ip(ip);
}
```

18.17.4 Public API

```c
/* Starts the service (registers the CLI handler). Call from ca_os_main(). */
void ca_iperf_service_start(ca_ipv4_t local_ip, ca_mac_t local_mac);

/* Updates the local IP after DHCP bind. */
void ca_iperf_update_local_ip(ca_ipv4_t ip);

/* Client mode: transmits bulk to remote_ip:port for duration_ms ms.
 * Blocking. Writes the result in *out. Returns false if connect fails. */
bool ca_iperf_client(ca_ipv4_t remote_ip, u16 port,
                     ca_ipv4_t local_ip, ca_mac_t local_mac,
                     u32 duration_ms, ca_iperf_result_t *out);

/* Server mode: accepts one connection on port.
```

```
 * Waits up to idle_timeout_ms for a client.
 * Blocking. Returns false if no client connects. */
bool ca_iperf_server(u16 port, ca_ipv4_t local_ip, ca_mac_t local_mac,
                     u32 idle_timeout_ms, ca_iperf_result_t *out);
```

Result Structure

```
typedef struct {
    u32 bytes_total;   /* byte TX (client) o RX (server) */
    u32 duration_ms;   /* actual duration */
    u32 bps;           /* bit/s = bytes_total / (duration_ms/1000) * 8 */
} ca_iperf_result_t;
```

18.17.5 CLI: command `iperf`

With `EN_CLI_IPERF 1`:

```
iperf help
iperf client <ip> [port=5001] [dur_s=10]
iperf server [port=5001] [idle_s=30]
tcp buf         -- pool free/held/leak (buffer leak diagnosis)
```

The CLI does not block: post the semaphore and return immediately. The result appears on the output when `iperf_task` terminates.

Client session (board -> PC)

```
# On the PC:
nc -l 5001 | pv > /dev/null

# On the board:
> iperf client 192.168.10.1 5001 10
  iperf RESULT: 39906910 bytes  10036 ms  31925528 bps
```

Server session (PC -> board)

```
# On the PC:
dd if=/dev/zero bs=64k | nc <board_ip> 5001

# On the board:
> iperf server 5001 30
  iperf RESULT: 38675400 bytes  10000 ms  30940320 bps
```

18.17.6 Typical Performance (NUCLEO-H753ZI, 100BASE-TX)

Mode	Average Throughput	Peak Throughput
Client (board TX -> PC RX)	~25 Mbps	~32 Mbps
Server (PC TX -> board RX)	~25 Mbps	~39 Mbps

Main limitations: - **CPU copying**: two `memcpy` per each TCP segment between DMA buffers and application buffers - **TCP window**: limited by the number of free buffers in the pool (64 x 2 KB) - **scheduler latency**: SysTick ~104 us; `__WFI()` in idle task indispensable

See **Example 44** for a complete application.

Chapter 19

caOS USB Driver: DWC2 Core

19.1 Low-level USB Driver

19.1.1 Overview

The caOS USB driver is a bare-metal **device controller** Full-Speed that exposes a generic endpoint API — USB descriptors, enumeration and classes are **not** in the driver: they live in the application (example 50) or in the `caos/usb/` services stack (CDC, MSC, NCM, ...).

The STM32 families handled by the project **do not all use the same USB controller**: under the same public API, two completely different hardware IPs coexist.

- **DWC2 OTG** (Synopsys DesignWare USB 2.0 OTG) — F4xx, F7xx, H7xx, U5xx. Architecture based on **FIFO** (slave or DMA), full OTG core.
- **USB_DRD_FS** — H5xx (H563). ST proprietary IP based on **PMA** (Packet Memory Area), **not** DWC2: no shared FIFO, dedicated HW buffers for endpoints. See the "The Two USB IPs" paragraph.

The rest of this chapter (per-EP code, public API, source layout) is common to both IPs; hardware differences are isolated in `hw/<family>/drivers/`.

The driver handles only:

1. **Init / clock / GPIO** of the OTG core for the family
2. **EP0 control**: SETUP reception, status stage, `SET_ADDRESS`
3. **Data endpoints** (bulk/interrupt): open/close, read/write, stall
4. **DWC2 ISR**: bus reset, RXFLVL, IEPINT/OEPINT → callback to the application

The driver class separation is the same as in `net` and `crypto`: the low-level HW stays in `caos/drivers/` + `hw/<family>/`, class services in `caos/usb/`.

Tested HW (all in **slave mode**, CPU copies the FIFO): - **NUCLEO-H753ZI** — OTG_FS CN14, 6 EP @ 0.579 MB/s - **NUCLEO-U575ZI-Q** — internal OTG_FS, 5 EP @ 0.466 MB/s - **STM32F4VE (black board)** — OTG_FS PA11/PA12, 3 EP @ 0.548 MB/s

The H7 driver in **DMA mode** (previous) is kept as `usb_hs_h7xx.c` for the future **OTG_HS** (480 Mbit/s), where bandwidth justifies the DMA. At Full-Speed the slave has no bottlenecks (CPU at 480 MHz copies the FIFO faster than the 12 Mbit/s bus) and on H7 it actually **outperforms** DMA (0.579 vs 0.491 MB/s) thanks to deeper per-EP queues; it also removes the fragility of the EP0 control path in DMA (shared RX FIFO for control+bulk).

19.1.2 The Two USB IPs

caOS supports two physically different USB device controllers behind the same endpoint API. The choice depends on the family, it is not configurable. | Aspect | **DWC2 OTG** | **USB_DRD_FS** | |———|———————|———————-| | Families | F4xx, F7xx, H7xx, U5xx | H5xx (H563) | | Origin | Synopsys DesignWare USB 2.0 OTG | ST proprietary (FS host/device) | | Data buffers | **FIFO** (RX shared among OUT EPs) | **PMA** — dedicated HW buffers per EP | | Mode | slave (CPU) or internal DMA | always PMA, CPU copies from/to PMA | | Buffer descriptors | EP registers + FIFO | BTABLE (2 words/EP) at start of PMA | | EP registers | `DIEPCTLn`/`DOEPCTLn` separate IN/OUT | `CHEPnR` single (bit toggle STAT/DTOG) | | USB clock | PLLQ 48 MHz (F4) / HSI48 (U5) | HSI48 (`USBSEL=11`) + CRS | | IRQ | `OTG_FS_IRQn` | `USB_DRD_FS_IRQn` | | HW reference | Family RM, OTG chapter | rm0481-h5, ch. 55 |

DWC2 is a full OTG core: OUT endpoints share a single RX FIFO and the driver dispatches packets from ISR `RXFLVL` to per-EP software rings (see the following two sections). It supports slave mode and internal DMA.

USB_DRD_FS (H5xx) is instead based on **PMA**: a linear 2 KB memory (512 32-bit words) where each endpoint has dedicated **hardware** TX and RX buffers, described by the Buffer Description Table (BTABLE) at the beginning of the PMA. There is no shared FIFO or software ring: the driver directly copies payload between PMA and application RAM. EP registers `CHEPnR` use *toggle* bit semantics (`STAT_TX`/`STAT_RX`/`DTOG` XOR on write) and *rc_w0* (`VTRX`/`VTTX`/`SETUP`), different from DWC2's `DIEPCTL`/`DOEPCTL`. Under the public API (`ca_usb_ep_open/read/write`, SETUP, enumeration), behavior is identical to other drivers.

The following two sections ("Two transfer modes" and "Per-EP code") describe the **DWC2** implementation. The H5 USB_DRD_FS IP has no FIFO or ring: the related PMA management is documented inline in `hw/h5xx/drivers/usb_fs_h5xx.c`.

19.1.3 Two transfer modes (DWC2)

The DWC2 core has two modes to move data between FIFO and RAM. caOS supports both; all **active** drivers use slave mode, DMA is reserved for future OTG_HS:

Mode	Families	Mechanism
Slave (CPU)	H7xx (FS), U5xx, F4xx	CPU reads/writes FIFO word-by-word in ISR (RXFLVL)
Internal DMA	H7xx (HS, future)	Core copies from/to RAM autonomously; driver `usb_hs_h7xx.c` parked

Both modes share the same public API; only the implementation in `hw/<family>/drivers/usb_<family>.c` changes.

Slave mode — the RX FIFO is shared among all OUT EPs: the ISR `RXFLVL` extracts the packet header (`GRXSTSP`), reads the payload word-by-word and dispatches it to the **per-EP ring** of the destination endpoint. **Flow-control lossless**: every OUT EP is armed with `PKTCNT=1`, so after each packet it automatically returns to NAK. The ISR `OEPINT` (XFRC) **re-arms the EP only if the RX ring has space**; if it is full it does NOT re-arm → the host gets NAKed and retransmits (no packet lost). `ca_usb_ep_read` re-arms the EP when the task frees a slot. This eliminates the drop-on-full from the previous version (which drained and discarded the already ACKed packet) — essential under load and in composite devices with saturated EPs.

The driver `usb_f4xx.c` is structurally twin to `usb_u5xx.c`; the differences from the U5 concern the hardware capabilities of the core:

Aspect	F4xx OTG_FS	U5xx OTG_FS
DMAEN	hardwired 0 (RM0090 §34.3.2)	0 (slave mode chosen)
Total EPs	4 (EP0..3), `USB_EP_MAX=4`	6 (EP0..5), `USB_EP_MAX=6`
Bulk data EPs	3 (EP1..3), `USB_NQEP=3`	5 (EP1..5), `USB_NQEP=5`
Total FIFO	320 word (1280 B)	320 word (1280 B)
VBUS sensing	`GCCFG.NOVBUSSENS` (GUID < 0x2000)	`GOTGCTL.BVALOEN/BVALOVAL`
USB Clock	PLLQ = 48 MHz	HSI48
IRQ	`OTG_FS_IRQn` (single)	`OTG_FS_IRQn` (single)

`GCCFG.NOVBUSSENS` is required on F4xx because the DWC2 core GUID is `< 0x2000` (F2/F4 generation): the `GOTGCTL.BVALOEN` field does not exist. On F4 boards, OTG_FS does not sense VBUS → suspend/resume (USBSUSP/WKUPINT) is the only reliable proxy for disconnect detection, as already on U5.

19.1.4 Per-EP Code (DWC2)

In slave mode, each data endpoint has **independent RX and TX queues** (ring SPSC, head-/tail per-EP, flat pool): no contention between endpoints, each can be served by a dedicated task. This allows composite devices (multiple parallel bulk EPs) as in example 50.

- **H7xx**: `USB_NQEP=6` data EPs, ring depth **uniform 128 slots per EP**. Pools (`s_qrx_pool` /`s_qtx_pool`) are located in `.usb_dma` (USB_SRAM D2, 128 KB) and are allocated **only for active cores** (`EN_USB_HS`/`EN_USB_FS` in `os_config.h`): with only FS, the depth doubles compared to dual-core (all RAM allocated to the active core). `USB_PIDX(n)` maps `usb_num` → pool instance.
- **U5xx**: `USB_NQEP=5` data EPs, variable ring depth (EP1/2=64, EP3=16, EP4/5=8 slots), flat pool.
- **F4xx**: `USB_NQEP=3` data EPs (EP1..3), uniform ring depth 64 slots per EP, flat pool of 192 slots.

Ringbuffer data copy uses `ca_memcpy_u32`/`ca_memcpy_u16` (fallback byte) depending on length alignment; bulk MPS packets (64 B) always go on the 32-bit path. FIFO writes/reads remain word-per-word loops (it is a fixed-address MMIO register, not a memory-to-memory copy).

> **Note on uniform depth**: the multi-EP loopback (ex50) automatically limits packets in flight to the firmware queue depth; with heterogeneous depths, shorter EPs would saturate. With lossless flow-control (above), drops no longer occur, but uniform depth keeps the pipelining balanced across EPs. **EP0 IN multi-packet** (slave U5): if the response to a `GET_DESCRIPTOR` exceeds `MPS` (e.g. config descriptor of 88 B with `MPS=64`), the driver sends the subsequent chunks on the **TXFE** interrupt (FIFO empty, `DIEPEMPMSK` bit 0). Without this chunking, the enumeration of a device with 5 EPs would fail.

19.1.5 Public API

All functions take `usb_num` as the first parameter (on H7 there are two OTG cores: `0`=HS, `1`=FS).

Initialization

```
bool ca_usb_init(u32 usb_num, const ca_usb_cb_t *cb);
```

Initialize clock, GPIO and DWC2 core, register callbacks and wait for the first bus reset from the host. Returns `false` if clock/GPIO fails.

```
typedef struct {
    ca_usb_reset_cb_t     on_reset;      /* bus reset */
    ca_usb_mounted_cb_t   on_mounted;    /* enumerated (with speed) */
    ca_usb_unmounted_cb_t on_unmounted;  /* scollegato */
    ca_usb_setup_cb_t     on_setup;      /* SETUP 8B su EP0 */
    ca_usb_rx_cb_t        on_rx;         /* OUT data ready on EPn */
    ca_usb_tx_done_cb_t   on_tx_done;    /* TX IN completata */
} ca_usb_cb_t;
```

The callbacks are called **by ISR**: they must only signal a task (`ca_notify_send_isr`), not block. Unused pointers go to `NULL`.

Endpoint

```
bool ca_usb_ep_open (u32 usb_num, u8 ep_addr, ca_usb_ep_type_t type, u16 mps);
bool ca_usb_ep_close(u32 usb_num, u8 ep_addr);
u16  ca_usb_ep_read (u32 usb_num, u8 ep_addr, u8 *buf, u16 max_len);
bool ca_usb_ep_write(u32 usb_num, u8 ep_addr, const u8 *buf, u16 len);
```

- `ep_addr` follows the USB convention: bit 7 = direction (`0x81` = EP1 IN, `0x01` = EP1 OUT). EP0 IN = `0x80`.
- `ca_usb_ep_read` returns the bytes extracted from the EP RX queue (0 if empty); does not block.
- `ca_usb_ep_write` **copies** the buffer to the TX queue before returning → the caller can reuse `buf` immediately. Returns `false` only when TX queue is full (backpressure): retry after `ca_os_yield()`.

```
typedef enum {
    CA_USB_EP_TYPE_CTRL = 0,
    CA_USB_EP_TYPE_ISOC = 1,
    CA_USB_EP_TYPE_BULK = 2,
    CA_USB_EP_TYPE_INTR = 3,
} ca_usb_ep_type_t;
```

Stall (Patch 1)

```
void ca_usb_ep_stall      (u32 usb_num, u8 ep_addr);
bool ca_usb_ep_clear_stall(u32 usb_num, u8 ep_addr);
bool ca_usb_ep_is_stalled (u32 usb_num, u8 ep_addr);
```

`ep_close` / `clear_stall` / `is_stalled` (Patch 1) follow, on **DWC2** cores, the known sequence A.1 (SNAK→EPDIS→flush for IN; SGONAK→GONAKEFF→EPDIS for OUT). Implemented on **H7, U5 and F4**. On **H5** (USB_DRD_FS) stall uses instead the `STAT_TX`/`STAT_RX = STALL` fields of register `CHEPnR`. F1/F7 remain stub (porting step 13).

Bus control

```
void ca_usb_set_address(u32 usb_num, u8 addr);   /* applies DCFG.DAD */
void ca_usb_connect    (u32 usb_num);            /* pull-up D+ */
void ca_usb_disconnect (u32 usb_num);            /* soft disconnect */
```

`ca_usb_set_address`: apply **immediately** after SETUP `SET_ADDRESS`, before the ZLP status (quirk DWC2 / ST HAL pattern). Deferred apply in `on_tx_done` is race-prone because the ZLP XFRC fires in a few µs.

19.1.6 Source layout

File	Content
`caos/drivers/inc/usb.h`	public types + API wrapper
`caos/drivers/src/usb.c`	extern HW + generic wrapper
`caos/drivers/inc/ca_glue_hw.h`	extern `ca_usb_fs_dev_*` / `ca_usb_hs_dev_*` declaration
`hw/h7xx/drivers/usb_h7xx.c`	DWC2 **slave** FIFO — H753/H747 OTG_FS (HW tested)
`hw/h7xx/drivers/usb_hs_h7xx.c`	DWC2 **DMA** — parked for future OTG_HS (not in build)
`hw/u5xx/drivers/usb_u5xx.c`	DWC2 **slave** FIFO — U575 (HW tested)
`hw/f4xx/drivers/usb_f4xx.c`	DWC2 **slave** FIFO — F407/F429/F446, no DMA (HW tested F407)
`hw/h5xx/drivers/usb_fs_h5xx.c`	**USB_DRD_FS** (PMA) — H563, non-DWC2 IP (HW tested)
`hw/f1xx,f7xx/drivers/usb_*.c`	stub (porting step 13)

`EN_USB` in `os_config.h` enables the driver.

19.1.7 Notes per family

- **CMSIS bit naming**: the same bit 7 of `GINTSTS` is called `USB_OTG_GINTSTS_BOUTNAKEFF` on H7 and `USB_OTG_GINTSTS_GONAKEFF` on U5/F4.
- **H7 OTG**: dual-core — `usb_num=0` → OTG_HS (ULPI, MPS up to 512); `usb_num=1` → OTG_FS (MPS 64). `EN_USB_HS`/`EN_USB_FS` in `os_config.h` select active cores and pool allocation (currently only FS, slave mode). The DMA EP0 control path on this core was fragile (shared RX FIFO for control+bulk, subsequent control transfers random, not hot-recoverable): rewriting in slave mode eliminated it. ex52 CDC: enum + echo + open/close repeated terminal **without HW reset** + replug → re-enumeration, all OK on H753.
- **U5 OTG_FS**: `USB_EP_MAX=6` → at most 5 data EPs + EP0.
- **F4 OTG_FS**: `USB_EP_MAX=4` → at most 3 data EPs + EP0. On F407/F429/F446 the bit `DMAEN` is hardwired to 0 (RM0090 §34.3.2): the driver always operates in slave mode regardless of configuration.
- **STUPCNT EP0 (F4)**: during bring-up on F407 it was found that `DOEPCTL0` requires `STUPCNT=3` (not 1) to correctly receive multiple consecutive SETUPs during enumeration. Value 1 caused `-110` on the host at second bus reset.
- **H5 USB_DRD_FS** (H563): non-DWC2 IP, 2 KB PMA with per-EP dedicated buffers (no FIFO, no ring). Clock 48 MHz from HSI48 with `USBSEL=11` and correction via CRS. Single endpoint register `CHEPnR` with *toggle* bits (`STAT_TX`/`STAT_RX`/`DTOG`) and *rc_w0* (`VTRX`/`VTTX`/`SETUP`): write 1 to preserve, 0 to clear. PMA management documented inline in `hw/h5xx/drivers/usb_fs_h5xx.c` (ref. rm0481-h5 ch. 55).

See also: example 50 (vendor-class bulk loopback) for full API usage in a multi-EP composite device.

Chapter 20

caOS USB Stack: Management and Classes

20.1 USB device stack: management and classes

20.1.1 Overview

Above the low-level DWC2 driver (S02_11_00), caOS builds a **composable device stack**: a *management* layer (`ca_usb_dev_mng`) that assembles configuration descriptors and dispatches SETUP requests, and a set of interchangeable **class services** (CDC, MSC, NCM, DFU, custom) at runtime. It lives in `caos/usb/`, in symmetry with `caos/net/` and `caos/crypto/`.

```
applicazione
        ca_usb_dev_mng_init / add / start

ca_usb_dev_mng (caos/usb/src/usb_mgmt.c)
        ca_usb_class_ops_t  (fan-out per servizio attivo)
             ca_usb_cdc    (CDC-ACM, seriale virtuale)
             ca_usb_msc    (Mass Storage, BOT/SCSI)
             ca_usb_ncm    (USB Ethernet, CDC-NCM)
             ca_usb_dfu    (DFU runtime, EP0 only)
             ca_usb_custom (vendor loopback, test)
        ca_usb_ep_open/read/write/...

driver DWC2 (caos/drivers/ + hw/<family>)
             hw/h7xx/drivers/usb_h7xx.c   slave FIFO (H753/H747 OTG_FS)
             hw/u5xx/drivers/usb_u5xx.c   slave FIFO (U575)
             hw/f4xx/drivers/usb_f4xx.c   slave FIFO (F407/F429/F446     OTG_FS
   no DMA)
```

20.1.2 Two-level model (D1)

- **compile-time**: `EN_USB_CDC`, `EN_USB_MSC`, `EN_USB_NCM`, `EN_USB_DFU`, `EN_USB_CUSTOM` in `os_config.h` → which classes are *available* in the binary.
- **runtime**: `ca_usb_dev_mng_add(&cfg)` / `remove(type)` → which classes are *active* at a given moment. Allows modal firmware.

20.1.3 API management (D18 — 5 functions)

```
bool ca_usb_dev_mng_init(ca_usb_speed_t speed, u32 usb_num);
    /* registers the driver cb */
bool ca_usb_dev_mng_add   (const ca_usb_device_type_t *cfg); /* adds a class */
```

```
bool ca_usb_dev_mng_remove(ca_usb_type_t type);
bool ca_usb_dev_mng_start (void);           /* build descriptors + connect */
bool ca_usb_dev_mng_stop  (void);
```

Typical usage (three lines are enough):

```
ca_usb_dev_mng_init(CA_USB_SPEED_FS, USB_NUM);
ca_usb_dev_mng_add(&s_ncm.header);   /* s_ncm static, persistent lifetime (D20) */
ca_usb_dev_mng_start();
```

20.1.4 Class framework — `ca_usb_class_ops_t`

Every service defines a singleton `const ca_usb_class_ops_t` with its handlers; the management invokes them via ops, without `switch` on the type:

Callback	Role
`build_iface_desc`	appends interface (+IAD) + endpoint to config descriptor
`pid_contribution`	composite PID (`PID_BASE_x + EP_DATA`)
`on_reset`	bus reset
`on_mounted` / `on_unmounted`	enumeration / disconnection (on U5 and H7: `USBSUSP` as proxy for disconnect, VBUS not wired on NUCLEO)
`on_configure`	opens EPs (`SET_CONFIGURATION`)
`on_set_interface`	alt setting (NCM: alt0=idle / alt1=active)
`on_setup`	class-level SETUP request
`on_rx` / `on_tx_done`	fan-out EP I/O
`get_string`	string descriptor index > 3 (e.g. `iMACAddress` NCM)

The cfg of each class starts with the `ca_usb_device_type_t {type, ops}` tag (D19), allowing direct style `sockaddr` cast. The cfg must be `static` (ideally `static const`): the management keeps the pointer without copying.

20.1.5 Class services

CDC-ACM — virtual serial port (example_52)

Enumerates with IAD + comm-interface + data-interface. The PC mounts the device as `/dev/ttyACMx`. Handles `SET/GET_LINE_CODING`, `SET_CONTROL_LINE_STATE` (DTR). `SET_LINE_CODING` is a control-OUT: the data-stage (7 B) arrives via `on_rx(0)`; only after the service emits the ZLP IN.

EP	Type	Define
`USB_CDC_EP_DATA` (default 3)	bulk IN+OUT	serial data
`USB_CDC_EP_NOTIF` (default 4)	interrupt IN	line status notifications

Application API: `ca_usb_cdc_write`, `ca_usb_cdc_connected`, `ca_usb_cdc_get_line`.

MSC — block device (example_53)

Implements BOT (Bulk-Only Transport) + subset SCSI (INQUIRY, READ/WRITE_CAPACITY, READ10/WRITE10, REQUEST_SENSE, MODE_SENSE6). The host manages the filesystem: caOS exposes only an array of 512 B blocks. The back-end is abstracted via callback `read(lba, buf, count)` / `write(lba, buf, count)` in `ca_usb_msc_cfg_t` — changing only these the service works on ramdisk, FLASH or SD card.

EP	Type	Define
`USB_MSC_EP_DATA` (default 2)	bulk IN+OUT	CBW/data/CSW

NCM — USB Ethernet (example_54 loopback, example_55 stack IP)

CDC-NCM 1.0: the PC sees the device as a network card (`usb0` / `enxXX`). The Ethernet frames travel encapsulated in NTB (1 datagram per block). Handles `SET_INTERFACE` alt0=idle / alt1=active (link up/down) and `iMACAddress` via `get_string`. Integrates with `caos/net` through the `ca_ncm_iface_get` (push model) adapter: `on_rx` → `ca_net_rx_push` → net task semaphore.

EP	Type	Define
`USB_NCM_EP_DATA` (default 1)	bulk IN+OUT	NTB Ethernet
`USB_NCM_EP_NOTIF` (default 5)	interrupt IN	link/speed notify

DFU runtime — Device Firmware Upgrade (example_57)

Exposes a **DFU interface** (class `0xFE` / subclass `0x01` / protocol `0x01`) **without data endpoint**: all dialog occurs on EP0. It does not contribute to the endpoint collision bitmap and can coexist with any other class without consuming data EPs.

Handled requests (DFU 1.1): `DFU_DETACH`, `DFU_GETSTATUS`, `DFU_GETSTATE`, `DFU_CLRSTATUS`, `DFU_ABORT` . `DFU_DNLOAD`/`DFU_UPLOAD` are not handled at runtime (require DFU mode) → STALL on EP0 is correct.

The application receives `on_detach()` and decides how to enter the bootloader (flag RAM no-init + reset to system or application bootloader).

EP	Type	Notes
—	EP0 only	`PID = USB_PID_BASE_DFU = 0x0040`

custom — vendor interface (example_51)

Reference implementation of `ca_usb_class_ops_t`: the minimal model to copy when writing a new class. Exposes a vendor interface (`0xFF`) with EP1 bulk IN+OUT and loopback.

20.1.6 Endpoint allocation

Endpoints are assigned by **queue depth / expected bandwidth**, without collision in the composite (validated at compile-time by `_Static_assert`, D16):

Class	EP DATA	EP NOTIF	Bandwidth / queue
NCM	1 (bulk)	5 (intr)	high / deep

Class	EP DATA	EP NOTIF	Bandwidth / queue
MSC	2 (bulk)	—	high / deep
CDC	3 (bulk)	4 (intr)	low / short
DFU	— (EP0 only)	—	—
custom	1 (bulk)	—	test / variable

Limits per family

Family	Max bulk data EPs	Notes
H753/H747	6 (EP1..6)	OTG_FS (slave FIFO)
U575	5 (EP1..5)	OTG_FS (slave FIFO, RM0456 §72.2.3)
F407/F429/F446	3 (EP1..3)	OTG_FS (slave FIFO, `USB_EP_MAX=4`, no DMA)

The composite CDC+MSC+NCM uses **5 EPs** (EP1..5): fits exactly in the U575, has margin on the H7, but **does not fit** in the F407 (3 data EPs). On F407, example 56 uses the bi-modal **NCM+MSC** mode (3 EPs, `EX56_HAS_CDC=0` is automatically set for `STM32F4`).

20.1.7 Composite PID (D14)

The device PID is the **sum** of the `pid_contribution` of all active classes:

Class	`USB_PID_BASE_x`	typical contribution
CDC	`0x0010`	`0x0010 + EP_DATA (3) = 0x0013`
MSC	`0x0020`	`0x0020 + EP_DATA (2) = 0x0022`
NCM	`0x0030`	`0x0030 + EP_DATA (1) = 0x0031`
DFU	`0x0040`	`0x0040` (fixed, no data EPs)
custom	`0x0000`	`0x0000 + EP_DATA (1) = 0x0001`

Examples: single CDC class → `PID = 0x0013`; composite CDC+MSC+NCM → `PID = 0x0013 + 0x0022 + 0x0031 = 0x0066`.

20.1.8 Device identity (os_config.h)

VID, release, and device strings are project configuration parameters, `usb` group, as the `USB_PID_BASE_x` in the table above — not constants in the code: | Symbol | Default | Descriptor | |—|—|—| | `USB_VID` | `0xCA01U` | `idVendor` | | `USB_BCD_DEVICE` | `0x0100U` | `bcdDevice` | | `USB_STR_MANUFACTURER` | `"caOS"` | manufacturer string | | `USB_STR_PRODUCT` | `"caOS USB Device"` | product string | | `USB_STR_SERIAL` | `"0001"` | serial number | | `USB_PID_BASE_x` | see above | contribution to composite PID |

`0xCA01` is the **development** VID, unregistered: caOS is software, and whoever builds a product sets their own VID and PID — `caos_config.py --set USB_VID=0xNNNNU <progetto>`, without touching the sources.

20.1.9 Composite devices

Multiple classes can coexist on the same device: just register more than one before `start`. The management builds **a single config descriptor** that concatenates the interfaces/IAD/endpoints of all active classes.

```
ca_usb_dev_mng_init(CA_USB_SPEED_FS, USB_NUM);
ca_usb_dev_mng_add(&s_cdc.header);   /* /dev/ttyACMx              */
ca_usb_dev_mng_add(&s_msc.header);   /* removable disk          */
ca_usb_dev_mng_add(&s_ncm.header);   /* usb0 (+ ca_net_init)      */
ca_usb_dev_mng_start();              /* single composite descriptor */
```

The device presents `bDeviceClass = 0xEF` (Miscellaneous) + `bDeviceProtocol = 1` (IAD), and the host loads a driver for each function.

2-class combinations: these are obtained by turning off a `EN_USB_X` — the EP allocation remains valid because it is a subset:

Combination	EPs used	Enters F407?
CDC+MSC+NCM	5	no (max 3 on F407)
MSC+NCM	3	yes
CDC+NCM	4	no
CDC+MSC	3	yes
single class	1–3	yes

Multi-round EP0 data-stage (descriptors > 127 B)

The config descriptor of a 3-class composite is ~183 B. The DWC2 register `DIEPTSIZ0.XFRSIZ` is **7-bit** (max 127 B per *single* EP0 transfer), so the descriptor must be sent in multiple **rounds** by reprogramming `DIEPTSIZ0`/`DIEPDMA` at each `XFRC` on EP0.

> **Critical rule**: every non-final round must be an **exact multiple of MPS** (64 B → 1 full packet). A *short* packet in the middle of the descriptor would close the control transfer from the host's perspective (→ timeout). Only the final round may end with a short packet.

Implementation: `ep0_tx_start_round()` in slave drivers `hw/u5xx`, `hw/h7xx` and `hw/f4xx`, with a 512 B EP0 staging buffer. Single classes (descriptor 127 B) use a single round, unchanged behavior.

20.1.10 Source file

```
caos/usb/inc/usb_mgmt.h    caos/usb/src/usb_mgmt.c     # management

```

20.1.11 Reference Examples

Example	Class	Tested Boards	HW Result
50	vendor bulk (direct driver, no mgmt)	H753, U575, F407	0.579 / 0.466 / 0.548 MB/s
51	custom (mgmt)	H753, U575, F407	10000/10000 loopback EP1
52	CDC-ACM	H753, U575, F407	echo 100/100 ttyACM[1]
53	MSC ramdisk	H753, U575, F407[2]	FAT12 mount/write/persist
54	NCM loopback L2	H753, U575, F407	arping 5/5 swap SADA
55	NCM + net stack (ping)	H753, U575, F407	ping 5/5 ~0.8 ms
56	composite CDC+MSC+NCM	U575, H753	ping+echo+FAT simultaneous
	composite NCM+MSC (F407)	F407[2]	ping+FAT (no CDC, 3 EP)
57	DFU runtime	H753, U575, F407	dfu-util -l OK + on_detach

[1] H753 ex52 CDC validated HW (slave driver): repeated echo + open/close of the terminal without HW reset + replug → re-enumerates. This was the case where the old DMA driver was not up to the task.
[2] F407 ramdisk 64 KB (`BLK_COUNT=128`), minimal FAT12; U575/H7 = 128 KB.

Chapter 21

FatFS on caOS: SDIO Driver

21.1 FatFS on caOS: SDIO driver

21.1.1 Overview

The caOS storage subsystem exposes a **FAT12/16/32 filesystem** (third-party library **FatFS**, `external/fatfs`) over a **bare-metal SDIO driver** for SDHC/SDXC SD cards. As with USB, net, and crypto, there is a clear separation between generic library/glue (`caos/`) and family-specific hardware implementation (`hw/<family>/drivers/`).

The subsystem is organized into three layers:

```
FatFS (external/fatfs, source/ff.c)
        configurazione: source/ffconf.h     redirect a caos_ffconf.h

fatfs_diskio.c (caos/drivers/src/fatfs_diskio.c)
        disk_initialize/status/read/write/ioctl     ca_sdio_*

ca_sdio (caos/drivers/inc/sdio.h + src/sdio.c)
        wrapper pubblico     extern ca_sdio_hw_* per famiglia

hw/<family>/drivers/sdio_<family>.c
```

Tested HW: **STM32F4VE (F407)** via generic DMA, **Nucleo-H563** and **Nucleo-H753** via SDMMC v2 with IDMA; microSD via 4-bit SDIO. See the complete application example (CLI `fat`) in the chapter "FatFS on SD card: SDIO driver with DMA" (example 58).

21.1.2 Layer 1 — FatFS and the ffconf.h redirect

FatFS resides as a third-party source in `external/fatfs/` (submodule). The only local modification to the submodule is precisely `source/ffconf.h`: the configuration (`FF_FS_*`, `FF_USE_*`, `FF_LFN_BUF`, ...) is normally written directly there, but in caOS that file **does not contain the configuration**: it only does

```
#include "../../caos_fatfs/caos_ffconf.h"
```

pointing to `external/caos_fatfs/caos_ffconf.h`, where the actual caOS-specific configuration resides.

Rationale — library/consumer ODR mismatch. `libfatfs.a` (build of `ff.c`) and the application consuming it (e.g., `example_58`) must see **exactly the same** `ffconf.h`, because macros like `FF_FS_EXFAT`, `FF_USE_LFN`, `FF_MAX_SS` change `sizeof(FATFS)`, `sizeof(FIL)`, and internal buffer layouts. If the library were compiled with one configuration and the application firmware included another (One Definition Rule violated at the binary struct level, not just symbols), the symptom is subtle: `f_mount()` returns `FR_OK` but subsequent operations see `"non montato"` or inconsistent data,

because the two sides read/write different offsets of the same structure (`FATFS::win[]` overflowing into subsequent fields like `s_mounted`, for example). The redirect to a single file (`caos_ffconf.h`, included in the same way by `fatfs.cmake` and by those using FatFS) eliminates the dual source of truth.

Library build (`external/caos_fatfs/fatfs.cmake`):

```
add_library(fatfs STATIC
    ${FATFS_DIR}/source/ff.c
    ${FATFS_DIR}/source/ffunicode.c
    ${CAOS_FATFS_DIR}/caos_ffsystem.c
)
target_include_directories(fatfs PUBLIC
    ${FATFS_DIR}/source
    ${CAOS_FATFS_DIR}
)
```

`caos_ffsystem.c` provides the FatFS-to-OS hooks required by `ff.c` when `FF_FS_REENTRANT`/dynamic allocation are enabled (mutex, malloc) adapted to caOS primitives.

21.1.3 Layer 2 — glue diskio (`fatfs_diskio.c`)

FatFS talks to the physical layer via the standard `diskio.h` interface (five functions, single drive `pdrv=0` = the SD card via `ca_sdio`):

```
DSTATUS disk_initialize(BYTE pdrv);
DSTATUS disk_status    (BYTE pdrv);
DRESULT disk_read      (BYTE pdrv, BYTE *buff, LBA_t sector, UINT count);
DRESULT disk_write     (BYTE pdrv, const BYTE *buff, LBA_t sector, UINT count);
DRESULT disk_ioctl     (BYTE pdrv, BYTE cmd, void *buff);
```

Mapping to the `ca_sdio` driver:

diskio function	Implementation
`disk_initialize`	`ca_sdio_init()`; if already initialized (`s_status==0`) no-op
`disk_status`	returns cache status (`STA_NOINIT` or 0)
`disk_read`	`ca_sdio_read_block()` loop for `count` sectors
`disk_write`	single `ca_sdio_write_blocks()` call (multi-block if `count>1`)
`disk_ioctl(CTRL_SYNC)`	`RES_OK` (no write cache to flush)
`disk_ioctl(GET_SECTOR_COUNT)`	`ca_sdio_get_block_count()`
`disk_ioctl(GET_SECTOR_SIZE)`	fixed at 512
`disk_ioctl(GET_BLOCK_SIZE)`	fixed at 1 (no erase-block hint)

`disk_write` **always** delegates to `ca_sdio_write_blocks()`, even for a single sector: it is the HW driver that decides whether to issue `CMD24` (single) or `CMD25` multi-block (see Layer 3).

An auxiliary function `disk_deinitialize(BYTE pdrv)` (declared `extern` by the caller, not part of the standard diskio interface) forces `STA_NOINIT`: used by the example after `f_fdisk()` to invalidate the cache state before the next `f_mkfs()`.

`get_fattime()` (required by FatFS for timestamps) reads the RTC via `ca_rtc_get()`; returns `0` (FatFS epoch date) if the RTC is not available.

21.1.4 Layer 3 — `ca_sdio` driver

Public API (`caos/drivers/inc/sdio.h`)

```
bool ca_sdio_init(void);
bool ca_sdio_read_block (u32 block, u8 *buf);
bool ca_sdio_write_block(u32 block, const u8 *buf);
bool ca_sdio_write_blocks(u32 block, const u8 *buf, u32 count);
u32  ca_sdio_get_block_count(void);
```

`buf` must be 4-byte aligned (HW drivers internally copy to an aligned bounce buffer when needed, but the public API requires it for efficiency). Addressing is always in **512-byte blocks** (SDHC).

Timeouts. No call waits forever: every wait on data, D0 busy and card state (CMD13) has a deadline in milliseconds, taken from the SD specification and defined per block in `sdio.h`:

Constant	Value	Reference
`CA_SDIO_READ_TIMEOUT_MS`	100 ms	maximum read access time
`CA_SDIO_WRITE_TIMEOUT_MS`	500 ms	write busy: 250 ms SDHC, 500 ms SDXC (the larger is used)

A write of `n` blocks waits at most `n  500 ms`. When the deadline passes the function returns `false`; the card is never abandoned before the time the specification grants it.

The wrapper in `caos/drivers/src/sdio.c` delegates to the `extern` functions `ca_sdio_hw_*` (one implementation per family, declared in `ca_glue_hw.h` according to the standard caOS driver pattern) and optionally registers a CLI node (`sdio info`, `sdio read <block>`) if `EN_CLI_SDIO` is enabled.

Enable defines in `os_config.h`:

```
#define EN_SDIO 1   /* driver SDIO/SDMMC */
#define EN_FAT  1   /* FatFS library + diskio glue */
```

The SDIO driver on F4xx also requires `EN_DMA=1` (the READ/WRITE data path passes through DMA2 Stream3); generic DMA initialization (`ca_dma_init()`) must be performed **before** SDIO init, which reserves the channel for the allocator.

F4xx HW Implementation (`hw/f4xx/drivers/sdio_f4xx.c`)

Pins (AF12):

Signal	Pin	Pull
D0..D3	PC8, PC9, PC10, PC11	pull-up
CLK	PC12	no pull
CMD	PD2	pull-up

Clock: 400kHz identification is mandatory per SD specification (`CLKDIV=118` → 48MHz/(118+2)), 24MHz 4-bit transfer after card selection (`CLKDIV=0` → 48MHz/2).

Data path — DMA2 Stream3 Channel4 (fixed SDIO mapping on F4xx), because pure polling at 24MHz results in `RXOVERR`:

- **READ**: *direct mode*, DMA as flow controller (`NDTR=128` word); the SDIO does not generate DMA requests below the remaining 8 words (threshold `RXFIFOHF`), so the last handful of words is drained via polling after `DBCKEND`.

- **WRITE single-block** (CMD24): *FIFO mode*, threshold=full, PFCTRL (the **SDIO** is the flow controller, not the DMA — RM0090 §31.3.2 point 4.d), burst INCR4 on peripheral and memory.
- **WRITE multi-block** (CMD25): in chunks of SDIO_BOUNCE_BLOCKS=8 blocks (4KB), with ACMD23 (pre-erase hint) before each chunk and CMD12 (STOP_TRANSMISSION) at the end — always, even on error, to bring the card out of the data state.

All transfers pass through a 32-byte aligned bounce buffer (s_bounce), because the FatFS buffer may not be 4-byte aligned while the DMA requires word alignment.

Only **SDHC/SDXC**: ca_sdio_hw_init() verifies CCS=1 in the OCR response of ACMD41 (bit 30 of RESP1) and explicitly fails if absent (init_fail("no-sdhc")).

Robustness points (portable to other families)

- **Time-based timeouts, not loop counts**: the waits were while (... && t--) loops with a fixed t, which lasted a few milliseconds and a different time on every MCU and clock. A card that took longer to program a block was abandoned in the middle of a write, and stayed in an abnormal state for minutes, even after an MCU reset (the card stays powered). Measured on H753 with inject (example 58): CK removed for 500 ms during a write gave WRITE FAIL and a wedged card; with the specification's deadlines the same write completes without errors, about 1 s longer, and the card stays healthy.

- PBURST **is not an "enable burst" flag**: it is a 2-bit field, where PBURST_0=bit0=01=INCR4 and PBURST_1=bit1=10=INCR8. INCR8 × 4B/word = 32B exceeds the DMA FIFO (16B), forbidden by RM0090 — the stream remains inert without obvious errors. Always use PBURST_0.

- **EN synchronization before reading NDTR**: after CR &= ~DMA_SxCR_EN one must wait for EN to read 0 before reading NDTR (RM0090 §10.3.14, the in-flight transfer must be completed) — otherwise the drain restarts from a wrong index and the sector results shifted by one word.

- **Clear** ICR **cross-clock-domain**: clearing STA flags crosses the SDIO_CK domain; at 400kHz these are microseconds, and an optimized binary (-O2) may re-read STA before the clear has arrived. Fix: wait_flags_clear() explicitly waits for zero after every write ICR. Bug reproducible only in **release** builds, not in debug.

H5xx / H7xx HW Implementation (SDMMC v2 with IDMA)

The H families use the **SDMMC version 2** controller, which integrates a dedicated **internal DMA (IDMA)**: a generic DMA channel is not needed (as on F4xx), the data path is entirely within the peripheral. The driver model is common to H5xx and H7xx; they differ only in two details:

	H5xx (H563)	H7xx (H753)
RCC Clock	AHB4ENR	AHB3ENR
IDMA base register	IDMABASER	IDMABASE0

Single-buffer IDMA sequence (aligned with the ST HAL order HAL_SD_ReadBlocks_DMA to avoid arming races):

1. DLEN + DCTRL (block size 512, direction; **without** DTEN: on SD, it is CMDTRANS that starts the transfer, not DTEN);

2. preset of only the CMDTRANS bit in CMD;
3. arm the IDMA: IDMABASER/IDMABASE0 = buffer, then IDMACTRL = IDMAEN;
4. command transmission (CPSMEN) — the DPSM starts with the IDMA already armed.

Completion on DATAEND. The **multi-block** (CMD25) is a single native IDMA transfer (no loop per block); CMD12 (STOP) closes the open-ended transmission after the transfer. The write then waits for the card to exit the programming state via BUSYD0 (hardware poll, no CMD13 per iteration) + a final CMD13 confirmation.

32-byte alignment quirk (fundamental). The IDMA transfers in **8-beat bursts (32 bytes)** and requires the buffer address to be 32-byte aligned; the caOS allocator only guarantees 8 bytes and FatFS passes buffers as such. With a buffer not aligned to 32, **the last half-word of the block is not committed to RAM** (last 2 bytes lost, but with valid CRC — the data arrives from the card, it is the IDMA→RAM write that loses it). The driver resolves this with a **static bounce buffer** aligned(32) **of 8 blocks (4KB)**: if the caller's buffer is 32-byte aligned, it uses direct IDMA, otherwise it goes through the bounce buffer (with memcpy for reading, copy-then-IDMA for writing; misaligned multi-block uses CMD25 in 8-block chunks).

D-cache (H7xx). caOS runs the H7 with **D-cache disabled** (the zero-copy ETH/USB stack uses non-cacheable MPU regions, so the cache has never been turned on). Consequently, IDMA buffers **do not** require cache maintenance. Warning: calling SCB_CleanDCache_by_Addr with the D-cache off generates a bus fault (imprecise write to SCB->DCCMVAC); if the D-cache were to be enabled in the future, maintenance would need to be reintroduced and conditioned on SCB->CCR & SCB_CCR_DC_Msk (cache actually active), not on __DCACHE_PRESENT. On H5xx (Cortex-M33), the D-cache is not present: no problem.

MPU heap guard (ARMv8-M, H5xx). On the H563 linker, the .heap section must be 32-byte aligned (ALIGN(32)): the heap-start MPU guard aligns _heap_start downwards to 32 bytes and, with an 8-byte heap, the RO region would encroach on the last bytes of .bss (driver state variables) → DACCVIOL. Latent on all ARMv8-M. The H753 linker (Cortex-M7) already has .heap ALIGN(32).

21.1.5 Status by family

Family	Status
F4xx (F407 tested STM32F4VE @24MHz, F446)	full driver with generic DMA (DMA2 **Stream3**; **Stream6 on the F446**, where Stream3 gets no requests): read DMA, write single CMD24 (FIFO+PFCTRL), write multi CMD25 (DMA in 8-block chunks)
H5xx (H563, tested Nucleo-H563 @25MHz)	SDMMC v2 **IDMA** + bounce aligned-32; read 1.6 MB/s, write single-block ~220 KB/s (card physical limit), mkfs ~0.5s
H7xx (H753, tested Nucleo-H753 @24MHz)	same as H5xx (IDMA+bounce); AHB3ENR/IDMABASE0; D-cache disabled → no cache maintenance; read 1.6 MB/s, write ~235 KB/s
U5xx (U575, tested Nucleo-U575 @24MHz)	like H5xx: SDMMC v2 **IDMA** + aligned-32 bounce, multi-block CMD25 in chunks; kernel clock from ICLK (CCIPR2.SDMMCSEL)

Family	Status
F7xx (F746/F767)	same IP as F4 (SDMMC1 v1): DMA2 **Stream3** channel 4 with the FIFO tail drained by hand; multi-block write as a single-block loop. No cache maintenance: the D-cache is off (`clock_f7xx.c` enables the I-cache only). No bench round recorded
F1xx	stub (no SDIO controller on the supported family)

21.1.6 File structure

File	Content
`caos/drivers/inc/sdio.h`	Public API
`caos/drivers/src/sdio.c`	public wrapper + extern HW + CLI `sdio`
`caos/drivers/inc/ca_glue_hw.h`	extern declaration `ca_sdio_hw_*`
`hw/f4xx/drivers/sdio_f4xx.c`	F4xx HW implementation, generic DMA (HW tested)
`hw/h5xx/drivers/sdio_h5xx.c`	SDMMC v2 IDMA + bounce aligned-32 (H563 HW tested)
`hw/h7xx/drivers/sdio_h7xx.c`	same as H5xx; `AHB3ENR`/`IDMABASE0`, D-cache off (H753 HW tested)
`hw/u5xx/drivers/sdio_u5xx.c`	like H5xx, IDMA + bounce (HW tested U575)
`hw/f7xx/drivers/sdio_f7xx.c`	SDMMC1 v1 with DMA2 Stream3, like F4xx
`hw/f1xx/drivers/sdio_f1xx.c`	stub
`caos/drivers/src/fatfs_diskio.c`	FatFS diskio glue → `ca_sdio`
`external/fatfs/`	FatFS library submodule (only local modification: redirect in `source/ffconf.h`)
`external/caos_fatfs/caos_ffconf.h`	caOS FatFS configuration (redirect from `source/ffconf.h`)
`external/caos_fatfs/caos_ffsystem.c`	FatFS→OS hooks (mutex/malloc)
`external/caos_fatfs/fatfs.cmake`	build `libfatfs.a`

See example chapter 58 (“FatFS on SD card: SDIO driver with DMA”) for complete practical usage: CLI `fat` (fdisk/mount/ls/blob/...), FAT context on heap, test output on real hardware.

Chapter 22

Centralized Power Manager

22.1 Centralized power manager

22.1.1 Overview

The `pwr` driver handles the **power management** of caOS: low-power modes (SLEEP/STOP/-STANDBY), CPU frequency scaling, and wakeup sources (RTC, external pin, LPTIM). It is a **centralized** power manager: the state of each peripheral is not tracked by an internal driver flag, but read **on-the-fly** directly from the hardware registers — RCC for clock gating, PWR block for voltage scaling, and wakeup flags.

```
ca_pwr_get_info()              reads RCC_xxxENR of every listed peripheral
ca_pwr_periph_table()             legge PWR->CR/CSR (VOS, standby flag)
```

No peripheral driver (`uart.c`, `spi.c`, `can.c`, ...) contains hooks to `pwr`: the information "this peripheral is powered on" is already written in the RCC enable bit since the peripheral itself was initialized, and `pwr` reads it from there. This avoids the classic (and fragile) pattern of keeping a duplicate counter/flag for each driver that must be manually kept in sync.

The subsystem follows the standard caOS driver architectural pattern, on three layers:

```
caos/drivers/inc/pwr.h          # API pubblica: ca_pwr_mode_t, ca_pwr_info_t,
    ca_pwr_enter()...
caos/drivers/src/pwr.c          # public wrapper + CLI "pwr" + retune
    coordination
        extern ca_pwr_hw_*

hw/<family>/drivers/pwr_<family>.c   # bare-metal CMSIS per family
```

Tested hardware: **U575, F407, H563, H753** (STOP and STANDBY; `stopms` on U575, H563 and H753). Reference application example: **example 59** (CLI `pwr`).

22.1.2 `pwr info` — power state snapshot

`ca_pwr_get_info(ca_pwr_info_t *info)` populates:

```
typedef struct {
    u32  sysclk_hz;         /* current SYSCLK */
    u32  sysclk_max_hz;     /* nominal SYSCLK of the board */
    u8   vos;               /* current voltage scaling; 0xFF = not available (F1)
     */
    bool standby_resume;    /* true if the boot comes from Standby */
    u16  periph_on;         /* peripherals with RCC clock active */
    u16  periph_total;      /* peripherals listed for the family */
} ca_pwr_info_t;
```

- `sysclk_hz` / `sysclk_max_hz`: useful for checking at a glance if frequency scaling (`ca_pwr_set_freq`) is active compared to the nominal value.
- `vos`: voltage scaling regulator output — on F1xx this concept does not exist (there is no VOS), so the value is conventionally `0xFF`.
- `standby_resume`: the current reset comes from a STANDBY wakeup (read once in `ca_pwr_init ()` and cached, because the HW flag is consumed/cleared at startup).
- `periph_on` / `periph_total`: count of peripherals with RCC enable bit active, based on a total census per family.

The peripheral table below is also exposed directly:

```
const ca_pwr_periph_t *ca_pwr_periph_table(u32 *count);
```

```
typedef struct {
    const char   *name;   /* es. "USART1" */
    const char   *bus;    /* es. "APB2" */
    volatile u32 *enr;    /* RCC xxxENR register */
    u32           mask;   /* clock enable bit */
} ca_pwr_periph_t;
```

Each entry points **directly** to the actual RCC register: it is not a static snapshot; the caller re-reads `*enr & mask` whenever it wants the updated state.

List of peripherals and delta vs baseline

`pwr info` **always** prints the list of peripherals with active clock, one line per bus (`AHB1:  / APB1 :  / APB2:  `). The count alone (`periph=14/81`) says little; the explicit list says *which* ones are on.

To make the information actionable, `ca_pwr_init()` captures a **read-only baseline**: a snapshot of the RCC bits that were on at the time of init ("cold"). Each subsequent `pwr info` compares the current state with that baseline and marks the deviations:

Marker	Meaning
`NOME`	on, consistent with the baseline
`NOME+`	turned on **after** init, was not in the baseline → **residual clock**
`off: NOME-`	was on at cold start, **now off**

```
pwr: sysclk=64000000/64000000 Hz  vos=1  standby_resume=no  periph=14/81
AHB1: GPIOA GPIOB DMA1+
APB1: USART2 PWR
APB2: USART1 SYSCFG RNG+
off: SPI3-
```

In the example `DMA1` and `RNG` are clocks enabled after init (candidates for shutdown before a stop), `SPI3` was turned off compared to cold boot. The baseline is **purely diagnostic**: no writes to RCC, no automatic restoration — active power gating, if needed, should be explicitly declared in the code, not derived from the hardware state.

22.1.3 Frequency scaling

```
u32 ca_pwr_set_freq(u16 scale);     /* scale = 1..99 (%) */
u32 ca_pwr_restore_freq(void);
```

`ca_pwr_set_freq` reduces SYSCLK by acting on the AHB prescaler (`HPRE`) instead of recalculating the PLL from scratch — it is the most efficient and reversible change. The delicate point is that **reducing the CPU frequency is not an isolated operation**: anyone deriving a time base from SYSCLK/HCLK must be recalibrated in a coordinated manner, otherwise it becomes silently incorrect (UART baud rate wrong, CAN bit-timing out of sync, SysTick no longer ticking at 1ms):

```
u32 ca_pwr_set_freq(u16 scale) {
    u32 f = ca_os_clock_reduce_freq(scale);
    ca_os_tick_retune();      /* SysTick: recompute the reload for 1 ms at the
    new HCLK */
    ca_uart_retune();         /* recompute BRR of every active UART */
#if EN_CAN
    ca_can_retune();          /* recomputes bxCAN/FDCAN bit timing */
#endif
    return f;
}
```

`ca_pwr_restore_freq()` performs the same coordinated retune to return to the nominal value. Peripherals with **kernel clock independent of HCLK** (USB at 48MHz, RTC on LSE/LSI) do not require retune: they are already decoupled from SYSCLK upstream.

The CLI (`pwr freq <1-99>`) also warns if the new HCLK violates a minimum constraint of currently active peripherals (e.g., Ethernet RMII requires HCLK 25MHz, USB FS DWC2 requires AHB 14.2MHz, WWDG has a window that scales with PCLK) — this is only an informative warning, it does not block the operation.

22.1.4 Low-power modes

```
int ca_pwr_enter(ca_pwr_mode_t mode, u32 wake_flags, u32 duration);
```

Mode	Behavior	Wake
`CA_PWR_MODE_SLEEP`	`WFI` simple, clock and RAM remain active	any IRQ (including SysTick)
`CA_PWR_MODE_STOP`	deepsleep, regulator in low-power, PLL off	returns to caller after clock reinit
`PWR_MODE_STANDBY`	RAM lost, almost everything off	**reset** (detectable via `standby_resume`)

`CA_PWR_MODE_SLEEP`

The simplest case: `__disable_irq()` + OS tick suspension + `WFI` + restoration. The clock remains active, so **any IRQ** (not just the declared wake source) exits the WFI. It does not require reinit of anything upon return.

`CA_PWR_MODE_STOP`

Deepsleep with regulator in low-power mode: PLL and high-frequency oscillators are turned off by the hardware upon entry. Upon wake-up, the CPU restarts on a slow default clock (MSI/HSI depending on the family), and it is necessary to **explicitly reinitialize the PLL** before doing anything else:

```
__disable_irq();
ca_os_tick_suspend();
ca_pwr_hw_enter_stop();          /* WFI in deepsleep, HW-specifico */

/* on wake-up: reinit right away, IRQs still disabled */
int rc = ca_os_clock_config();
SystemCoreClockUpdate();
ca_os_tick_retune();
ca_os_tick_resume();
ca_uart_retune();
#if EN_CAN
ca_can_retune();
#endif
__enable_irq();
```

The reinit occurs **before** re-enabling IRQs and before any `printf`/sleep: a scheduler cycle at the slow post-wake clock would cost real seconds (tasks are calibrated for the full clock) and would also skew the measurement of time spent in stop.

Critical point — the OS tick remains stopped during STOP. The time that passes in deepsleep is not counted by the scheduler: the sleeps of ongoing tasks (`ca_os_sleep`) **shift** forward by the entire duration of the stop. If an independent watchdog is active (IWDG, which runs on LSI and does not stop in stop mode), its timeout must be sized to exceed the maximum expected duration of the stop, otherwise the system will reset itself during the sleep period. The limit is `ca_wdt_max_timeout_ms(CA_WDT_TYPE_IWDG)`: ~32.7 s on F4/F7/H7, ~131 s on H5/U5 (§11.10).

`PWR_MODE_STANDBY`

The deepest mode: RAM is not retained, wake-up **is a core reset**, not a "return" from `ca_pwr_enter`. The application distinguishes a normal boot from a post-standby boot by reading `ca_pwr_info_t::standby_resume` immediately after `ca_pwr_init()`.

```
__disable_irq();
ca_os_tick_suspend();
for (u32 i = 0; i < 8U; i++) {
    NVIC->ICER[i] = 0xFFFFFFFFU;   /* disable */
    NVIC->ICPR[i] = 0xFFFFFFFFU;   /* clear pending */
}
SCB->ICSR = SCB_ICSR_PENDSVCLR_Msk | SCB_ICSR_PENDSTCLR_Msk;
ca_pwr_hw_enter_standby();   /* does not return */
```

A full purge of the NVIC (disable + clear pending on all 8 registers) before the internal `WFI` is **necessary**, not defensive: if any interrupt remains pending (typically OTG with the USB console active, or SysTick just suspended but not yet consumed), the `WFI` behaves like a nop and execution continues beyond it — meaning STANDBY is never reached, and the code hangs at the next point because there is nothing coherent left to execute (peripherals already half-powered down).

22.1.5 Wake-up sources

`wake_flags` is a bitmask that can be combined; **at least one** is mandatory (otherwise `ca_pwr_enter` rejects with `-1`, to avoid entering a low-power mode from which there is no return):

Flag	Source	Requires	duration
CA_PWR_WAKE_RTC	RTC Alarm (h:m:s match)	ca_rtc_init	**seconds**
CA_PWR_WAKE_PIN	WKUP1 pin (PA0 on most families)	—	ignored
CA_PWR_WAKE_LPTIM	LPTIM1 one-shot on LSI	**U5xx/H5xx/H7xx/F7xx**	**milliseconds** (max 262144, resolution ~31 µs)

Semantics of duration

The duration field changes **unit of measurement** depending on the flag used, because they are different hardware counters:

- CA_PWR_WAKE_RTC: duration in **SECONDS**, the absolute time now + duration is calculated (24h wrap) and programmed as a second/minute/hour match on the RTC alarm A.
- CA_PWR_WAKE_LPTIM: duration in **MILLISECONDS**, LPTIM1 counts on the LSI clock with fine resolution (up to ~31 µs), useful for rapid tests or short duty-cycle cycles where one second of RTC granularity would be too coarse.
- CA_PWR_WAKE_PIN: duration is not used (the pin is a pure external edge).

If CA_PWR_WAKE_RTC | CA_PWR_WAKE_LPTIM are combined in a single call, duration is applied to **both** with their respective units (same numerical value, interpreted twice) — in typical usage, only one timer is combined, possibly with the pin.

Wake from a driver LPTIM (EN_LPTIM)

An LPTIM driver instance initialized with wake=true (ca_lptim_init_periodic/oneshot) is an **implicit** wake-up source: ca_pwr_enter(CA_PWR_MODE_STOP, 0, 0) accepts entering Stop even with wake_flags=0 — the pwr queries ca_lptim_wake_active() and re-enables the LPTIM NVIC after the purge (on F7/H7 the EXTI 23/47 line is already armed by the driver at start). The periodic wake-armed is not touched upon wake: it continues to count and can wake subsequent Stops (ex61 phase C pattern).

Mutual exclusion guard: CA_PWR_WAKE_LPTIM (stopms) arms LPTIM1 directly, so if the driver owns LPTIM1 (ca_lptim_is_busy(1)), ca_pwr_enter with that flag returns -1.

Wake from LPUART (EN_LPUART)

Same pattern as LPTIM: an LPUART initialized with wake=true (ca_lpuart_init) is an implicit wake-up source — **receiving a character wakes the MCU** from Sleep/Stop, the byte is not lost (kernel clock HSI16+HSIKERON active in Stop) and is delivered to the callback after wake-up. The pwr queries ca_lpuart_wake_active() and re-enables the LPUART NVIC (on H7, the EXTI 34 line is armed by the driver). Typical scenario: CLI console on LPUART that responds to the first key press with the MCU in Stop (ex62).

22.1.6 Status by family

Family	STOP	STANDBY	`stopms` (LPTIM)	VOS
U575	HW tested	HW tested	HW tested	available
F407	HW tested	HW tested	not available (no LPTIM)	available
H563	HW tested	HW tested	HW tested	available
H753	HW tested	HW tested	HW tested	available
F7xx	build-only	build-only	build-only	available
F1xx	build-only	build-only	not available (no LPTIM)	`0xFF` (not applicable)

Wake-up via LPTIM (`stopms`, sub-millisecond resolution) is implemented on **U5xx, H5xx, H7xx and F7xx** and validated on U575, H563 and H753 hardware (F7xx build-only pending test board). The implementation handles the two variants of the LPTIM IP: v2 on U5/H5 (register `DIER`), v1 on H7/F7 (register `IER`, writable only when the timer is disabled); on H7 and F7, the LPTIM1 interrupt also passes through an EXTI line that must be unmasked so that the event wakes the system from STOP. F4xx and F1xx do not have an LPTIM block usable in this configuration and therefore remain limited to RTC wake-up (1s granularity) or pins.

22.1.7 Implementation notes

- **"Stale" wakeup flags**: PWR/RTC status flags signaling the last wakeup cause are stored in the backup domain, powered by the backup battery (VBAT) even when the board is powered off. A flag can therefore remain set from a previous wakeup cycle and must be **explicitly cleared before re-arming** a new wake (e.g., `ca_rtc_clear_alarm` after each use), otherwise the subsequent reading of `standby_resume` or the alarm will be ambiguous.
- **NVIC purge before STANDBY**: see above — a pending IRQ makes the `WFI` a nop. This applies to any peripheral with an active IRQ at the time of the call (typically OTG/USB or SysTick).
- **NVIC mask during STOP**: as with standby, a pending IRQ (typically OTG/USB with active CDC console) makes the `WFI` a nop and STOP is never reached. However, in the STOP path, the NVIC is still needed for wakeup: `ca_pwr_enter` therefore saves the `ISER` state, masks everything, clears pending bits, re-enables **only** the requested wake sources (hook for `ca_pwr_hw_stop_wake_nvic` family), and restores the saved state upon return.
- **HSI48 after STOP on U5xx/H5xx/H7xx**: if the CDC (USB) console is active, HSI48 (the dedicated USB kernel clock) must be **explicitly turned back on** upon wakeup from STOP, because STOP turns it off along with the rest of the high-frequency oscillators, and it is not part of the generic system PLL reinit. Without this step, the USB remains silently dead after wake, even though there is no visible error. Handled in `enter_stop` on U5, H5, and H7 (F4 is immune: the 48MHz derives from PLLQ, restored by the clock reinit).
- **IWDG and STOP duration**: as mentioned above, the OS tick is stopped during stop but IWDG (on LSI) is not — size the timeout accordingly.

22.1.8 Configuration

```
#define EN_PWR      1   /* power manager driver */
#define EN_PWR_DBG  1   /* low-power register dump via CLI "pwr dbg"     U5xx/
    F4xx only */
#define EN_CLI_PWR  1   /* CLI node "pwr" */
```

EN_PWR_DBG enables ca_pwr_hw_dbg_dump() (raw dump of relevant low-power registers) and is only available for the U5xx and F4xx families at this stage. The list of peripherals with delta vs baseline (above) is instead **always** in pwr info and does not depend on EN_PWR_DBG.

22.1.9 File structure

File	Content
caos/drivers/inc/pwr.h	Public API: ca_pwr_mode_t, ca_pwr_info_t, ca_pwr_periph_t, CA_PWR_WAKE_* flags
caos/drivers/src/pwr.c	Public wrapper + retune coordination + pwr CLI
caos/drivers/inc/ca_glue_hw.h	ca_pwr_hw_* extern declaration
hw/<family>/drivers/pwr_<family>.c	HW implementation per family (init, enter_stop, enter_standby, get_vos, max_freq, periph_table, standby_resumed, wake_pin_enable, lptim_arm/disarm, dbg_dump)

See chapter example 59 for complete practical usage: pwr CLI (info, freq, restore, sleep, stop, stopms, standby, alarm, dbg) with tests on real hardware.

Chapter 23

Migrating from FreeRTOS, Zephyr and ThreadX to caOS

23.1 Migrating from FreeRTOS, Zephyr and ThreadX to caOS

23.1.1 Overview

This chapter is for anyone who has an application written on FreeRTOS, Zephyr or ThreadX and wants to port it to caOS. Sections 1-9 cover FreeRTOS; sections 10 and 11 cover Zephyr and ThreadX and refer back to the earlier ones for everything the ports have in common. There is no compatibility layer: the code has to be rewritten on the `ca_*` API. The translation is almost always one to one, because the two kernels offer the same objects (tasks, semaphores, mutexes, queues, notifications, event groups, stream buffers, software timers). The real work is not renaming calls, but recognising the places where **the same call behaves differently**.

The chapter follows this order:

1. application structure: startup, `main`, clock;
2. tasks, priorities, stacks;
3. time and tick;
4. critical sections and scheduler lock;
5. synchronization and communication objects;
6. heap;
7. semantic differences to know before porting;
8. summary table and checklist;
9. from Zephyr to caOS (section 10);
10. from ThreadX to caOS (section 11).

caOS timeouts are in milliseconds, not ticks (section 5.1): every `xTicksToWait` must be converted, together with `portMAX_DELAY`.

23.1.2 1. Application structure

1.1 No `main`, no `vTaskStartScheduler`

In FreeRTOS the application owns `main()`: it initializes the hardware, creates the tasks and calls `vTaskStartScheduler()`, which never returns. In caOS `main()` belongs to the system: it initializes clock, memory, tick and console, then calls two functions that the application must provide.

FreeRTOS	caOS
`main()`: hardware init	`ca_os_configure()`: peripherals and services (stdout, CLI, drivers)
`main()`: `xTaskCreate(...)`	`ca_os_main()`: `ca_os_job(...)`
`vTaskStartScheduler()`	`ca_os_run(true)` at the end of `ca_os_main()`

```c
#include "caos.h"

void ca_os_configure(void) {
    EVAL_STDOUT(
        ca_stdout_init();
        ca_stdout_set_sender(STDOUT);
        ca_stdout_create_thread();
    )
}

void ca_os_main(void) {
    ca_os_job("worker", CA_TH_LEVEL3, worker, NULL,
              STACK_MEDIUM, CA_JOB_STD, CA_FAULT_ASSERT);
    ca_os_run(true);
}
```

A task created with `ca_os_job()` is **immediately schedulable**: there is no separate "start". `ca_os_run(true)` activates the scheduler but does not start anything new. To choose the start order, create the task with `ca_os_job_suspend()` (same signature, created suspended) and release it later with `ca_os_resume_handle()`.

1.2 Clock and HAL tick

caOS configures the MCU clock by itself and uses the SysTick as the system tick. From a CubeMX-generated project you must therefore **remove**:

- `SystemClock_Config()`: it would reprogram the clocks after caOS and skew the tick;
- `HAL_InitTick()` / `HAL_IncTick()`: the SysTick belongs to caOS.

caOS is bare-metal on CMSIS and does not use the HAL. Application code that calls the HAL can be kept, but the port concerns the **kernel API**, not an entire CubeMX project. Where the HAL asks for `HAL_GetTick()`, the equivalent value is `ca_os_tick_ms()`.

1.3 Configuration

`FreeRTOSConfig.h` corresponds to the project config `os_config_<project>.h`. It is not written by hand: it is generated and modified with `tools/caos_config.py` (see the configuration chapter). Optional objects have their own flag: `EN_NOTIFY`, `EN_EVENT`, `EN_STREAM`, `EN_SW_TIMER`, `EN_BARRIER`. In the FREE version the configuration is fixed and all these objects are already enabled.

23.1.3 2. Tasks

2.1 Function signature

	FreeRTOS	caOS
signature	`void f(void *arg)`	`u32 f(void *arg)`

	FreeRTOS	caOS
task end	`vTaskDelete(NULL)`, never `return`	`return 0`

The argument is the same: the pointer passed at creation. The only difference is the return type. A caOS task can **return**: the kernel removes it, frees its resources and keeps the returned value as the exit code. In FreeRTOS a `return` from a task is an error.

```
/* FreeRTOS */
static void blink(void *arg) {
    const u32 period = (u32)arg;
    for (;;) {
        toggle_led();
        vTaskDelay(pdMS_TO_TICKS(period));
    }
}
xTaskCreate(blink, "blink", 256, (void *)500, 2, NULL);

/* caOS */
static u32 blink(void *arg) {
    const u32 period = (u32)(uintptr_t)arg;
    for (;;) {
        toggle_led();
        ca_os_sleep(period);
    }
    return 0;
}
ca_os_job("blink", CA_TH_LEVEL2, blink, (void *)500,
          STACK_SMALL, CA_JOB_STD, CA_FAULT_ASSERT);
```

2.2 Creation

```
ca_task_handle_t ca_os_job(const char *name, u16 priority, ca_task_fn_t func,
                           void *arg, ca_stack_size_t stack_size,
                           ca_job_type type, u8 fault_type);
```

Compared with `xTaskCreate()` there are two extra parameters:

- `type`: `CA_JOB_STD`, or the variants with FPU context (`JOB_FLOAT_POINT`, `CA_JOB_SAFE_FLOAT_POINT`) for tasks that use floating point. In FreeRTOS the FPU context is handled by the port; in caOS it is declared.
- `fault_type`: what the kernel does if the task faults (`CA_FAULT_ASSERT`, `CA_FAULT_RESTART_THREAD`, `CA_FAULT_EXEC_EMERGENCY`, `CA_FAULT_CHECK`). In FreeRTOS a fault stops the whole system; in caOS the policy is per task.

2.3 Stack: size and placement

FreeRTOS asks for the stack in **words**; caOS in classes: `STACK_SMALL`, `STACK_MEDIUM`, `STACK_LARGE`, `STACK_KERNEL`.

The classes are **ratios** of `STACK_MIN`, which changes with the family:

MCU	STACK_MIN	SMALL	MEDIUM	LARGE	KERNEL
F103	256	512 B	1 KB	1 KB	1 KB
F407, F429, F446, F746	512	1 KB	2 KB	4 KB	8 KB
F767	1024	2 KB	4 KB	8 KB	16 KB
U575, H563, H753	2048	4 KB	8 KB	16 KB	32 KB

The same `STACK_SMALL` is therefore 1 KB on an F446 and 4 KB on a U575. A task sized on a large board must be rechecked on the small ones. Actual usage can be read at runtime from the CLI.

`xTaskCreateStatic()` **has no equivalent**, and that is by design: in caOS the stack is always allocated by the kernel, in fast memory (CCM/DTCM where available), with an MPU guard and a canary. A user-supplied stack would usually end up in slower RAM and without protection. The static buffer of the FreeRTOS code is simply removed.

2.4 Handles

`TaskHandle_t` corresponds to `ca_task_handle_t`. A caOS handle contains a **generation number**: if the task has terminated and its slot has been reused, the `*_handle` functions fail instead of acting on the new task. In FreeRTOS a stale handle points to freed memory.

FreeRTOS	caOS
`xTaskGetCurrentTaskHandle()`	`ca_os_self_handle()`
`vTaskDelete(h)`	`ca_os_remove_job_handle(h)`
`vTaskDelete(NULL)`	`return 0` from the task function
`vTaskSuspend(h)` / `vTaskResume(h)`	`ca_os_suspend_handle(h)` / `ca_os_resume_handle(h)`
`vTaskPrioritySet(h, p)`	`ca_os_set_priority_handle(h, p)`

Do not store the `thid` (the numeric index of the task) instead of the handle: it is a **position** in the task list and changes when another task is removed.

2.5 Priorities: CFS levels, not fixed priorities

This is the deepest difference between the two kernels.

FreeRTOS is **preemptive with fixed priorities**: the ready task with the highest priority always runs. A high-priority task that never blocks **starves** all the ones below it.

caOS uses a **weighted CFS** scheduler. The seven levels `CA_TH_LEVEL0 ... CA_TH_LEVEL6` are **weights** (1, 2, 4, 8, 16, 32, 64) that share the CPU among the ready tasks in proportion:

Two always-ready tasks	FreeRTOS (prio 3 vs 1)	caOS (LEVEL5 vs LEVEL3)
“high” task	100 %	32 / (32 + 8) = 80 %
“low” task	0 % (starved)	8 / (32 + 8) = 20 %

The idle task is outside the CFS and takes no share from anyone.

How to map: FreeRTOS priorities are spread over the levels in the same order (`tskIDLE_PRIORITY + 1` → `CA_TH_LEVEL0` or `LEVEL1`, the highest → `LEVEL6`). Code that uses priority only as “this is more important than that” ports this way. Code that relies on strict preemption for mutual exclusion must instead be **rethought**, of the kind “the high task is never interrupted by the low one, so no lock is needed”: in caOS the low task runs anyway, for its share. There a mutex or the scheduler lock is needed (section 4).

23.1.4 3. Time

3.1 The tick depends on the MCU

In FreeRTOS `configTICK_RATE_HZ` is chosen by the application, usually 1000 Hz. In caOS the tick is fixed per board (`OS_TICK_US` in `objmap.h`):

MCU	tick
F103	2 ms
F407, F429, F446, U575	250 µs
F746, F767	200 µs
H563, H747, H753	100 µs

The caOS API works almost entirely in **milliseconds**, not ticks: the `pdMS_TO_TICKS()` conversion disappears. `ca_os_tick()` returns raw ticks, `ca_os_tick_ms()` milliseconds.

3.2 Waiting

FreeRTOS	caOS
`vTaskDelay(pdMS_TO_TICKS(ms))`	`ca_os_sleep(ms)`
`vTaskDelayUntil(&last, period)`	`ca_os_sleep_until(&last_ms, period_ms)`
`xTaskGetTickCount()`	`ca_os_tick()` (ticks) / `ca_os_tick_ms()` (ms)
`taskYIELD()`	`ca_os_yield()`
`xTaskAbortDelay(h)`	`ca_os_wake_up_handle(h)` (only on a task in `ca_os_sleep`)

There is also `ca_os_delay_ms()`, but it does **not** correspond to `vTaskDelay`: it is a busy wait (with WFI) to be used **before** the scheduler, in `ca_os_configure()`. Called from a task it triggers a safeguard. From a task always use `ca_os_sleep()`.

`ca_os_sleep_until()` wants `last_ms` initialized with `ca_os_tick_ms()`:

```
u32 last = ca_os_tick_ms();
for (;;) {
    sample();
    ca_os_sleep_until(&last, 10);   /* every 10 ms, no drift */
}
```

In caOS `xTaskAbortDelay()` applies only to a task stopped in `ca_os_sleep()`. There is no way to interrupt from outside a task blocked on a semaphore, a queue or a mutex: this is a design choice. Whoever needs it uses a timeout and rechecks a condition on wake-up.

23.1.5 4. Critical sections and scheduler lock

FreeRTOS	caOS	what it blocks
`taskENTER_CRITICAL()` / `taskEXIT_CRITICAL()`	`ca_enter_critical()` / `ca_exit_critical()`	all IRQs (PRIMASK), nestable
`vTaskSuspendAll()` / `xTaskResumeAll()`	`ca_os_sched_lock()` / `ca_os_sched_unlock()`	only the context switch, IRQs enabled

`ca_os_sched_lock()` nests. While it is held, interrupts are served but the kernel does not take the CPU away from the task: a switch requested in the meantime happens at the last `ca_os_sched_unlock()`. The same rules as FreeRTOS apply: do not block (sleep, waits) while holding the lock, and do not use it from an ISR. If the task faults while holding the lock, the kernel releases it.

23.1.6 5. Synchronization and communication

5.1 Timeouts

In FreeRTOS every wait takes `TickType_t xTicksToWait`, with `0` = do not wait and `portMAX_DELAY` = forever. caOS follows the same rule for **all** blocking objects (semaphores, mutexes, condvars, queues, notifications, event groups, streams, message buffers), but the value is in **milliseconds**:

FreeRTOS	caOS
`0`	`CA_NO_WAIT_TIME` (equals 0)
`pdMS_TO_TICKS(ms)`	`ms`
`portMAX_DELAY`	`CA_WAIT_FOREVER`

The two constants are in `common.h`. There are also calls without a timeout, equivalent to `CA_WAIT_FOREVER` (`ca_sem_wait`, `ca_mutex_lock`, `ca_cond_wait`) and to `CA_NO_WAIT_TIME` (`ca_sem_trywait`, `ca_mutex_trylock`, `ca_queue_*_trysend` / `*_tryreceive`).

5.2 Semaphores and mutexes

FreeRTOS	caOS
`xSemaphoreCreateBinary()`	`ca_sem_init(&s, "name", 0, 1)`
`xSemaphoreCreateCounting(max, init)`	`ca_sem_init(&s, "name", init, max)` (note the order)
`xSemaphoreTake(s, t)`	`ca_sem_timedwait(&s, ms)` / `ca_sem_wait(&s)`
`xSemaphoreGive(s)` / `...FromISR`	`ca_sem_post(&s)` (also valid from ISR)
`xSemaphoreCreateMutex()`	`ca_mutex_init(&m)`
`xSemaphoreTake(m, t)` / `Give(m)`	`ca_mutex_timedlock(&m, ms)` / `ca_mutex_lock(&m)` / `ca_mutex_unlock(&m)`
`xSemaphoreCreateRecursiveMutex()`	`ca_rmutex_init(&r)`, then `ca_rmutex_lock/unlock`

There is no `Create` that allocates and returns a handle: the object's memory is supplied by the caller and the `*_init` initializes it. It can be a static variable, a field of another struct or a heap block. For an object created at runtime and shared between tasks, the counterpart of `xSemaphoreCreate*()` is `ca_memory_allocate_shared()` followed by the `*_init`. With `ca_memory_allocate()`, instead, the object would disappear when the task that created it exits (section 6).

```
ca_semaphore_t *s = ca_memory_allocate_shared(sizeof(ca_semaphore_t));
if (s != NULL) {
    ca_sem_init(s, "rx", 0, 1);     /* = xSemaphoreCreateBinary() */
}
```

In FreeRTOS `xSemaphoreGive()` on a semaphore already at its maximum fails silently. In caOS the same case is written `ca_sem_post_capped()`, designed for ISRs that signal an event and need not care whether the task is lagging behind.

caOS mutexes have **priority inheritance** (Zephyr scheme): the holder of the mutex inherits the level of the highest waiter and gives it back on unlock.

5.3 Queues

caOS has two variants with the same API: `ca_queue_static_*` (buffer declared with `CAQUEUE_STATIC_DEFINE`) and `ca_queue_heap_*` (buffer from the heap, `ca_queue_heap_init` / `ca_queue_heap_destroy`).

FreeRTOS	caOS (static variant)
`xQueueCreateStatic(n, size, ...)`	`CAQUEUE_STATIC_DEFINE(q, n, size)`
`xQueueCreate(n, size)`	`ca_queue_heap_init(&q, size, n)`
`xQueueSend` / `xQueueSendToBack`	`ca_queue_static_send(&q.q, &x, ms)`
`xQueueSendToFront`	`ca_queue_static_send_front(&q.q, &x, ms)`
`xQueueReceive`	`ca_queue_static_receive(&q.q, &x, ms)`
`xQueuePeek`	`ca_queue_static_peek(&q.q, &x)`
`xQueueOverwrite`	`ca_queue_static_overwrite(&q.q, &x)` (single-element queues only)
`xQueueReset`	`ca_queue_static_reset(&q.q)`
`uxQueueMessagesWaiting` / `uxQueueSpacesAvailable`	`ca_queue_static_count` / `ca_queue_static_available`
`xQueueSendFromISR` / `xQueueReceiveFromISR`	`ca_queue_static_send_isr` / `ca_queue_static_receive_isr`

```c
/* FreeRTOS */
QueueHandle_t q = xQueueCreate(8, sizeof(msg_t));
xQueueSend(q, &m, portMAX_DELAY);
if (xQueueReceive(q, &m, 0) == pdTRUE) { ... }       /* poll */

/* caOS */
CAQUEUE_STATIC_DEFINE(q, 8, sizeof(msg_t));
ca_queue_static_send(&q.q, &m, CA_WAIT_FOREVER);
if (ca_queue_static_receive(&q.q, &m, CA_NO_WAIT_TIME)) { ... }  /* poll */
```

Queues are always used through the `.q` member of the union defined by the macro.

5.4 Task notifications

FreeRTOS	caOS
`xTaskNotify(h, v, eSetBits)`	`ca_notify_send_handle(h, v, CA_NOTIFY_ACTION_SET_BITS)`
`xTaskNotify(h, v, eIncrement)`	`... CA_NOTIFY_ACTION_INCREMENT`
`xTaskNotify(h, v, eSetValueWithOverwrite)`	`... CA_NOTIFY_ACTION_OVERWRITE`
`xTaskNotify(h, v, eSetValueWithoutOverwrite)`	`... CA_NOTIFY_ACTION_SET_IF_EMPTY`
`xTaskNotify(h, 0, eNoAction)`	`... CA_NOTIFY_ACTION_NONE`
`xTaskNotifyGive(h)`	`ca_notify_give_inc(h)`
`ulTaskNotifyTake(pdTRUE, t)`	`ca_notify_take(ms)`
`xTaskNotifyWait(0, clrExit, &v, t)`	`v = ca_notify_wait(clear_on_exit, ms)`
`...FromISR`	`ca_notify_send_handle_isr(h, v, action)`

`ca_notify_give(h, v)` is **not** `xTaskNotifyGive`: it writes the value (`OVERWRITE`), it does not increment. The counterpart of `xTaskNotifyGive` is `ca_notify_give_inc(h)`.

`ca_notify_wait()` returns the received value, and `0` both on timeout and when the notification value was zero: a protocol that uses the value zero must be rethought. `ulBitsToClearOnEntry` of `xTaskNotifyWait` has no parameter: it is obtained with `ca_notify_clear(0xFFFFFFFF)` before the wait.

5.5 Event groups

FreeRTOS	caOS
`xEventGroupCreate()`	`ca_event_init(&eg)`
`xEventGroupSetBits` / `...FromISR`	`ca_event_set(&eg, bits)` / `ca_event_set_isr`
`xEventGroupClearBits`	`ca_event_clear(&eg, bits)`
`xEventGroupWaitBits(eg, b, clr, pdTRUE, t)`	`ca_event_wait_all(&eg, b, clr, ms)`
`xEventGroupWaitBits(eg, b, clr, pdFALSE, t)`	`ca_event_wait_any(&eg, b, clr, ms)`
`xEventGroupGetBits`	`ca_event_get(&eg)`
`xEventGroupSync`	no direct equivalent; for a rendezvous of N tasks: `ca_barrier_init` / `ca_barrier_wait`

5.6 Stream and message buffers

FreeRTOS	caOS
`xStreamBufferCreate(size, trig)`	`ca_stream_init(&sb, size)`, then `ca_stream_set_trigger`
`xStreamBufferCreateStatic`	`ca_stream_init_static(&sb, buf, size)`
`xStreamBufferSend` / `Receive`	`ca_stream_send` / `ca_stream_receive`
`...FromISR`	`ca_stream_send_isr` / `ca_stream_receive_isr`
`xMessageBuffer*`	`ca_stream_*` with the message length written at the head by the application

5.7 Software timers

FreeRTOS	caOS
(daemon task, `configUSE_TIMERS`)	`ca_sw_timer_init()` once, before creating timers
`xTimerCreate(name, period, autoReload, id, cb)`	`ca_sw_timer_create(period_ms, CA_TIMER_PERIODIC / CA_TIMER_ONE_SHOT, cb, arg)`
`xTimerStart` / `Stop` / `Reset`	`ca_sw_timer_start` / `ca_sw_timer_stop` / `ca_sw_timer_reset`
`xTimerChangePeriod`	`ca_sw_timer_set_period`
`xTimerDelete`	`ca_sw_timer_delete`
`...FromISR`	`_isr` variants

The callback has signature `void cb(void *arg)` and, as in FreeRTOS, runs in the timer service task: it must not block.

23.1.7 6. Heap

FreeRTOS	caOS
`pvPortMalloc(n)`	`ca_memory_allocate_shared(n)`
`vPortFree(p)`	`ca_memory_free(p, NULL, false)`
`xPortGetFreeHeapSize()`	`ca_memory_get_avail_memory()`

In caOS every block allocated with `ca_memory_allocate()` **belongs to the task** that requested it, and the kernel frees it when the task terminates or is removed: no memory leaks from finished tasks. In FreeRTOS memory from `pvPortMalloc()` has no owner.

FreeRTOS code often allocates in one task and passes the block to another (a message, a buffer, a shared object). If the allocating task terminates first, with `ca_memory_allocate()` the block would be freed from under the recipient. This is why the counterpart of `pvPortMalloc` is `ca_memory_allocate_shared()`: same heap, no owner, freed only by `ca_memory_free()`. Use `ca_memory_allocate()` only where the block really stays with the task.

The third argument of `ca_memory_free()` (`wiped`) zeroes the block before freeing it: use it for keys and sensitive data.

23.1.8 7. Semantic differences

The translated code compiles and works; what can change is **timing** and **ordering**. These points must be known before the port, not discovered after.

Weighted scheduler (section 2.5). A high-level task does not starve the low ones. Code that uses priority as an implicit lock must be protected with a mutex or with `ca_os_sched_lock()`.

An ISR does not bring the switch forward. In FreeRTOS `portYIELD_FROM_ISR(pdTRUE)` makes the woken task run as soon as the ISR ends. In caOS the task woken by an ISR starts at the next scheduler pass: at the tick, or earlier if the running task yields by itself. The exception is when the ISR interrupts the idle task: then the switch is immediate. The ISR→task latency is therefore at most one tick (100–250 µs on the current MCUs). This is a choice for predictability: no interrupt lengthens or shortens a task's slice. Work with a tight deadline goes **in the ISR**, the task keeps the processing. `portYIELD_FROM_ISR` is removed from the code.

FIFO wake-up order. In FreeRTOS, on a contended queue or semaphore, the highest-priority waiter is woken. In caOS **the first to arrive** is woken; the priority only decides how much CPU it gets afterwards. Code that relies on "the most important task always takes the semaphore first" must be reviewed.

No interruption of waits. See section 3.2: use a timeout.

Handles with generation. A stale handle fails, it does not hit another task (section 2.4).

Per-task faults. A task fault does not stop the system if the task is created with `CA_FAULT_RESTART_THREAD`: the kernel removes it, frees its resources and restarts it. `configASSERT` corresponds to `CA_SAFEGUARD(cond, msg)`, which uses the same mechanism.

Stacks always protected. MPU guard and canary on every stack replace `configCHECK_FOR_STACK_OVERFLOW` and `vApplicationStackOverflowHook`, with no configuration.

Per-task watchdog. `ca_os_thread_set_watchdog(cycles)` sets a CPU-cycle budget for the calling task; if it is exceeded, the kernel removes the task (`task watchdog on!`). `ca_os_thread_reset_watchdog()` resets the count. Only running time is counted: it detects a task that consumes too much CPU, not one stuck in a wait.

23.1.9 8. Summary table

FreeRTOS	caOS
`main` + `vTaskStartScheduler`	`ca_os_configure` + `ca_os_main` + `ca_os_run(true)`
`xTaskCreate`	`ca_os_job` (`ca_os_job_suspend` to start suspended)
`xTaskCreateStatic`	`ca_os_job` (stack always owned by the kernel)
`vTaskDelete`	`ca_os_remove_job_handle` / `return 0`

FreeRTOS	caOS
`vTaskDelay` / `vTaskDelayUntil`	`ca_os_sleep` / `ca_os_sleep_until`
`vTaskSuspend` / `vTaskResume`	`ca_os_suspend_handle` / `ca_os_resume_handle`
`vTaskPrioritySet`	`ca_os_set_priority_handle`
`taskYIELD`	`ca_os_yield`
`portYIELD_FROM_ISR`	(removed)
`taskENTER/EXIT_CRITICAL`	`ca_enter_critical` / `ca_exit_critical`
`vTaskSuspendAll` / `xTaskResumeAll`	`ca_os_sched_lock` / `ca_os_sched_unlock`
semaphores, mutexes	`ca_sem_*`, `ca_mutex_*`, `ca_rmutex_*`
queues	`ca_queue_static_*`, `ca_queue_heap_*`
notifications	`ca_notify_*`
event groups	`ca_event_*`
stream / message buffers	`ca_stream_*`
software timers	`ca_sw_timer_*`
`pvPortMalloc` / `vPortFree`	`ca_memory_allocate_shared` / `ca_memory_free`
`configASSERT`	`CA_SAFEGUARD`

Left out, with no equivalent: queue sets, co-routines, FreeRTOS MPU wrappers, SMP.

23.1.10 9. Porting checklist

1. `main()` becomes `ca_os_configure()` + `ca_os_main()`; remove `SystemClock_Config()` and the HAL tick.
2. Task signatures from `void f(void *arg)` to `u32 f(void *arg)`, with `return 0` instead of `vTaskDelete (NULL)`.
3. Stacks from words to `STACK_*` classes, rechecked on the smallest board.
4. Priorities on the `CA_TH_LEVEL0..6` levels; look for code that uses priority as mutual exclusion.
5. `vTaskDelay` → `ca_os_sleep`, never `ca_os_delay_ms` from a task.
6. Timeouts from ticks to milliseconds; `portMAX_DELAY` → `CA_WAIT_FOREVER`.
7. `xTaskNotifyGive` → `ca_notify_give_inc`, not `ca_notify_give`.
8. `pvPortMalloc` → `ca_memory_allocate_shared` where the block passes between tasks.
9. Remove `portYIELD_FROM_ISR`; move work with a tight deadline into the ISR.
10. Check code that relies on priority-ordered wake-up on IPC.

23.1.11 10. From Zephyr to caOS

Zephyr is closer to caOS than FreeRTOS: timeouts have the same form, the scheduler lock has the same semantics, and the priority inheritance of caOS mutexes follows the Zephyr scheme. This section reports only what is specific to Zephyr; for startup, stacks, tick, heap and scheduling differences, sections 1-7 apply.

10.1 Direct correspondences

Zephyr	caOS	Note
`K_NO_WAIT` / `K_FOREVER` / `K_MSEC(ms)`	`CA_NO_WAIT_TIME` / `CA_WAIT_FOREVER` / `ms`	same semantics on all objects
`k_msleep(ms)`, `k_sleep(K_MSEC(ms))`	`ca_os_sleep(ms)`	

Zephyr	caOS	Note
`k_yield()`	`ca_os_yield()`	
`k_wakeup(t)`	`ca_os_wake_up_handle(h)`	in both it only wakes a sleeping thread
`k_current_get()`	`ca_os_self_handle()`	
`k_thread_suspend` / `k_thread_resume`	`ca_os_suspend_handle` / `ca_os_resume_handle`	
`k_thread_abort(t)`	`ca_os_remove_job_handle(h)`	
`k_thread_priority_set(t, p)`	`ca_os_set_priority_handle(h, p)`	different scale, section 10.2
`k_sched_lock()` / `k_sched_unlock()`	`ca_os_sched_lock()` / `ca_os_sched_unlock()`	nestable, IRQs enabled
`irq_lock()` / `irq_unlock(key)`	`ca_enter_critical()` / `ca_exit_critical()`	
`k_spin_lock` / `k_spin_unlock`	`ca_spinlock_lock_irq` / `ca_spinlock_unlock_irq`	
`k_sem_init(s, init, limit)`	`ca_sem_init(&s, "name", init, limit)`	
`k_sem_take(s, t)` / `k_sem_give(s)`	`ca_sem_timedwait(&s, ms)` / `ca_sem_post(&s)`	`give` beyond the limit: `ca_sem_post_capped`
`k_sem_count_get(s)`	`ca_sem_getvalue(&s)`	
`k_condvar_wait(cv, m, t)` / `signal` / `broadcast`	`ca_cond_timedwait(&cv, &m, ms)` / `ca_cond_signal` / `ca_cond_broadcast`	
`K_MSGQ_DEFINE(q, size, n, align)`	`CAQUEUE_STATIC_DEFINE(q, n, size)`	
`k_msgq_put` / `k_msgq_get` / `k_msgq_peek` / `k_msgq_purge`	`ca_queue_static_send` / `_receive` / `_peek` / `_reset`	
`k_event_post` (OR of the bits)	`ca_event_set`	
`k_event_set` (replaces the bits)	`ca_event_clear` + `ca_event_set`	
`k_event_wait` / `k_event_wait_all`	`ca_event_wait_any` / `ca_event_wait_all`	
`k_pipe_put` / `k_pipe_get`	`ca_stream_send` / `ca_stream_receive`	
`k_malloc` / `k_free`	`ca_memory_allocate_shared` / `ca_memory_free`	section 6

10.2 Correspondences with adaptation

Thread function. In Zephyr the signature is `void f(void *p1, void *p2, void *p3)`, in caOS `u32 f(void *arg)`. When more parameters are needed they are gathered in a struct and its address is passed; it must stay valid for the whole life of the thread (static, or allocated with `ca_memory_allocate_shared`).

Stack and static definition. `K_THREAD_STACK_DEFINE` and `K_THREAD_DEFINE` have no equivalent: the stack is always allocated by the kernel, in fast, protected memory (section 2.3). `k_thread_create(...)` becomes `ca_os_job(...)`; a thread created with a start delay is created with `ca_os_job_suspend()` and released with `ca_os_resume_handle()` at the right moment.

Priorities and cooperative threads. In Zephyr a lower number means a higher priority, and negative values denote **cooperative** threads, which are never interrupted by another thread. caOS has seven weighted CFS levels (section 2.5), with the highest at `CA_TH_LEVEL6`, and has no

cooperative threads. A cooperative thread is ported as a normal thread; the sections that rely on not being interrupted are enclosed between `ca_os_sched_lock()` and `ca_os_sched_unlock()`.

Recursive mutex. `k_mutex` is **recursive** and has priority inheritance. In caOS the two properties live in different objects: `ca_mutex_*` has priority inheritance but is not recursive, `ca_rmutex_*` is recursive but without priority inheritance. Code that re-takes a mutex it already owns must be ported to `ca_rmutex_*` and loses priority inheritance; where priority inheritance is needed, the re-entry must be removed. This is the most insidious difference of the port, because a `ca_mutex_lock` repeated by the same task gives no compilation error.

Timers. In Zephyr the expiry function of `k_timer` runs in **ISR** context; in caOS the one of `ca_sw_timer_*` runs in the timer service task (section 5.7). Code written for Zephyr is already ISR-safe and works as is; `k_timer_status_sync()` has no equivalent and is replaced by a semaphore given by the callback.

Workqueues. `k_work_submit` corresponds to `ca_pool_submit` (thread pool, dedicated chapter). Delayed work (`k_work_schedule`) is obtained with a one-shot `ca_sw_timer` whose callback calls `ca_pool_submit`.

FIFOs, LIFOs, queues and pointer stacks. `k_fifo`, `k_lifo`, `k_queue` and `k_stack` are pointer queues with no size limit. In caOS they become a fixed-capacity queue holding pointers (`CAQUEUE_STATIC_DEFINE(q, n, sizeof(void *))`); LIFO behaviour is obtained with `ca_queue_static_send_front`. The capacity must be sized: where Zephyr always enqueues, caOS can answer "queue full".

10.3 Semantic differences

They are the same as for the FreeRTOS port (section 7):

- **Wake-up order**: Zephyr wakes by priority, caOS in order of arrival (FIFO).
- **Wake-up from ISR**: Zephyr switches thread on ISR exit if the woken one has higher priority; caOS at the next tick, unless the ISR interrupted the idle task.
- **Faults**: instead of `k_sys_fatal_error_handler`, caOS applies a per-task policy (`fault_type`) and can call an emergency handler (`ca_task_set_emergency_exec`). MPU guard and canary are active on every stack with no configuration, unlike `CONFIG_MPU_STACK_GUARD`.

10.4 Out of scope

The port concerns the kernel API. The following are left out and must be rewritten on the caOS counterparts:

Zephyr	caOS
Kconfig, `prj.conf`, devicetree	project config (`os_config_*.h`) and the board's `objmap.h`
driver model (`DEVICE_DT_GET`, `gpio_pin_configure_dt`, ...)	`ca_*` drivers indexed by peripheral number
`LOG_INF` / `LOG_ERR`	`ca_stdout_printf_n`
shell	CLI (`ca_cli_register`)
BSD sockets	`ca_tcp_*`, `ca_udp_*`

No equivalent: userspace, SMP, `k_poll`, `k_mbox`.

23.1.12 11. From ThreadX to caOS

ThreadX (Azure RTOS, now Eclipse ThreadX) has a small, regular API: every object has `tx_<object>_create`, operations return a code (`TX_SUCCESS`, `TX_NO_INSTANCE`, ...) and all waits take a timeout in ticks. Two fundamental choices coincide with caOS: wait lists are **FIFO** by default, and the values `TX_NO_WAIT` (0) and `TX_WAIT_FOREVER` (`0xFFFFFFFF`) are the same as `CA_NO_WAIT_TIME` and `CA_WAIT_FOREVER`. The unit changes: ThreadX counts in ticks, caOS in milliseconds.

11.1 Startup

`main()` calls `tx_kernel_enter()`, which calls `tx_application_define()` where the objects are created, and then never returns. In caOS the content of `tx_application_define()` goes into `ca_os_main()`, followed by `ca_os_run(true)` (section 1.1). The `first_unused_memory` parameter, used to carve out memory pools, has no equivalent: the caOS heap is already initialized by the system.

11.2 Direct correspondences

ThreadX	caOS	Note
`TX_NO_WAIT` / `TX_WAIT_FOREVER` / ticks	`CA_NO_WAIT_TIME` / `CA_WAIT_FOREVER` / ms	same values, different unit
`tx_thread_sleep(ticks)`	`ca_os_sleep(ms)`	
`tx_thread_relinquish()`	`ca_os_yield()`	
`tx_thread_identify()`	`ca_os_self_handle()`	
`tx_thread_suspend` / `tx_thread_resume`	`ca_os_suspend_handle` / `ca_os_resume_handle`	
`tx_thread_terminate` + `tx_thread_delete`	`ca_os_remove_job_handle`	
`tx_thread_priority_change`	`ca_os_set_priority_handle`	different scale, section 11.3
`tx_thread_wait_abort`	`ca_os_wake_up_handle`	only on a task in `ca_os_sleep` (section 3.2)
`tx_interrupt_control(TX_INT_DISABLE / restore)`	`ca_enter_critical()` / `ca_exit_critical()`	
`tx_semaphore_get(&s, t)` / `tx_semaphore_put(&s)`	`ca_sem_timedwait(&s, ms)` / `ca_sem_post(&s)`	
`tx_semaphore_ceiling_put(&s, max)`	`ca_sem_post_capped(&s)`	the ceiling is the one given to `ca_sem_init`
`tx_queue_send` / `tx_queue_receive`	`ca_queue_static_send` / `ca_queue_static_receive`	
`tx_queue_front_send` / `tx_queue_flush`	`ca_queue_static_send_front` / `ca_queue_static_reset`	
`tx_event_flags_set(&g, f, TX_OR)`	`ca_event_set(&g, f)`	
`tx_event_flags_set(&g, f, TX_AND)`	`ca_event_clear(&g, ~f)`	in ThreadX `TX_AND` clears the bits outside `f`
`tx_event_flags_get(..., TX_OR / TX_AND, ...)`	`ca_event_wait_any` / `ca_event_wait_all`	
`TX_OR_CLEAR` / `TX_AND_CLEAR`	`auto_clear = true`	
`tx_byte_allocate` / `tx_byte_release`	`ca_memory_allocate_shared` / `ca_memory_free`	section 6
`tx_block_allocate` / `tx_block_release`	`ca_block_alloc` / `ca_block_free`	`tx_block_pool_create` → `ca_block_pool_init`

11.3 Correspondences with adaptation

Thread function. ThreadX uses `void f(ULONG input)`, caOS `u32 f(void *arg)`: an integer is passed as `(void *)(uintptr_t)n` and read back with `(u32)(uintptr_t)arg`.

`tx_thread_create`**.** It takes name, entry, input, **caller-supplied stack**, priority, preemption threshold, time slice and `auto_start`. In caOS it becomes `ca_os_job()`:

- the stack is allocated by the kernel (section 2.3): the ThreadX buffer is removed and the size is converted to a `STACK_*` class;
- `TX_DONT_START` corresponds to `ca_os_job_suspend()`;
- the time slice has no parameter: CPU sharing is decided by the CFS.

Priorities and preemption threshold. In ThreadX `0` is the highest priority and the value grows towards the lower ones (32 levels by default). caOS has seven weighted levels, with the highest at `CA_TH_LEVEL6` (section 2.5). The **preemption threshold** (a thread that can be interrupted only by those above the threshold) has no equivalent: sections that use it to avoid being interrupted are enclosed between `ca_os_sched_lock()` and `ca_os_sched_unlock()`.

Mutexes. As in Zephyr, `TX_MUTEX` is **recursive**, and priority inheritance is chosen at creation (`TX_INHERIT` / `TX_NO_INHERIT`). In caOS: `TX_INHERIT` without re-entry → `ca_mutex_*`; re-entry without `TX_INHERIT` → `ca_rmutex_*`; the two together do not exist (section 10.2).

Semaphores. `tx_semaphore_create` has no maximum; `ca_sem_init` requires one. For a pure counting semaphore pass the maximum value the program can reach.

Queues. ThreadX messages are 1, 2, 4, 8 or 16 32-bit words and the buffer is supplied by the caller. In caOS the size is free, in bytes: `CAQUEUE_STATIC_DEFINE(q, n, words * 4)`.

Block pools. `ca_block_alloc` does not wait: with the pool empty it returns `NULL`. The `wait_option` of `tx_block_allocate` is obtained by pairing the pool with a counting semaphore initialized to the number of blocks.

Timers. `tx_timer_create` takes separate initial delay and reschedule period; `ca_sw_timer_create` has only one. If the two values differ, create a one-shot timer on the initial delay and have the callback reprogram it with `ca_sw_timer_set_period` and restart it. In both systems the callback runs in the timer service task, except with `TX_TIMER_PROCESS_IN_ISR`.

`tx_thread_wait_abort`**.** In ThreadX it interrupts any wait; in caOS only sleep (section 3.2). For the other waits use a timeout and a condition rechecked on wake-up.

11.4 Semantic differences

- **Wake-up order**: both FIFO by default. `tx_*_prioritize`, which moves the highest-priority waiter to the head, has no equivalent.
- **Wake-up from ISR**: ThreadX switches thread on ISR exit, caOS at the next tick (section 7).
- **Return codes**: ThreadX returns `UINT` with distinct codes (`TX_NO_INSTANCE`, `TX_QUEUE_FULL`, `TX_DELETED`, ...); caOS returns `bool` (or the data). Code that distinguishes between error cases must be rewritten.
- **Faults and stacks**: `tx_thread_stack_error_notify` and stack checking are replaced by the always-active MPU guard and canary and by the per-task fault policy (section 7).

11.5 Out of scope

Azure RTOS / ThreadX	caOS
NetX Duo	network stack `ca_net_*`, `ca_tcp_*`, `ca_udp_*`
FileX	FatFS on SDIO

Azure RTOS / ThreadX	caOS
USBX	USB device stack `caos/usb/`
TraceX	CLI command `sched` and task statistics

No equivalent: GUIX, LevelX, ThreadX Modules, SMP.

Part II

Practical Examples

Chapter 24

Hello World: the First Program on caOS

24.1 Example 1 — Hello World: the first program on caOS

24.1.1 Introduction

Every journey begins with a first step. In the world of programming, that first step is traditionally called “Hello World”: a very simple program whose sole purpose is to demonstrate that the development environment works and that our code can “talk” to the outside world.

In the case of a microcontroller, “talking to the outside world” means sending a message through a serial port (UART) or a debug channel (ITM/SWO). There is no monitor connected, there is no graphical terminal: our program lives inside a chip the size of a fingernail, and the proof that it works is a line of text that appears on a terminal connected via USB cable.

This first example is intentionally minimal. **It does not use the scheduler**, it does not create tasks, it does not leverage any advanced operating system mechanisms. It is pure sequential code, like a traditional “bare metal” program, but executed within the caOS infrastructure.

Why start so simple? Because before understanding how a multitasking system works, you must ensure that the foundations are working: the processor clock is configured correctly, the debug UART transmits, the `ca_printf` function produces readable output. If something goes wrong at this level, adding tasks and a scheduler would only complicate the diagnosis.

24.1.2 The source code

The file is located in `examples/example_1/ca_os_ex1.c`:

```
1  #include "caos.h"
2
3  /**
4   * @brief User module initialization
5   * @details Function called by the system before the scheduler starts.
6   *          In this example nothing needs initializing.
7   */
8  void ca_os_configure(void) {
9      // No extra initialization
10 }
11
12 /**
13  * @brief Main task
14  * @details Endless loop that prints a message every second.
15  *          Does not use the scheduler (no call to ca_os_run).
16  */
17 void ca_os_main(void) {
18     while(1) {
```

```
19          u32 E = 0x123;
20          u16 V = 0x456;
21          u8  T = 0x78;
22          char buffer[128];
23          ca_printf(STDOUT, buffer, sizeof(buffer),
24                    "Hello from CAOS ! E=%08X V=%04x T=%02x\r\n", E, V, T);
25          ca_os_delay_ms(1000);
26      }
27  }
```

24.1.3 Line-by-line analysis

`#include "caos.h"`

All caOS programs include a single header: `caos.h`. This file in turn includes everything necessary: type definitions (`u8`, `u16`, `u32`), kernel function prototypes, drivers, logs, and so on. There is no need to search for and include dozens of separate files.

`void ca_os_configure(void)`

This function **must be defined by the user** (even if empty). It is called by the system during initialization, before the scheduler starts. It is used to initialize additional hardware modules (I2C, SPI, USB, log, CLI, etc.). In this example, nothing is needed, so the function is empty.

`void ca_os_main(void)`

This is the entry function of the caOS application. It is the equivalent of the `main()` function in a traditional C program, but with one important difference: when `ca_os_main` is called, the system has already completed basic hardware initialization (clocks, debug peripherals, MPU, log system). The programmer finds an environment that is already ready.

The `while(1)` loop

Since in this example we **do not activate the scheduler** (we do not call `ca_os_run`), the code runs in a classic infinite loop, exactly as it would in a bare metal program. The processor executes instructions one after the other, without interruptions, without context switches, without other tasks.

The `E`, `V`, `T` variables

These are three variables of different sizes: 32-bit, 16-bit, and 8-bit. They serve as an example to demonstrate that the `ca_printf` correctly handles different hexadecimal print formats (`%08X`, `%04x`, `%02x`). In a real project, they could represent an error code, a value read from a sensor, and a status flag.

`ca_printf(STDOUT, buffer, sizeof(buffer), ...)`

This is the caOS formatted print function. It works similarly to the standard C `printf`, but with some differences designed for an embedded system:

- `STDOUT`: indicates the output channel (the debug UART or ITM, depending on the configuration in `os_config.h`).
- `buffer`: a temporary buffer provided by the caller. Unlike the library `printf`, which uses internal buffers (and is therefore not thread-safe without precautions), here the buffer is explicit and local to the function stack.

- `sizeof(buffer)`: the maximum size, to avoid buffer overflows.
- The rest is the classic `printf` format with variable arguments.

`ca_os_delay_ms(1000)`

Introduces a delay of 1000 milliseconds (1 second). This is an **active** wait function (busy-wait): the processor counts clock cycles without doing anything useful. In a system with an active scheduler, one would use `ca_os_sleep()`, which instead "puts the task to sleep" and leaves the CPU free for other tasks. But here, without a scheduler, the active delay is the only option.

24.1.4 What this example teaches us

1. **The minimum structure of a caOS program**: include `caos.h`, implement `ca_os_main`, and the system takes care of the rest.
2. **Debug output works**: if we see the message on the terminal, we know that clock, UART, and `ca_printf` are configured correctly.
3. **Without a scheduler, the behavior is sequential**: the processor executes the while loop continuously, monopolizing the CPU. This is exactly the starting "bare metal" behavior.

The next step will be to activate the scheduler and create actual tasks: that is where caOS shows its value compared to bare metal.

24.1.5 Example output

Below is the output produced by the example on the debug serial port:

```
================================================
 -- c.a.O.S --
   build : b8eeed75+dev - 2026-02-14 17:45:54
   MCU : STM 32 F:H7xx T:753
================================================
   System Clock: 480000000 Hz
   SysTick: 47999 clocks per tick
   Debug UART3 Baudrate: 4000000 bps
================================================
Hello from CAOS ! E=00000123 V=0456 T=78
Hello from CAOS ! E=00000123 V=0456 T=78
```

Chapter 25

Scheduling and Memory Allocation

25.1 Example 2 — Scheduling and memory allocation

25.1.1 Introduction

In the first example, we saw a program running in an infinite loop, by itself, without any other task. It is the simplest way to use a microcontroller, but also the most limited: if the program needs to do two things "simultaneously" (for example, reading a sensor and blinking an LED), the programmer must devise state machines, flags, and manual timing.

This second example takes a leap forward: **it activates the caOS scheduler and creates two independent tasks** that run in parallel. Furthermore, each task uses **dynamic memory allocation** to request a block of RAM from the heap, use it, and then return it to the system.

25.1.2 What is scheduling?

Imagine an office with only one desk (the CPU) and two employees (the tasks). They cannot both sit at the desk at the same time, but a supervisor (the scheduler) makes them take turns: "You work for a while, then you get up and it is the other one's turn." If an employee has nothing to do (they are sleeping with `ca_os_sleep`), the supervisor gives the desk to whoever has work to do.

This mechanism is called **cooperative/preemptive multitasking**: each task believes it has the CPU all to itself, but in reality, the scheduler alternates them so quickly (every fraction of a millisecond) that it seems they are running in parallel.

25.1.3 What is dynamic memory allocation?

In a traditional C program on a PC, when memory is needed, `malloc` is used. On a microcontroller, the situation is more delicate: RAM is scarce (tens or hundreds of KB), there is no operating system to manage virtual memory, and an error can crash the entire system.

caOS provides its own memory allocator (`ca_memory_allocate` / `ca_memory_free`) which offers important guarantees:

- **Owner tracking**: every allocated block knows which task owns it. If a task is terminated, the system can automatically free its memory.
- **MPU protection**: heap boundaries are protected by the Memory Protection Unit (MPU). If a bug causes a write beyond the heap, the processor generates a fault instead of silently corrupting other data.
- **Thread-safe**: multiple tasks can allocate and free memory simultaneously without corrupting the allocator's internal structures.

25.1.4 The source code

The file is located in `examples/example_2/ca_os_ex2.c`:

```c
#include "caos.h"

static u32 terminate;

static u32 task_1_exec(void *arg) {
    const u32 p1 = (u32)(uintptr_t)arg;
    char *p = ca_memory_allocate(1024);
    int count = 0;
    ca_stdout_printf_n("TASK 1: par1=%u", p1);
    while(terminate) {
        count++;
        ca_memset(p, 0, 1024);
        ca_stdout_printf_n("TASK 1: Hi!");
        ca_os_sleep(391);
    }
    ca_memory_free(p, NULL, false);
    return 0;
}

static u32 task_2_exec(void *arg) {
    const u32 p1 = (u32)(uintptr_t)arg;
    char *p = ca_memory_allocate(512);
    int count = 0;
    ca_stdout_printf_n("TASK 2: par1=%u", p1);
    while(terminate) {
        count++;
        ca_memset(p, 0, 50);
        ca_stdout_printf_n("TASK 2: hello!");
        ca_os_sleep(457);
    }
    ca_memory_free(p, NULL, false);
    return 0;
}

void ca_os_main(void) {
    terminate = 1;
    ca_os_job("t1_w1", CA_TH_LEVEL3, task_1_exec, (void *)(uintptr_t)1,
                       STACK_MEDIUM, CA_JOB_STD, CA_FAULT_ASSERT);
    ca_os_job("t1_w2", CA_TH_LEVEL3, task_2_exec, (void *)(uintptr_t)3,
                       STACK_MEDIUM, CA_JOB_STD, CA_FAULT_ASSERT);
    ca_os_run(true);
}
```

25.1.5 Detailed analysis

The `terminate` variable

```c
static u32 terminate;
```

It is a global variable shared between tasks. As long as it is 1, the tasks continue to run in their `while` loop. If someone were to set it to 0, both tasks would exit the loop, free the allocated memory, and terminate with `return 0`. It is a simple mechanism to control the life of tasks from the outside.

The task function

```c
static u32 task_1_exec(void *arg) {
    (void)arg;
```

Each task in caOS is a function with this signature: - `idx`: task index assigned by the scheduler (useful for debugging). - `p1`: parameter passed during task creation. It can be used for any purpose: an address, a configuration value, an ID. - **Returns** `u32`: the return value (0 = success). caOS can use it for diagnostics.

Memory allocation

```
char *p = ca_memory_allocate(1024);
```

At the beginning of the task, before entering the loop, we allocate 1024 bytes from the heap. This is an operation that must be performed with awareness:

- The allocator aligns the requested size to 8 bytes.
- Internally, it adds a management header (28 bytes) to track the block.
- The block is marked as "BUSY" and associated with the current task.
- If there is not enough memory, it returns `NULL`.

Task 2 instead allocates 512 bytes: different sizes to demonstrate that the allocator correctly handles multiple blocks of different sizes.

The work loop

```
while(terminate) {
    count++;
    ca_memset(p, 0, 1024);
    ca_stdout_printf_n("TASK 1: Hi!");
    ca_os_sleep(391);
}
```

At each iteration, the task:

1. **Increments a counter** (`count++`).
2. **Clears the allocated buffer** with `ca_memset`. In a real program, useful data would be written and read here. The zero-fill serves to demonstrate that the buffer is accessible throughout its entire length without generating faults.
3. **Prints a message** to the debug port.
4. **Sleeps** for 391 ms with `ca_os_sleep(391)`.

The crucial difference compared to the `ca_os_delay_ms` of example 1 is that `ca_os_sleep` **does not waste CPU cycles**. When a task calls `ca_os_sleep`, the scheduler puts it into the "sleeping" state and passes the CPU to another task (or to the idle task). When the time expires, the scheduler wakes it up and puts it back in the queue for execution.

The two tasks have different sleep times (391 ms and 457 ms) precisely to show that the scheduler manages them independently: they do not march in lockstep, each has its own rhythm.

Memory deallocation

```
ca_memory_free(p, NULL, false);
```

When the task exits the loop (if `terminate` becomes 0), it frees the allocated block: - `p`: the pointer to be freed. - `NULL`: we do not need to know the freed size. - `false`: we do not want a secure "wipe" of the data (useful for sensitive data such as passwords or cryptographic keys; it is not needed here).

Task creation

```
ca_os_job("t1_w1", CA_TH_LEVEL3, task_1_exec, (void *)(uintptr_t)1,
                   STACK_MEDIUM, CA_JOB_STD, CA_FAULT_ASSERT);
```

The `ca_os_job` function registers a new task in the scheduler. The parameters are:

Parameter	Value	Meaning
name	`"t1_w1"`	Readable name for debugging and logs
priority	`CA_TH_LEVEL3`	Priority level (higher = more important)
function	`task_1_exec`	The function that the task will execute
p1	`1`	Parameter passed to the function
stack	`STACK_MEDIUM`	Task stack size
type	`CA_JOB_STD`	Standard task (not daemon, not one-shot)
fault	`CA_FAULT_ASSERT`	Behavior in case of error (assert)

Starting the scheduler

```
ca_os_run(true);
```

This call starts the scheduler and never returns. From this moment on, the CPU is managed by the scheduler, which alternates between the registered tasks. The `true` parameter enables system tasks (audit log, debug CLI).

25.1.6 What this example teaches us

1. **The transition from bare metal to multitasking**: simply create the task functions, register them with `ca_os_job`, and call `ca_os_run`.
2. **`ca_os_sleep` vs `ca_os_delay_ms`**: the former is cooperative (it releases the CPU), the latter is busy-wait (it wastes cycles). In a multitasking system, always use `ca_os_sleep`.
3. **Dynamic memory is protected**: the allocator tracks who owns what, and the MPU monitors the heap boundaries.
4. **Tasks are independent**: each has its own stack, its own rhythm, and its own allocated memory. The scheduler takes care of making them coexist.

25.1.7 Example output

Below is the output produced by the example on the debug serial port:

```
================================================
 -- c.a.O.S --
   build : b8eeed75+dev - 2026-02-14 17:45:54
   MCU : STM 32 F:H7xx T:753
================================================
   System Clock: 480000000 Hz
   SysTick: 47999 clocks per tick
   Debug UART3 Baudrate: 4000000 bps
================================================
TASK 1: par1=1
TASK 2: par1=3
TASK 2: hello!
TASK 1: Hi!
TASK 1: Hi!
TASK 2: hello
```

Chapter 26

Mutex and Shared Resource Access

26.1 Example 3 — LED and GPIO CLI

26.1.1 Introduction

This example demonstrates two driver CLIs that complement each other: the one for `led.c`, which reasons in terms of the board ("turn on LED 2"), and the one for `gpio_driver.c`, which reaches any pin ("read PA0"). A monitor task blinks LD1 every second. **The example does not register any custom CLI hook**: both command sets come from their respective drivers.

The two CLIs are intentionally present together. `led` is portable and does not require knowing the pinout; `gpio` is not portable but reaches everything. On a newly arrived board, ex3 is usually the first thing to be programmed, so raw pin access is useful in the simplest example and not just in ex21/67/83.

Supported Hardware

The example **contains no pins**: how many LEDs the board has and which pins they are on is stated by `CA_LED_TABLE` in the board's `objmap.h`, and the example reaches it only through the `ca_led_*` API. It therefore runs on any part without modifications, and on a board with only one LED (F407, F103) `ca_led_count()` responds 1 without the need for invented pins to make the CLI compile.

Board	Available LEDs
Nucleo-H753ZI	LD1 PB0, LD2 PE1, LD3 PB14
NUCLEO-U575ZI-Q	LD1 PC7, LD2 PB7, LD3 PG2
NUCLEO-H563ZI	LD1 PB0, LD2 PF4, LD3 PG4
NUCLEO-F446ZE	LD1 PB0, LD2 PB7, LD3 PB14
STM32F4VE (F407)	D2 PA6 (only one)

CLI Commands (driver `led.c`, `EN_CLI_LED=1`)

Command	Description
`led info`	How many LEDs the board has and status of each
`led on <n>`	Turns on LED n (1..`ca_led_count()`)
`led off <n>`	Turns off LED n
`led tog <n>`	Toggle and print new status

`n` = LED index, from 1 to `ca_led_count()`. An out-of-range index fails instead of writing to a pin that does not carry an LED.

CLI Commands (driver `gpio_driver.c`, `EN_CLI_GPIO=1`)

Command	Description
`gpio info <P> <n>`	Mode, type, pull, AF and level of a pin
`gpio all <P>`	Decoding of all 16 pins of the port
`gpio get <P> <n>`	Reads the pin status
`gpio set <P> <n> <0|1>`	Writes the pin
`gpio tog <P> <n>`	Toggles the pin

`P` = A..K, `n` = 0..15.

`gpio set` and `gpio tog` write to **any** pin, LED or not. On a pin configured as an alternate function — a UART, the SWD — an active peripheral is overwritten. `info`, `all` and `get` are read-only and do not carry this risk. ### STDOUT Log (every 1 s)

```
EX3: tick=NNNNN  LED1=N
```

26.1.2 Architecture

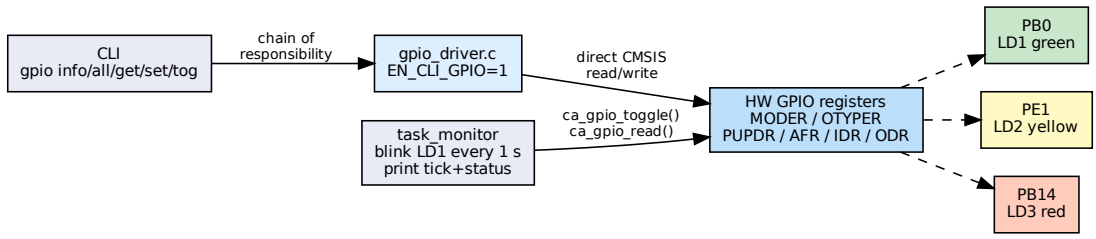

Figure 26.1: LED and GPIO CLI Architecture — Example 3

26.1.3 Source code

The file is located in `examples/example_3/ca_os_ex3.c`.

The example does not contain a pin table: `ca_led_init()` reads the `CA_LED_TABLE` of the board and configures everything itself.

```
void ca_os_configure(void)
{
    /* Clock, pin configuration and "all off" for every LED of the board */
    ca_led_init();
    ...
}
```

26.1.4 Detailed analysis

1. How the two CLIs are registered

`led.c` registers its own node within `ca_led_init()`. The GPIO node, on the other hand, is registered **only within** `ca_gpio_init_port()` and not in `ca_gpio_configure()`: this way, an application that does not touch the GPIOs does not carry that CLI along with it.

This example never calls `ca_gpio_init_port()` directly — it reaches it through the LED driver, which invokes it for the port of every declared LED:

```
/* hw/common/led.c */
ca_gpio_init_port(s_leds[i].port);
ca_gpio_configure(s_leds[i].port, s_leds[i].pin, ...);
```

Registration occurs only once thanks to the internal guard, even if the board's LEDs are on three different ports:

```
static bool s_cli_registered = false;
if (!s_cli_registered) { ca_cli_register(&s_gpio_cli_node); s_cli_registered =
    true; }
```

A practical consequence follows: `EN_CLI_GPIO=1` alone **is not enough**. If an application calls neither `ca_gpio_init_port()` nor anything that does so on its behalf, the `gpio` commands are not registered and the console responds `huh!` even though the flag is enabled.

2. Task monitor

Single task. Toggles LD1 every second with `ca_led_toggle(1)` and prints the read-back status with `ca_led_get(1)`. The other LEDs remain off at startup and are controlled only via CLI.

3. Command `gpio info <P> <n>`

Reads the MODER, OTYPER, PUPDR, AFR, and IDR registers and decodes:

Field	Register	Bit/pin	Values
Mode	MODER	2 bits per pin	IN / OUT / ALT / ANALOG
Type	OTYPER	1 bit per pin	PP (push-pull) / OD (open-drain)
Pull	PUPDR	2 bits per pin	NOPULL / PU / PD
AF	AFR[0/1]	4 bits per pin	AF0..AF15 (only if ALT)
State	IDR	1 bit per pin	0 / 1

Example:

```
> gpio info C 7
GPIO PC7: OUT  PP  NOPULL  IDR=1

> gpio info A 9
GPIO PA9: ALT  PP  NOPULL  AF7  IDR=1
```

The second line is instructive: PA9 is the AF7 of USART1, which is the console itself. It is the quickest way to verify that a pin has actually been switched to the expected peripheral.

4. `gpio all <P>` command

It iterates over the 16 pins of the port and prints the decoding of each one, preceded by a line with raw MODER and IDR for quick reference:

```
> gpio all C
GPIO PC  (MODER=A8000280 IDR=0080)
  PC7: OUT    PP NOPULL =1
  ...
```

26.1.5 Expected output

At startup

The banner has no branches for boards: the number of LEDs is declared by the board.

```
EX3: LED and GPIO CLI - this board has 3 LED(s)
Commands: led info | led on 1 | led off 1 | led tog 1
          gpio info A 0 | gpio all A | gpio get A 0   (P=A..K, n=0..15)
```

The suggestions `gpio` name only port A and only read commands: which port drives an LED changes with the board and `ca_led_*` does not expose it, so a `set` suggested on a guessed pin could drive something real.

Periodic log (every 1 s)

```
EX3: tick=1000  LED1=1
EX3: tick=2000  LED1=0
EX3: tick=3000  LED1=1
```

Typical test sequence

```
> led info
--- LEDs (3) ---
  1: ON
  2: off
  3: off

> led on 2
led 2 ON

> gpio all A
GPIO PA  (MODER=... IDR=...)
  PA0: IN     PP NOPULL =0
  ...

> gpio info A 0
GPIO PA0: IN  PP  NOPULL  IDR=0
```

26.1.6 Required configuration in `os_config.h`

```
#define ENABLE_CLI    1
#define EN_LED        1
#define EN_CLI_LED    1
#define EN_CLI_GPIO   1
#define ENABLE_STDOUT 1
```

26.1.7 Summary

1. `ca_led_init()` — clock, pins, and "all off" from `CA_LED_TABLE`, without `#if`
2. `led info|on|off|tog <n>` — LEDs in board terms, portable
3. `gpio info <P> <n>` — complete decoding of a pin from HW registers
4. `gpio all <P>` — overview of the 16 port pins
5. `gpio get/set/tog` — raw real-time I/O, on any pin
6. **No local CLI hook** — both CLIs live in their respective drivers
7. **The GPIO CLI registers in `ca_gpio_init_port()`** — you get here via `ca_led_init()`, not with a direct call

Chapter 27

Queues: Inter-Task Communication

27.1 Example 4 — Code Queue: task-to-task communication via queues

27.1.1 Introduction

In the previous examples, we saw how to create tasks, how to manage dynamic memory, and how to protect access to shared resources using mutexes. However, one fundamental element for building complex systems is still missing: **task-to-task communication**.

So far, each task has worked in isolation, or at most shared global variables protected by mutexes. But in many real-world cases, a task must **send data** to another: a sensor that acquires data and sends it to a processing task, a task that receives commands from a serial port and forwards them to a control task, or a data producer feeding a consumer.

This example introduces caOS **queues**: special data structures that allow a task to **send messages** to another in a safe, synchronized, and conflict-free manner. A queue is like a box with two openings: on one side, **producers** insert messages, and on the other, **consumers** retrieve them in the order they arrived (FIFO: First In, First Out).

In this example, we have **two producers** and **two consumers** sharing a single queue. The producers generate messages containing an ID, a sequence number, and a calculated value; the consumers receive and print them. We will see how the queue automatically handles synchronization: if the queue is full, producers wait; if it is empty, consumers wait.

27.1.2 What is a queue?

A queue in caOS is a thread-safe data structure that enables communication between tasks:

- **Producer**: a task that **inserts** messages into the queue using `ca_queue_static_send`.
- **Consumer**: a task that **retrieves** messages from the queue using `ca_queue_static_receive`.
- **Circular buffer**: the queue uses a circular array of slots, where each slot contains a message.
- **Automatic synchronization**: if the queue is full, `send` waits (or fails if a timeout occurs); if it is empty, `receive` waits (or fails if a timeout occurs).
- **FIFO order**: messages exit in the same order they entered.

Queues are particularly useful for: - Smoothing out production spikes: a fast task produces data that a slow task consumes. - Decoupling different logic: the producer does not need to know who receives the data. - Handling asynchronous events: a task receives commands or notifications from other tasks or interrupts.

27.1.3 The source code

The file is located in `examples/example_4/ca_os_ex4.c`:

```c
#include "caos.h"

/* Message exchanged between producers and consumers */
typedef struct {
    u32 producer_id;
    u32 sequence;
    u32 value;
} Message;

/* Static queue: 8 slots of Message (12 bytes each) */
#define MSG_SIZE  12
CAQUEUE_STATIC_DEFINE(msg_queue, 8, MSG_SIZE);

static u32 running;

static u32 producer_1(void *arg) {
    (void)arg;
    u32 seq = 0;
    ca_stdout_printf_n("Producer 1 started");
    while(running) {
        Message msg = { .producer_id = 1, .sequence = seq, .value = seq * 10 };
        if (ca_queue_static_send(&msg_queue.q, &msg, 500)) {
            ca_stdout_printf_n("P1 sent: seq=%u val=%u", msg.sequence, msg.value
    );
            seq++;
        } else {
            ca_stdout_printf_n("P1: queue full (timeout)");
        }
        ca_os_sleep(300);
    }
    return 0;
}

static u32 producer_2(void *arg) {
    (void)arg;
    u32 seq = 0;
    ca_stdout_printf_n("Producer 2 started");
    while(running) {
        Message msg = { .producer_id = 2, .sequence = seq, .value = seq * 100 };
        if (ca_queue_static_send(&msg_queue.q, &msg, 500)) {
            ca_stdout_printf_n("P2 sent: seq=%u val=%u", msg.sequence, msg.value
    );
            seq++;
        } else {
            ca_stdout_printf_n("P2: queue full (timeout)");
        }
        ca_os_sleep(500);
    }
    return 0;
}

static u32 consumer_1(void *arg) {
    (void)arg;
    Message msg;
    ca_stdout_printf_n("Consumer 1 started");
    while(running) {
        if (ca_queue_static_receive(&msg_queue.q, &msg, 1000)) {
            ca_stdout_printf_n("C1 recv: from P%u seq=%u val=%u",
                               msg.producer_id, msg.sequence, msg.value);
        } else {
```

```
59              ca_stdout_printf_n("C1: queue empty (timeout)");
60          }
61      }
62      return 0;
63  }
64
65  static u32 consumer_2(void *arg) {
66      (void)arg;
67      Message msg;
68      ca_stdout_printf_n("Consumer 2 started");
69      while(running) {
70          if (ca_queue_static_receive(&msg_queue.q, &msg, 1000)) {
71              ca_stdout_printf_n("C2 recv: from P%u seq=%u val=%u",
72                                 msg.producer_id, msg.sequence, msg.value);
73          } else {
74              ca_stdout_printf_n("C2: queue empty (timeout)");
75          }
76      }
77      return 0;
78  }
79
80  void ca_os_main(void) {
81      running = 1;
82
83      ca_os_job("prod_1", CA_TH_LEVEL3, producer_1, NULL,
84                          STACK_MEDIUM, CA_JOB_STD, CA_FAULT_ASSERT);
85      ca_os_job("prod_2", CA_TH_LEVEL3, producer_2, NULL,
86                          STACK_MEDIUM, CA_JOB_STD, CA_FAULT_ASSERT);
87      ca_os_job("cons_1", CA_TH_LEVEL3, consumer_1, NULL,
88                          STACK_MEDIUM, CA_JOB_STD, CA_FAULT_ASSERT);
89      ca_os_job("cons_2", CA_TH_LEVEL3, consumer_2, NULL,
90                          STACK_MEDIUM, CA_JOB_STD, CA_FAULT_ASSERT);
91
92      ca_os_run(true);
93  }
```

27.1.4 Architecture

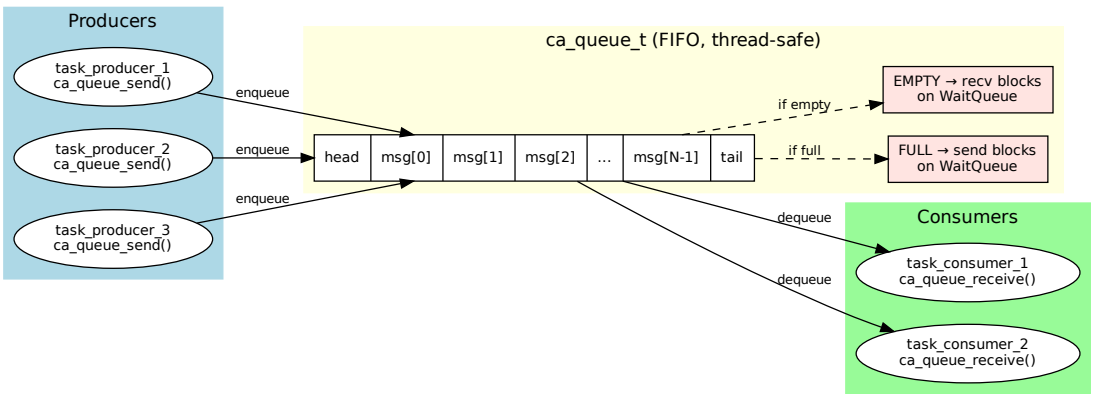

Figure 27.1: Message queue flow — producers and consumers

The diagram shows the flow of messages from the shared queue: the three producer tasks insert messages into the queue (`ca_queue_static_send`); the two consumers extract the messages (`ca_queue_static_receive`). If the queue is full, the producer blocks; if it is empty, the consumer blocks. Both wake up automatically when the state of the queue changes.

27.1.5 Detailed analysis

The message structure

```
typedef struct {
    u32 producer_id;
    u32 sequence;
    u32 value;
} Message;
```

This is the data structure that will be exchanged between producers and consumers:

- `producer_id`: identifies which producer generated the message (1 or 2).
- `sequence`: sequential message number (0, 1, 2, ...).
- `value`: value calculated by the producer (depends on the producer).

This structure represents a simple example of a useful payload: in a real system, it could contain sensor data, commands, events, processing results, etc.

Static queue definition

```
#define MSG_SIZE  12
CAQUEUE_STATIC_DEFINE(msg_queue, 8, MSG_SIZE);
```

Here we define a **static queue** (allocated in fixed RAM, not dynamic):

- `msg_queue`: name of the queue variable (it will be of type `ca_queue_static_t`).
- `8`: number of slots available in the queue (maximum capacity).
- `MSG_SIZE`: size in bytes of each message (12 bytes for the `Message` structure).

The `CAQUEUE_STATIC_DEFINE` macro automatically creates the queue data structure and the internal buffer to store the 12-byte messages. Being static, the memory is allocated at compile time and does not change during execution.

The control variable `running`

```
static u32 running;
```

As in the previous examples, this global variable controls the life of the tasks. As long as it is 1, all tasks continue to run in their `while` loop. When someone sets it to 0, all tasks will exit the loops and terminate.

The producers: `producer_1` and `producer_2`

```
static u32 producer_1(void *arg) {
    (void)arg;
    u32 seq = 0;
    ca_stdout_printf_n("Producer 1 started");
    while(running) {
        Message msg = { .producer_id = 1, .sequence = seq, .value = seq * 10 };
        if (ca_queue_static_send(&msg_queue.q, &msg, 500)) {
            ca_stdout_printf_n("P1 sent: seq=%u val=%u", msg.sequence, msg.value
    );
```

```
            seq++;
        } else {
            ca_stdout_printf_n("P1: queue full (timeout)");
        }
        ca_os_sleep(300);
    }
    return 0;
}
```

Let's analyze the operation of producer 1:

1. **Initialization**: starts with `seq = 0` and prints a startup message.
2. **Message creation**: at each iteration, it creates a new message with:
   - `producer_id = 1` (identifies the producer)
   - `sequence = seq` (progressive number)
   - `value = seq * 10` (calculated value)
3. **Message sending**: `ca_queue_static_send` attempts to insert the message into the queue:
   - **First parameter**: pointer to the queue (`&msg_queue`)
   - **Second parameter**: pointer to the message to be sent (`&msg`)
   - **Third parameter**: timeout in milliseconds (`500`)
   - Returns `true` if the sending is successful, `false` if the queue was full and the timeout expired
4. **Result handling**: if the sending is successful, it prints a message and increments `seq`; otherwise, it signals that the queue was full.
5. **Waiting**: `ca_os_sleep(300)` causes a 300 ms wait before the next message.

Producer 2 is identical, but: - It has `producer_id = 2` - It calculates `value = seq * 100` (grows more rapidly) - It waits 500 ms between one message and the next (less frequent)

This difference in frequency and value allows one to clearly see in the output which producer generated each message.

The consumers: `consumer_1` and `consumer_2`

```
static u32 consumer_1(void *arg) {
    (void)arg;
    Message msg;
    ca_stdout_printf_n("Consumer 1 started");
    while(running) {
        if (ca_queue_static_receive(&msg_queue.q, &msg, 1000)) {
            ca_stdout_printf_n("C1 recv: from P%u seq=%u val=%u",
                               msg.producer_id, msg.sequence, msg.value);
        } else {
            ca_stdout_printf_n("C1: queue empty (timeout)");
        }
    }
    return 0;
}
```

Consumers operate symmetrically to producers:

1. **Message declaration**: `Message msg` is used to receive the message.
2. **Message reception**: `ca_queue_static_receive` attempts to retrieve a message:
   - **First parameter**: pointer to the queue (`&msg_queue`)
   - **Second parameter**: pointer to the message where data should be copied (`&msg`)

- **Third parameter**: timeout in milliseconds (`1000`)
- Returns `true` if a message was received, `false` if the queue was empty and the timeout expired

3. **Result handling**: if a message is received, it prints its fields; otherwise, it signals that the queue was empty.
4. **Infinite loop**: continues as long as `running` is true.

Consumers do not have fixed waits: when the queue is full, they receive immediately; when it is empty, they wait up to 1 second for a new message.

Timeouts in queue operations

The functions `ca_queue_static_send` and `ca_queue_static_receive` accept a timeout parameter:

- `ca_queue_static_send(queue, msg, 500)`: if the queue is full, it waits for a maximum of 500 ms. If a slot becomes free within that time, it inserts the message and returns `true`. Otherwise, it returns `false`.
- `ca_queue_static_receive(queue, msg, 1000)`: if the queue is empty, it waits for a maximum of 1000 ms. If a message arrives within that time, it receives it and returns `true`. Otherwise, it returns `false`.

These timeouts are important because: - They prevent a task from blocking indefinitely if the queue is full or empty - They allow handling anomalous situations (for example, if a producer is much faster than all consumers) - They allow performing other operations while waiting (even if we do not do so in this example)

Task registration and startup

```
void ca_os_main(void) {
    running = 1;

    ca_os_job("prod_1", CA_TH_LEVEL3, producer_1, NULL,
                        STACK_MEDIUM, CA_JOB_STD, CA_FAULT_ASSERT);
    ca_os_job("prod_2", CA_TH_LEVEL3, producer_2, NULL,
                        STACK_MEDIUM, CA_JOB_STD, CA_FAULT_ASSERT);
    ca_os_job("cons_1", CA_TH_LEVEL3, consumer_1, NULL,
                        STACK_MEDIUM, CA_JOB_STD, CA_FAULT_ASSERT);
    ca_os_job("cons_2", CA_TH_LEVEL3, consumer_2, NULL,
                        STACK_MEDIUM, CA_JOB_STD, CA_FAULT_ASSERT);

    ca_os_run(true);
}
```

Here, 4 tasks are created: - Two producers (1 and 2) with different frequencies - Two consumers (1 and 2) that receive messages in FIFO order - All have the same priority (`CA_TH_LEVEL3`) and stack size (`STACK_MEDIUM`)

27.1.6 Typical execution scenario

With this configuration, an interesting communication scenario occurs:

1. **The two producers** start sending messages simultaneously:

   - Producer 1: every 300 ms, with `value = seq * 10`
   - Producer 2: every 500 ms, with `value = seq * 100`

2. **The queue** accumulates messages up to a maximum of 8 slots.
3. **The two consumers** retrieve messages in FIFO order:
   - Whoever reaches the queue first receives the oldest message
   - If the queue is empty, they wait for up to 1 second
4. **Result**: in the output, you will see messages coming from both producers, received by both consumers, in the order in which they were sent.

27.1.7 What this example teaches us

1. **Queues facilitate communication between tasks**: there is no need to share variables or use complex mutexes. Simply send and receive messages.
2. **Synchronization is automatic**: the queue takes care of managing concurrency between producers and consumers.
3. **Timeouts prevent indefinite blocking**: if the queue is full or empty, tasks can handle the situation instead of hanging.
4. **Data maintains integrity and order**: thanks to the FIFO mechanism, messages arrive in the same order they were sent.
5. **Producer-consumer architectures**: this pattern is very common in real-time systems and allows for decoupling different logic.

27.1.8 Example output

Below is the output produced by the example on the debug serial port:

```
================================================
 -- c.a.O.S --
   build : 51ada1e4+dev - 2026-02-14 18:46:10
   MCU : STM 32 F:H7xx T:753
================================================
   System Clock: 480000000 Hz
   SysTick: 47999 clocks per tick
   Debug UART3 Baudrate: 4000000 bps
================================================
Producer 1 started
P1 sent: seq=0 val=0
Producer 2 started
P2 sent: seq=0 val=0
Consumer 2 started
C2 recv: from P1 seq=0 val=0
C2 recv: from P2 seq=0 val=0
Consumer 1 started
P1 sent: seq=1 val=10
C2 recv: from P1 seq=1 val=10
P2 sent: seq=1 val=100
C1 recv: from P2 seq=1 val=100
P1 sent: seq=2 val=20
C2 recv: from P1 seq=2 val=20
P1 sent: seq=3 val=30
C1 recv: from P1 seq=3 val=30
P2 sent: seq=2 val=200
```

Chapter 28

Recursive Mutex: Handling Recursion in Multitasking

28.1 Example 5 — Recursive mutex: managing recursion in multitasking

28.1.1 Introduction

In the previous examples, we saw how standard mutexes protect access to shared resources between tasks. However, there is a specific scenario where a standard mutex is not sufficient: when a task that **already owns a mutex** attempts to acquire it again, for example due to a recursive call or a nested function.

In a standard mutex, this secondary acquisition attempt by the same task would cause a **deadlock**: the task would block itself, because it would wait for the mutex to be released, but only the task itself can do so, and it will not be able to do so until it finishes the function it is waiting for.

The **recursive mutex** solves this problem by allowing a task that is already an owner to acquire the mutex again. Each acquisition increments an **internal counter**, and only when the number of releases equals the number of acquisitions does the mutex actually become free for other tasks.

28.1.2 What is a recursive mutex?

A recursive mutex (or reentrant mutex) is an advanced version of the standard mutex that:

- Maintains an **acquisition count** (lock count)
- Tracks which task is the **current owner**
- Allows the owner to acquire the mutex additional times
- Requires an equal number of releases to actually free the mutex
- Prevents deadlock in case of multiple acquisitions by the same task

28.1.3 The source code

The file is located in `examples/example_5/ca_os_ex5.c`:

```
#include "caos.h"

static u32 running;
static ca_recursive_mutex_t rmtx;

// Recursive function that uses the recursive mutex
static void recursive_function(const char* task_name, int depth) {
```

```
8       // Try to take the recursive mutex
9       ca_rmutex_lock(&rmtx);
10
11      // Print the recursion level and the task name
12      ca_stdout_printf_n("%s: entered recursion level %d, lock count: %u",
13                         task_name, depth, ca_rmutex_get_count(&rmtx));
14
15      // If we are at a given recursion level, recurse
16      if (depth > 0) {
17          recursive_function(task_name, depth - 1);
18      }
19
20      // Print when leaving the recursion level
21      ca_stdout_printf_n("%s: exiting recursion level %d, lock count: %u",
22                         task_name, depth, ca_rmutex_get_count(&rmtx));
23
24      // Release the mutex (note: since it is recursive,
25      // we must release as many times as the locks taken)
26      ca_rmutex_unlock(&rmtx);
27  }
28
29  static u32 task_1_exec(void *arg) {
30      const u32 p1 = (u32)(uintptr_t)arg;
31      const u32 idx = ca_os_thid_from_handle(ca_os_self_handle());
32      ca_stdout_printf_n("TASK recursive_1 started: idx=%u p1=%u", idx, p1);
33
34      while(running) {
35          // Take the recursive mutex
36          ca_rmutex_lock(&rmtx);
37          ca_stdout_printf_n("TASK recursive_1 acquired mutex, lock count: %u",
38                             ca_rmutex_get_count(&rmtx));
39
40          // Call the recursive function with a given level
41          recursive_function("TASK recursive_1", 2);
42
43          ca_stdout_printf_n("TASK recursive_1 about to release mutex, lock count:
        %u",
44                             ca_rmutex_get_count(&rmtx));
45
46          // Release the recursive mutex (it is actually released
47          // only when the lock count goes back to 0)
48          ca_rmutex_unlock(&rmtx);
49
50          ca_os_sleep(1000);
51      }
52      return 0;
53  }
54
55  static u32 task_2_exec(void *arg) {
56      const u32 p1 = (u32)(uintptr_t)arg;
57      const u32 idx = ca_os_thid_from_handle(ca_os_self_handle());
58      ca_stdout_printf_n("TASK recursive_2 started: idx=%u p1=%u", idx, p1);
59
60      while(running) {
61          // Short pause to let the first task get the mutex
62          ca_os_sleep(300);
63
64          // Try to take the recursive mutex
65          if (ca_rmutex_trylock(&rmtx)) {
66              ca_stdout_printf_n("TASK recursive_2 acquired mutex, lock count: %u"
        ,
67                                 ca_rmutex_get_count(&rmtx));
68
```

```
69              // Simulate some work
70              ca_stdout_printf_n("TASK recursive_2 doing some work...");
71
72              // Release the recursive mutex
73              ca_rmutex_unlock(&rmtx);
74          } else {
75              ca_stdout_printf_n("TASK recursive_2: mutex busy (owner may be in
    recursion)");
76          }
77
78          ca_os_sleep(800);
79      }
80      return 0;
81  }
82
83  void ca_os_main(void) {
84      running = 1;
85
86      // Initialize the recursive mutex
87      ca_rmutex_init(&rmtx);
88
89      // Crea i task
90      ca_os_job("rec_1", CA_TH_LEVEL2, task_1_exec, (void *)(uintptr_t)1,
91                        STACK_MEDIUM, CA_JOB_STD, CA_FAULT_ASSERT);
92      ca_os_job("rec_2", CA_TH_LEVEL2, task_2_exec, (void *)(uintptr_t)3,
93                        STACK_MEDIUM, CA_JOB_STD, CA_FAULT_ASSERT);
94
95      ca_os_run(true);
96  }
```

28.1.4 Architecture

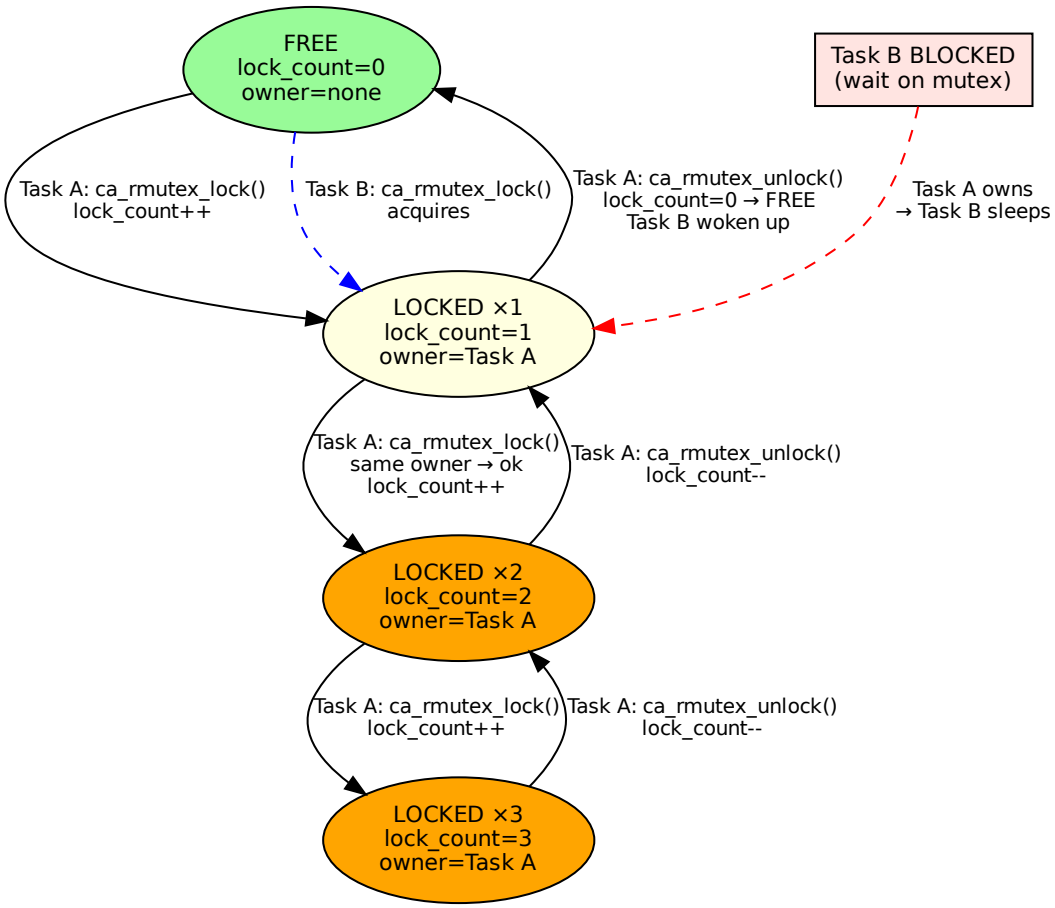

Figure 28.1: Recursive mutex states — lock count transitions

The diagram shows the state transitions of the recursive mutex. Unlike the simple mutex, the same task can acquire the lock multiple times: each call to `ca_rmutex_lock` increments the counter; only when the counter returns to zero is the mutex free and another task can acquire it. A different task that calls `ca_rmutex_lock` when the mutex is owned blocks until it is fully released.

28.1.5 Detailed analysis

Shared variables

```
1 static u32 running;
2 static ca_recursive_mutex_t rmtx;
```

- `running`: control variable to keep tasks active.
- `rmtx`: the recursive mutex shared between tasks.

Recursive mutex initialization

```
ca_rmutex_init(&rmtx);
```

As with a standard mutex, the recursive mutex must be initialized before use with the dedicated function `ca_rmutex_init`.

Recursive function

```
static void recursive_function(const char* task_name, int depth) {
    ca_rmutex_lock(&rmtx);
    ca_stdout_printf_n("%s: entered recursion level %d, lock count: %u",
                       task_name, depth, ca_rmutex_get_count(&rmtx));

    if (depth > 0) {
        recursive_function(task_name, depth - 1);
    }

    ca_stdout_printf_n("%s: exiting recursion level %d, lock count: %u",
                       task_name, depth, ca_rmutex_get_count(&rmtx));

    ca_rmutex_unlock(&rmtx);
}
```

This function demonstrates the core concept of a recursive mutex:

1. **Acquisition**: Each call to `ca_rmutex_lock` increments the internal count, even if the task is already the owner.
2. **Counting**: The `ca_rmutex_get_count` function shows how many locks are currently active.
3. **Recursion**: The function calls itself recursively, further increasing the count.
4. **Release**: Each `ca_rmutex_unlock` decrements the count, but the mutex remains occupied until the count returns to zero.

Main task (recursive_1)

The first task demonstrates the typical use of a recursive mutex:

1. Acquires the mutex with `ca_rmutex_lock`.
2. Calls the recursive function which acquires the mutex again.
3. Releases the mutex with `ca_rmutex_unlock`.

Thanks to the recursive mutex, the task does not deadlock even if it acquires the mutex multiple times.

Second task (recursive_2)

The second task shows how the recursive mutex behaves with respect to other tasks:

1. Uses `ca_rmutex_trylock` to try to acquire the mutex without blocking.
2. If the mutex is occupied (by the first task in recursion), it prints an appropriate message.
3. If it succeeds in acquiring it, it performs some work and then releases it.

Key differences from a standard mutex

- **Recursion allowed**: A task can acquire a recursive mutex multiple times without deadlock.
- **Internal counting**: The mutex keeps track of how many times it has been acquired by the same task.
- **Balanced release**: An equal number of releases is required to actually free the mutex.

28.1.6 When to use recursive mutexes

Recursive mutexes are useful in these scenarios:

1. **Recursive functions**: When a function that acquires a mutex can call itself.
2. **Nested calls**: When a function protected by a mutex calls other functions that are also protected by the same mutex.
3. **Legacy code**: When it is not possible to restructure the code to avoid multiple acquisitions.

28.1.7 Beware of potential issues

- **More complex debugging**: Since the internal count is hidden, it is more difficult to diagnose unbalanced acquisition/release issues.
- **Performance**: Recursive mutexes have a slightly higher overhead compared to standard mutexes.
- **Better design**: Often, good code design can avoid the need for recursive mutexes.

28.1.8 Important considerations for the embedded world

As indicated in the `hw/h7xx/h753/objmap.h` file, the STM32H753 microcontroller used in the Nucleo-H753ZI board has limited resources:

- **Limited stack**: Although the average stack is 8KB (`STACK_MEDIUM = 8192` bytes) and the large one is 16KB (`STACK_LARGE = 16384` bytes), recursion can quickly consume this memory.
- **Defined stack size**: As can be seen from `objmap.h`, the stack sizes are predefined and limited:

```
#define STACK_MIN       2048
typedef enum {
    STACK_SMALL  = (STACK_MIN*2),       /**< 4096 byte */
    STACK_MEDIUM = (STACK_SMALL*2),     /**< 8192 byte */
    STACK_LARGE  = (STACK_MEDIUM*2),    /**< 16384 byte */
    STACK_XLARGE = (STACK_LARGE*2),     /**< 32768 byte */
    STACK_KERNEL = (STACK_LARGE*2)      /**< 32768 byte */
} ca_stack_size_t;
```

  In the embedded world, **the use of recursion is strongly discouraged** for the following reasons:

1. **Unpredictable stack consumption**: Each recursive call adds a new frame to the stack, and in resource-constrained systems, this can very easily lead to a stack overflow.
2. **Debugging difficulty**: Stack overflow errors in embedded systems can be very difficult to diagnose.
3. **Unpredictable execution times**: The depth of recursion can vary based on input data, making it difficult to guarantee deterministic execution times.
4. **Inefficient memory usage**: Recursion requires additional stack space for each call, whereas iterative solutions are generally more efficient.

For these reasons, whenever possible, it is always better to replace recursion with an iterative solution, even if it requires restructuring the code.

28.1.9 What this example teaches us

1. **The difference between standard and recursive mutexes**: How the recursive mutex allows multiple acquisitions by the same task.
2. **Internal counting**: How the mutex keeps track of how many times it has been acquired.
3. **Deadlock prevention**: How the recursive mutex avoids deadlock in recursion scenarios.
4. **Behavior towards other tasks**: How the mutex remains occupied for other tasks as long as the count has not returned to zero.

28.1.10 Example output

Below is the output produced by the example on the debug serial port:

```
================================================
 -- c.a.O.S --
   build : 77af553c+dev - 2026-02-15 20:02:40
   MCU : STM 32 F:H7xx T:753
================================================
   System Clock: 480000000 Hz
   SysTick: 47999 clocks per tick
   Debug UART3 Baudrate: 4000000 bps
================================================
TASK recursive_1 started: idx=3 p1=1
TASK recursive_1 acquired mutex, lock count: 1
TASK recursive_2 started: idx=4 p1=3
TASK recursive_1: entered recursion level 2, lock count: 2
TASK recursive_1: entered recursion level 1, lock count: 3
TASK recursive_1: entered recursion level 0, lock count: 4
TASK recursive_1: exiting recursion level 0, lock count: 4
TASK recursive_1: exiting recursion level 1, lock count: 3
TASK recursive_1: exiting recursion level 2, lock count: 2
TASK recursive_1 about to release mutex, lock count: 1
TASK recursive_2 acquired mutex, lock count: 1
TASK recursive_2 doing some work...
```

28.1.11 Verification of waits with timeout (`twait`)

Since 09/27, a task waiting for a recursive mutex **with timeout** (`ca_rmutex_timedlock()`) is added to the same wait list as those waiting without a timeout, parked in `SLEEP` until expiration, and the signaler wakes it up immediately (S2_02 §8.8). Previously, it performed polling every 10 ms outside the list: it would wake up up to 10 ms after the signal.

The command `twait [sec]` (default 3 s) measures it with a peer task created at the first call. The wait runs in the command task:

1. **latency** — 300 cycles: the peer holds the mutex and releases it after a random 1..8 ms; the waiter, with a 20 ms timeout, must obtain it (`lost=0`), not before the signal (`spur=0`), and be running within 2 ms (`lat_max` limit, in ticks);
2. **timeout** — the peer holds the mutex for the entire test; for `sec` seconds, T = 1..20 ms: the return never arrives **before** T (`early=0`), at most 2 ms later (`late=0`), and always with `false` (`got=0`).

One line, terminated by `PASS` or `FAIL`. On H753 (tick 200 µs):

```
TW rmutex : rounds=300 lat_max=0/10 lost=0 spur=0 | tmo n=291 early=0 late=0 got
   =0 over_max=0/10  PASS
```

On the previous kernel: FAIL, `lat_max=50/10`: the 10 ms polling.

In the bank is case `timed_wait` of `test_ex05.cpp` (helper `test/hw_test/inc/caosTimedWait.h`). Manually:

```
caos_shell -e 5 -q -t 40 -u "TW .*(PASS|FAIL)" -g "^TW" "twait 3"
```

Chapter 29

Semaphore: Controlling Access to Shared Resources

29.1 Example 6 — Semaphore: controlling access to shared resources

29.1.1 Introduction

In the previous examples, we saw how mutexes protect exclusive access to shared resources between tasks. However, there is a different scenario where we have **a pool of identical resources** and we want to limit the number of tasks that can access these resources simultaneously. In this case, mutexes are not the ideal solution, because they allow access to only one instance of the resource.

The **semaphore** is the right synchronization primitive for this scenario. Unlike the mutex, which is binary (it can only be free or occupied), a semaphore maintains a **count** of available resources. When a task requests a resource, the count decreases; when it releases it, the count increases. If the count is zero, subsequent tasks are blocked while waiting.

In this example, we simulate a shared resource control system using a semaphore to limit the number of tasks that can simultaneously access a pool of resources.

29.1.2 What is a semaphore?

A semaphore is a synchronization primitive that:

- Maintains a **count of available resources**
- Allows multiple tasks to access simultaneously up to a maximum limit
- Blocks tasks when all resources are occupied
- Unblocks tasks when a resource becomes available

Semaphores are particularly useful for:

1. **Traffic control**: Limiting the number of tasks that can access a resource
2. **Resource pools**: Managing a limited set of identical resources
3. **Producer-consumer synchronization**: Coordinating tasks that produce and consume data

29.1.3 The source code

The file is located in `examples/example_6/ca_os_ex6.c`:

```c
#include "caos.h"

/*
 * Example of semaphore usage
 *
 * In this example we simulate a system that controls shared resources
 * using semaphores. We have a pool of resources (for example, database connections,
 * accesses to a hardware device, etc.) and several tasks that request them.
 *
 * The semaphore is used to limit the number of tasks that can access
 * the shared resources at the same time.
 */

#define NUM_RESOURCES 3  // Number of available resources
#define NUM_PRODUCERS 2  // Number of producer tasks
#define NUM_CONSUMERS 4  // Number of consumer tasks

static u32 running;
static ca_semaphore_t resource_semaphore;  // Semaphore to control access to the resources

// Array to track the state of the resources
static u32 resource_status[NUM_RESOURCES];
static ca_mutex_t resource_mutex;  // Mutex to protect access to the array

static u32 producer_task(void *arg) {
    const u32 p1 = (u32)(uintptr_t)arg;
    const u32 idx = ca_os_thid_from_handle(ca_os_self_handle());
    char task_name[32];
    snprintf(task_name, sizeof(task_name), "PRODUCER_%u", idx);

    ca_stdout_printf_n("%s started: idx=%u p1=%u", task_name, idx, p1);

    while(running) {
        // Wait a bit before requesting a resource
        ca_os_sleep(500 + (idx * 200));  // Different delay for each producer

        // Try to take a resource (waiting at most 1000ms)
        if (ca_sem_timedwait(&resource_semaphore, 1000)) {
            // We got access to a resource
            ca_stdout_printf_n("%s: acquired resource", task_name);

            // Look for a free resource to use
            u32 resource_idx = (u32)-1;
            ca_mutex_lock(&resource_mutex);
            for (int i = 0; i < NUM_RESOURCES; i++) {
                if (resource_status[i] == 0) {  // Resource free
                    resource_status[i] = idx + 1;  // Assign it to this producer
                    resource_idx = i;
                    break;
                }
            }
            ca_mutex_unlock(&resource_mutex);

            if (resource_idx != (u32)-1) {
                // Simulate using the resource
                ca_stdout_printf_n("%s: using resource %u", task_name, resource_idx);

                // Use the resource for a while
                ca_os_sleep(800);

```

```
61                  // Free the resource
62                  ca_mutex_lock(&resource_mutex);
63                  resource_status[resource_idx] = 0;  // Mark as free
64                  ca_mutex_unlock(&resource_mutex);
65
66                  ca_stdout_printf_n("%s: released resource %u", task_name,
    resource_idx);
67              } else {
68                  ca_stdout_printf_n("%s: ERROR - no free resource found!",
    task_name);
69              }
70
71              // Release the semaphore to let other tasks access it
72              ca_sem_post(&resource_semaphore);
73          } else {
74              // Timeout: we could not get a resource within the time limit
75              ca_stdout_printf_n("%s: timeout waiting for resource", task_name);
76          }
77      }
78
79      return 0;
80  }
81
82  static u32 consumer_task(void *arg) {
83      const u32 p1 = (u32)(uintptr_t)arg;
84      const u32 idx = ca_os_thid_from_handle(ca_os_self_handle());
85      char task_name[32];
86      snprintf(task_name, sizeof(task_name), "CONSUMER_%u", idx);
87
88      ca_stdout_printf_n("%s started: idx=%u p1=%u", task_name, idx, p1);
89
90      while(running) {
91          // Wait a bit before checking the state
92          ca_os_sleep(700 + (idx * 100));
93
94          // Check the state of the resources
95          ca_mutex_lock(&resource_mutex);
96          u32 busy_resources = 0;
97          for (int i = 0; i < NUM_RESOURCES; i++) {
98              if (resource_status[i] != 0) {
99                  busy_resources++;
100             }
101         }
102         ca_mutex_unlock(&resource_mutex);
103
104         ca_stdout_printf_n("%s: %u/%u resources busy", task_name, busy_resources
    , NUM_RESOURCES);
105
106         // Check the semaphore value
107         u32 sem_value = ca_sem_getvalue(&resource_semaphore);
108         ca_stdout_printf_n("%s: semaphore value: %u", task_name, sem_value);
109     }
110
111     return 0;
112 }
113
114 void ca_os_main(void) {
115     running = 1;
116
117     // Initialize the semaphore with NUM_RESOURCES available
118     ca_sem_init(&resource_semaphore, NUM_RESOURCES, NUM_RESOURCES);
119
120     // Initialize the mutex that protects access to the resource array
```

```
121     ca_mutex_init(&resource_mutex);
122 
123     // Initialize the state of the resources
124     for (int i = 0; i < NUM_RESOURCES; i++) {
125         resource_status[i] = 0;  // All resources are free at the start
126     }
127 
128     // Creiamo i task produttori
129     for (int i = 0; i < NUM_PRODUCERS; i++) {
130         char task_name[16];
131         snprintf(task_name, sizeof(task_name), "prod_%d", i+1);
132         ca_os_job(task_name, CA_TH_LEVEL2, producer_task, (void *)(uintptr_t)i,
133                           STACK_LARGE, CA_JOB_STD, CA_FAULT_ASSERT);
134     }
135 
136     // Creiamo i task consumatori
137     for (int i = 0; i < NUM_CONSUMERS; i++) {
138         char task_name[16];
139         snprintf(task_name, sizeof(task_name), "cons_%d", i+1);
140         ca_os_job(task_name, CA_TH_LEVEL2, consumer_task, (void *)(uintptr_t)i,
141                           STACK_MEDIUM, CA_JOB_STD, CA_FAULT_ASSERT);
142     }
143 
144     ca_os_run(true);
145 }
```

29.1.4 Architecture

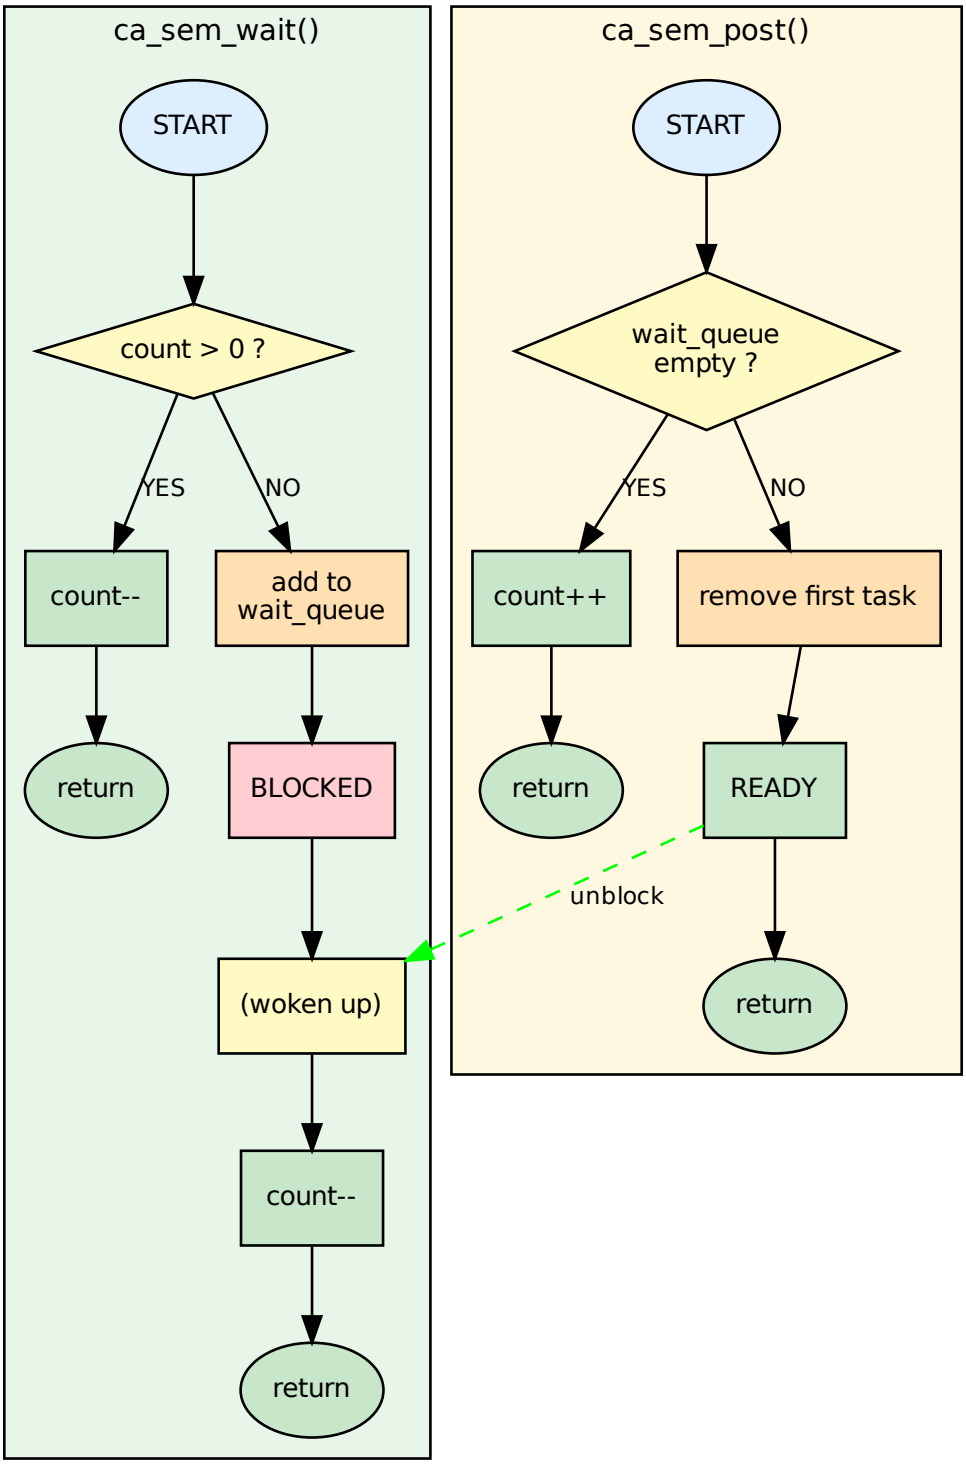

Figure 29.1: Semaphore flow — shared resource access control

The diagram shows the behavior of the counting semaphore: the initial value represents the available resources. Each `ca_sem_wait` decrements the counter; if the value is already zero, the task blocks. Each `ca_sem_post` increments the counter and wakes up a waiting task. In this example, the semaphore controls access to a pool of `NUM_RESOURCES=3` resources shared between producers and consumers.

29.1.5 Detailed analysis

Configuration constants

```
#define NUM_RESOURCES 3  // Number of available resources
#define NUM_PRODUCERS 2  // Number of producer tasks
#define NUM_CONSUMERS 4  // Number of consumer tasks
```

These constants define the system configuration: - **NUM_RESOURCES**: The total number of resources in the pool (3 in this case) - **NUM_PRODUCERS**: The number of tasks that will request access to the resources - **NUM_CONSUMERS**: The number of tasks that will monitor the system status

Shared variables

```
static u32 running;
static ca_semaphore_t resource_semaphore;  // Semaphore to control access to the
    resources

// Array to track the state of the resources
static u32 resource_status[NUM_RESOURCES];
static ca_mutex_t resource_mutex;  // Mutex to protect access to the array
```

- `running`: Control variable to keep tasks active.
- `resource_semaphore`: The semaphore that controls access to resources.
- `resource_status`: Array that tracks the status of each resource.
- `resource_mutex`: Mutex to protect access to the shared resource array.

Initialization

```
void ca_os_main(void) {
    running = 1;

    // Initialize the semaphore with NUM_RESOURCES available
    ca_sem_init(&resource_semaphore, NUM_RESOURCES, NUM_RESOURCES);

    // Initialize the mutex that protects access to the resource array
    ca_mutex_init(&resource_mutex);

    // Initialize the state of the resources
    for (int i = 0; i < NUM_RESOURCES; i++) {
        resource_status[i] = 0;  // All resources are free at the start
    }
    ...
}
```

The semaphore is initialized with an initial value equal to the number of available resources. This means that initially, all resources are available for use.

Producer task

```
static u32 producer_task(void *arg) {
    const u32 idx = ca_os_thid_from_handle(ca_os_self_handle());
    (void)arg;
    ...
    if (ca_sem_timedwait(&resource_semaphore, 1000)) {
        // We got access to a resource
        ca_stdout_printf_n("%s: acquired resource", task_name);

        // Look for a free resource to use
        u32 resource_idx = (u32)-1;
        ca_mutex_lock(&resource_mutex);
        for (int i = 0; i < NUM_RESOURCES; i++) {
            if (resource_status[i] == 0) {  // Resource free
                resource_status[i] = idx + 1;  // Assign it to this producer
                resource_idx = i;
                break;
            }
        }
        ca_mutex_unlock(&resource_mutex);

        if (resource_idx != (u32)-1) {
            // Simulate using the resource
            ca_stdout_printf_n("%s: using resource %u", task_name, resource_idx)
    ;

            // Use the resource for a while
            ca_os_sleep(800);

            // Free the resource
            ca_mutex_lock(&resource_mutex);
            resource_status[resource_idx] = 0;  // Mark as free
            ca_mutex_unlock(&resource_mutex);

            ca_stdout_printf_n("%s: released resource %u", task_name,
    resource_idx);
        }

        // Release the semaphore to let other tasks access it
        ca_sem_post(&resource_semaphore);
    } else {
        // Timeout: we could not get a resource within the time limit
        ca_stdout_printf_n("%s: timeout waiting for resource", task_name);
    }
    ...
}
```

The producer task:

1. **Requests a resource** using `ca_sem_timedwait` with a timeout of 1000ms
2. **If it succeeds in obtaining the resource**, it searches for an actually free resource in the array
3. **Uses the resource** for a period of time (simulated with `ca_os_sleep`)
4. **Releases the resource** by updating the state and incrementing the semaphore count with `ca_sem_post`

Semaphore operations

- `ca_sem_timedwait(&resource_semaphore, 1000)`: Decrements the semaphore count. If the count is already zero, the task waits up to 1000ms for an available resource.

- `ca_sem_post(&resource_semaphore)`: Increments the semaphore count, signaling that a resource has been released and is now available for other tasks.

Consumer task

Consumer tasks monitor the system state:

1. **Check the status of resources** in the `resource_status` array
2. **Read the semaphore value** using `ca_sem_getvalue`
3. **Print information** about the system state

Key differences from the mutex

- **Multiple count**: The semaphore maintains a count of available resources, while the mutex is binary (free/busy).
- **Multiple access**: Multiple tasks can obtain the semaphore simultaneously up to the set limit, while only one task at a time can obtain the mutex.
- **Different purpose**: Semaphores are used to control access to a pool of resources, mutexes to protect critical sections.

29.1.6 When to use semaphores

Semaphores are useful in these scenarios:

1. **Resource pool**: When you have a limited number of identical resources to share among tasks.
2. **Traffic throttling**: When you want to limit the number of tasks that can perform a certain operation simultaneously.
3. **Producer-consumer synchronization**: To coordinate tasks that produce and consume data through a limited buffer.

29.1.7 What this example teaches us

1. **Semaphore operation**: How the count controls access to resources.
2. **The difference from the mutex**: How semaphores allow multiple accesses up to a limit.
3. **Managing a resource pool**: How to limit access to a fixed number of shared resources.
4. **Synchronization operations**: How to use `timedwait`, `post` and `getvalue` to control and monitor the semaphore.

29.1.8 Example output

Below is the output produced by the example on the debug serial port:

```

CONSUMER_5: 0/3 resources busy
```

29.1.9 Verification of waits with timeout (`twait`)

Since 09/27, a task waiting for a semaphore **with timeout** (`ca_sem_timedwait()`) registers in the same wait list as those waiting without a timeout, parked in `SLEEP` until expiration, and the signaler wakes it up immediately (S2_02 §8.8). Previously, it performed polling every 10 ms outside the list: it would wake up up to 10 ms after the signal.

The command `twait [sec]` (default 3 s) measures it with a peer task created at the first call. The wait runs in the command task:

1. **latency** — 300 loops: the peer performs `ca_sem_post()` after a random 1..8 ms; the waiter, with a 20 ms timeout, must obtain it (`lost=0`), not before the signal (`spur=0`), and be running within 2 ms (`lat_max` limit, in ticks);
2. **timeout** — no one performs `post`; for `sec` seconds, T = 1..20 ms: the return never arrives **before** T (`early=0`), at most 2 ms after (`late=0`), and always with `false` (`got=0`).

One line, closed by `PASS` or `FAIL`. On H753 (tick 200 µs):

```
TW sem : rounds=300 lat_max=0/10 lost=0 spur=0 | tmo n=291 early=0 late=0 got=0
    over_max=0/10  PASS
```

On the previous kernel: FAIL, `lat_max=45/10`.

In the bank, it is case `timed_wait` of `test_ex06.cpp` (helper `test/hw_test/inc/caosTimedWait.h`). Manually:

```
caos_shell -e 6 -q -t 40 -u "TW .*(PASS|FAIL)" -g "^TW" "twait 3"
```

Chapter 30

Condition Variable: Producer-Consumer Coordination

30.1 Example 7 — Condition Variable: producer-consumer coordination

30.1.1 Introduction

In the previous examples, we saw how mutexes protect access to shared resources and how semaphores control access to a pool of resources. However, there is an even more complex scenario where a task must **wait for a specific condition** before proceeding.

For example, in a producer-consumer system, the consumer must wait for the buffer to be non-empty before extracting data, while the producer must wait for the buffer to be non-full before inserting data. Simple mutexes are not sufficient for this type of coordination: **condition variables** are needed.

A condition variable allows a task to suspend itself until a certain condition becomes true. When another task modifies the condition, it can wake up the waiting tasks. This mechanism is particularly useful for:

1. **Producer-consumer coordination**: The consumer waits for the buffer to be non-empty, the producer waits for it to be non-full
2. **Event notification**: A task waits for another to perform an action
3. **Complex synchronization**: When simple mutual exclusion is not enough

30.1.2 What is a condition variable?

A condition variable is a synchronization primitive that:

- Allows a task to **wait for a condition** while temporarily releasing a mutex
- Allows other tasks to **signal** when the condition is met
- Supports both **single signals** (`signal`) and **broadcasts** (`broadcast`)
- Can include **timeouts** to avoid infinite waits

Condition variables are always used **together with a mutex**. The typical sequence is:

1. Acquire the mutex
2. Check the condition
3. If the condition is not met, call `ca_cond_wait` (releases the mutex and waits)
4. When it wakes up, re-check the condition
5. Perform the required work
6. Release the mutex

30.1.3 The source code

The file is located in `examples/example_7/ca_os_ex7.c`:

```c
#include "caos.h"

/*
 * Example of condition variable usage
 *
 * In this example we simulate a producer-consumer system that uses
 * a condition variable to coordinate access to a shared resource.
 * We have a shared buffer and two tasks: a producer that puts data
 * into the buffer and a consumer that takes them out. The condition variable
    lets
 * the consumer be suspended when the buffer is empty and the producer
 * when the buffer is full.
 */

#define BUFFER_SIZE 5
static u32 buffer[BUFFER_SIZE];
static u32 head = 0;  // Head index (next item to read)
static u32 tail = 0;  // Tail index (next item to write)
static u32 count = 0; // Number of items in the buffer

static u32 running;
static ca_mutex_t buffer_mutex;      // Mutex per proteggere l'accesso al buffer
static ca_condvar_t buffer_not_full;  // Condition variable for buffer not full
static ca_condvar_t buffer_not_empty; // Condition variable for buffer not empty

// Function to check whether the buffer is full
static bool is_buffer_full(void) {
    return count == BUFFER_SIZE;
}

// Function to check whether the buffer is empty
static bool is_buffer_empty(void) {
    return count == 0;
}

// Function to put an item into the buffer
static void put_item(u32 item) {
    if (is_buffer_full()) {
        return; // Buffer full
    }
    buffer[tail] = item;
    tail = (tail + 1) % BUFFER_SIZE;
    count++;
}

// Function to take an item out of the buffer
static u32 get_item(void) {
    if (is_buffer_empty()) {
        return 0; // Buffer empty
    }
    u32 item = buffer[head];
    head = (head + 1) % BUFFER_SIZE;
    count--;
    return item;
}

static u32 producer_task(void *arg) {
    const u32 p1 = (u32)(uintptr_t)arg;
    const u32 idx = ca_os_thid_from_handle(ca_os_self_handle());
    char task_name[32];
```

```
60      snprintf(task_name, sizeof(task_name), "PRODUCER_%u", idx);
61
62      ca_stdout_printf_n("%s started: idx=%u p1=%u", task_name, idx, p1);
63
64      u32 item = 100; // Inizia a produrre da 100
65
66      while(running) {
67          // Take the mutex to access the buffer
68          ca_mutex_lock(&buffer_mutex);
69
70          // Wait while the buffer is full
71          while(is_buffer_full()) {
72              ca_stdout_printf_n("%s: buffer full, waiting...", task_name);
73              // Use cond_wait to release the mutex and wait until someone
74              // signals that the buffer is no longer full
75              ca_cond_wait(&buffer_not_full, &buffer_mutex);
76          }
77
78          // Now we can put an item into the buffer
79          put_item(item);
80          ca_stdout_printf_n("%s: put item %u, count=%u", task_name, item, count);
81
82          // Signal that the buffer is no longer empty
83          ca_cond_signal(&buffer_not_empty);
84
85          // Release the mutex
86          ca_mutex_unlock(&buffer_mutex);
87
88          item++; // Next item to produce
89
90          // Wait a bit before producing the next item
91          ca_os_sleep(500);
92      }
93
94      return 0;
95  }
96
97  static u32 consumer_task(void *arg) {
98      const u32 p1 = (u32)(uintptr_t)arg;
99      const u32 idx = ca_os_thid_from_handle(ca_os_self_handle());
100     char task_name[32];
101     snprintf(task_name, sizeof(task_name), "CONSUMER_%u", idx);
102
103     ca_stdout_printf_n("%s started: idx=%u p1=%u", task_name, idx, p1);
104
105     while(running) {
106         // Take the mutex to access the buffer
107         ca_mutex_lock(&buffer_mutex);
108
109         // Wait while the buffer is empty
110         while(is_buffer_empty()) {
111             ca_stdout_printf_n("%s: buffer empty, waiting...", task_name);
112             // Use cond_wait to release the mutex and wait until someone
113             // signals that the buffer is no longer empty
114             ca_cond_wait(&buffer_not_empty, &buffer_mutex);
115         }
116
117         // Now we can take an item out of the buffer
118         u32 item = get_item();
119         ca_stdout_printf_n("%s: got item %u, count=%u", task_name, item, count);
120
121         // Signal that the buffer is no longer full
122         ca_cond_signal(&buffer_not_full);
```

```
123
124         // Release the mutex
125         ca_mutex_unlock(&buffer_mutex);
126
127         // Simulate some processing of the item
128         ca_os_sleep(800);
129     }
130
131     return 0;
132 }
133
134 void ca_os_main(void) {
135     running = 1;
136
137     // Initialize the mutex and the condition variables
138     ca_mutex_init(&buffer_mutex);
139     ca_cond_init(&buffer_not_full);
140     ca_cond_init(&buffer_not_empty);
141
142     // Crea i task
143     ca_os_job("prod_1", CA_TH_LEVEL2, producer_task, (void *)(uintptr_t)1,
144                         STACK_MEDIUM, CA_JOB_STD, CA_FAULT_ASSERT);
145     ca_os_job("cons_1", CA_TH_LEVEL2, consumer_task, (void *)(uintptr_t)2,
146                         STACK_MEDIUM, CA_JOB_STD, CA_FAULT_ASSERT);
147
148     ca_os_run(true);
149 }
```

30.1.4 Architecture

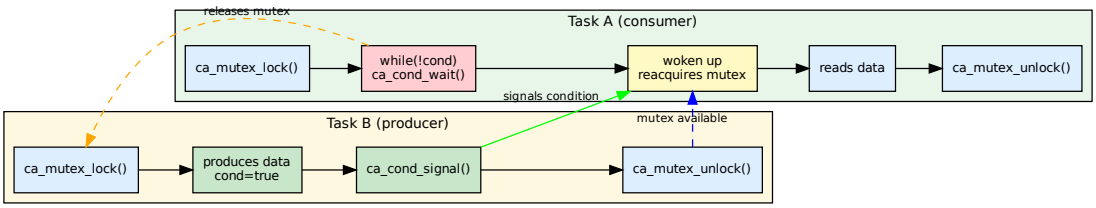

Figure 30.1: Condition variable sequence — producer-consumer coordination

The diagram shows the interaction sequence between producer and consumer via condition variable. The consumer waits (`ca_cond_wait`) until the buffer contains data; the producer inserts an element and signals (`ca_cond_signal`) waking up the consumer. The condition variable is always used together with a mutex that protects the shared buffer.

30.1.5 Detailed analysis

Shared variables

```
1 static u32 buffer[BUFFER_SIZE];
2 static u32 head = 0;  // Head index (next item to read)
3 static u32 tail = 0;  // Tail index (next item to write)
4 static u32 count = 0; // Number of items in the buffer
```

These variables represent a circular buffer shared between producer and consumer:

- `buffer`: The array containing the data
- `head`: Index of the next element to read
- `tail`: Index of the next element to write
- `count`: Number of elements currently in the buffer

All these variables are protected by the mutex `buffer_mutex`.

Condition variables

```
static ca_mutex_t buffer_mutex;      // Mutex per proteggere l'accesso al buffer
static ca_condvar_t buffer_not_full;  // Condition variable for buffer not full
static ca_condvar_t buffer_not_empty; // Condition variable for buffer not empty
```

We have three synchronization primitives:

- `buffer_mutex`: Protects access to shared variables
- `buffer_not_full`: Signals when the buffer is not full (producer can insert)
- `buffer_not_empty`: Signals when the buffer is not empty (consumer can extract)

Utility functions

The functions `is_buffer_full()`, `is_buffer_empty()`, `put_item()` and `get_item()` are utility functions that operate on the buffer. They are simple functions that do not require synchronization because they will only be called when the mutex is acquired.

Producer task

```
static u32 producer_task(void *arg) {
    (void)arg;
    // ...
    while(running) {
        // Take the mutex to access the buffer
        ca_mutex_lock(&buffer_mutex);

        // Wait while the buffer is full
        while(is_buffer_full()) {
            ca_stdout_printf_n("%s: buffer full, waiting...", task_name);
            // Use cond_wait to release the mutex and wait until someone
            // signals that the buffer is no longer full
            ca_cond_wait(&buffer_not_full, &buffer_mutex);
        }

        // Now we can put an item into the buffer
        put_item(item);
        ca_stdout_printf_n("%s: put item %u, count=%u", task_name, item, count);

        // Signal that the buffer is no longer empty
        ca_cond_signal(&buffer_not_empty);

        // Release the mutex
        ca_mutex_unlock(&buffer_mutex);
        // ...
    }
}
```

The producer task:

1. **Acquires the mutex** to safely access shared variables
2. **Checks if the buffer is full** using `is_buffer_full()`

3. **If it is full**, it calls `ca_cond_wait(&buffer_not_full, &buffer_mutex)`:
    - Automatically releases the mutex
    - Suspends itself until someone calls `ca_cond_signal(&buffer_not_full)`
    - When it wakes up, it automatically re-acquires the mutex
4. **Inserts an element** into the buffer using `put_item()`
5. **Signals that the buffer is no longer empty** with `ca_cond_signal(&buffer_not_empty)`
6. **Releases the mutex** with `ca_mutex_unlock()`

Consumer task

```
static u32 consumer_task(void *arg) {
    (void)arg;
    // ...
    while(running) {
        // Take the mutex to access the buffer
        ca_mutex_lock(&buffer_mutex);

        // Wait while the buffer is empty
        while(is_buffer_empty()) {
            ca_stdout_printf_n("%s: buffer empty, waiting...", task_name);
            // Use cond_wait to release the mutex and wait until someone
            // signals that the buffer is no longer empty
            ca_cond_wait(&buffer_not_empty, &buffer_mutex);
        }

        // Now we can take an item out of the buffer
        u32 item = get_item();
        ca_stdout_printf_n("%s: got item %u, count=%u", task_name, item, count);

        // Signal that the buffer is no longer full
        ca_cond_signal(&buffer_not_full);

        // Release the mutex
        ca_mutex_unlock(&buffer_mutex);
        // ...
    }
}
```

The consumer task:

1. **Acquires the mutex** to safely access shared variables
2. **Checks if the buffer is empty** using `is_buffer_empty()`
3. **If it is empty**, it calls `ca_cond_wait(&buffer_not_empty, &buffer_mutex)`:
    - Automatically releases the mutex
    - Suspends itself until someone calls `ca_cond_signal(&buffer_not_empty)`
    - When it wakes up, it automatically re-acquires the mutex
4. **Extracts an element** from the buffer using `get_item()`
5. **Signals that the buffer is no longer full** with `ca_cond_signal(&buffer_not_full)`
6. **Releases the mutex** with `ca_mutex_unlock()`

Coordination sequence

Coordination between producer and consumer works as follows:

1. The **producer** inserts data and signals `buffer_not_empty` when it adds something
2. The **consumer** waits for `buffer_not_empty` when the buffer is empty

3. The **consumer** extracts data and signals `buffer_not_full` when it removes something
4. The **producer** waits for `buffer_not_full` when the buffer is full

This bidirectional coordination allows for an efficient flow of data between the two tasks.

Using `while` instead of `if`

It is essential to use `while` instead of `if` when checking the condition:

```
while(is_buffer_full()) {
    ca_cond_wait(&buffer_not_full, &buffer_mutex);
}
```

This is because:

1. **Spurious wakeups**: A task might wake up without the condition actually having changed
2. **Multiplexing**: There could be multiple tasks waiting on the same condition variable
3. **Safety**: Re-checking the condition ensures that the logic is correct

Initialization

```
void ca_os_main(void) {
    running = 1;

    // Initialize the mutex and the condition variables
    ca_mutex_init(&buffer_mutex);
    ca_cond_init(&buffer_not_full);
    ca_cond_init(&buffer_not_empty);
    // ...
}
```

As with all synchronization primitives, mutexes and condition variables must be initialized before use.

30.1.6 API

The main functions for condition variables are:

- `ca_cond_init(cv)`: Initializes a condition variable
- `ca_cond_wait(cv, mutex)`: Waits for the condition to become true, temporarily releasing the mutex
- `ca_cond_signal(cv)`: Wakes up a task waiting on this condition variable
- `ca_cond_broadcast(cv)`: Wakes up all tasks waiting on this condition variable
- `ca_cond_timedwait(cv, mutex, timeout_ms)`: Like `wait` but with a timeout

30.1.7 What this example teaches us

1. **Complex coordination**: How to use condition variables to coordinate tasks that must wait for specific conditions
2. **Producer-consumer pattern**: A fundamental concurrent programming model
3. **Correct use with mutexes**: How to combine mutexes and condition variables to protect shared data
4. **Conditional waits**: How to suspend a task until a condition is met
5. **Mutual signaling**: How tasks wake each other up when conditions change

30.1.8 Example output

Below is the output produced by the example on the debug serial port:

```

30.1.9 Verification of waits with timeout (`twait`)

Since 09/27, a task waiting for a condition variable **with timeout** (`ca_cond_timedwait()`) registers in the same wait list as those waiting without a timeout, parked in `SLEEP` until expiration, and the signaler wakes it up immediately (S2_02 §8.8). Previously, it performed polling every 10 ms outside the list: it would wake up up to 10 ms after the signal.

The command `twait [sec]` (default 3 s) measures it with a peer task created at the first call. The wait runs in the command task:

1. **latency** — 300 cycles: the peer sets the flag and performs `ca_cond_signal()` after a random 1..8 ms; the waiter, with a timeout of 20 ms, must obtain it (`lost=0`), not before the signal (`spur=0`), and be running within 2 ms (`lat_max` limit, in ticks);
2. **timeout** — no one signals; for `sec` seconds, T = 1..20 ms: the return never arrives **before** T (`early=0`), at most 2 ms after (`late=0`), and always with `false` (`got=0`).

One line, closed by `PASS` or `FAIL`. On H753 (tick 200 µs):

```
TW cond : rounds=300 lat_max=0/10 lost=0 spur=0 | tmo n=291 early=0 late=0 got=0
    over_max=0/10  PASS
```

On the previous kernel: PASS: the waiter with timeout was already in the list (in `SLEEP`). Here `twait` is a regression; the two fixes (mutex released before parking, parking inside the lock) have a window that is too narrow for this test.

In the bench, it is case `timed_wait` of `test_ex07.cpp` (helper `test/hw_test/inc/caosTimedWait.h`). Manually:

```
caos_shell -e 7 -q -t 40 -u "TW .*(PASS|FAIL)" -g "^TW" "twait 3"
```

Chapter 31

Critical Sections: Protecting Data by Disabling Interrupts

31.1 Example 8 — Critical sections: data protection with interrupt disabling

31.1.1 Introduction

In the previous examples, we saw how mutexes, semaphores, and condition variables protect access to resources shared between tasks. All these primitives have a cost: they require data structures, wait queues, and can block waiting tasks. However, there is a scenario where a lighter and more immediate protection is needed: when the block of code to be protected is **very short** and cannot tolerate even the overhead of a mutex.

Critical sections are the simplest and most direct mechanism for protecting shared data. They work by temporarily disabling interrupts, ensuring that no context switch occurs during the execution of the protected code. This makes them ideal for atomic operations on a few variables, where the execution time is minimal.

Critical sections in caOS support **nesting**: it is possible to nest multiple `ca_enter_critical` / `ca_exit_critical` without issues. Only the first call disables interrupts, and only the last one re-enables them. This is fundamental when functions protected by a critical section call other functions that are also protected.

31.1.2 What is a critical section?

A critical section is a protection mechanism that:

- **Disables interrupts** to prevent context switching
- Supports **nesting** via an internal counter
- Does not require additional data structures (no mutexes, no wait queues)
- Is the **lightest** protection mechanism available

Critical sections are particularly useful for:

1. **Short atomic operations**: Updating one or a few shared variables safely
2. **Consistent reads**: Reading a set of related variables without them being modified halfway through
3. **Task-ISR protection**: Ensuring consistency between code executed by tasks and interrupt handlers

31.1.3 The source code

The file is located in `examples/example_8/ca_os_ex8.c`:

```c
#include "caos.h"

/*
 * Example of critical section usage
 *
 * Critical sections temporarily disable interrupts to guarantee
 * that a block of code runs without interruptions.
 * They support nesting: only the first ca_enter_critical() disables the IRQs,
 * only the last ca_exit_critical() re-enables them.
 *
 * A writer task updates a shared variable and a reader task reads it.
 * Both use critical sections to keep the data consistent.
 */

static u32 running;
static u32 shared_counter = 0;
static u32 write_count = 0;
static u32 read_count = 0;

// Task that updates the shared variable
static u32 task_writer(void *arg) {
    const u32 p1 = (u32)(uintptr_t)arg;
    const u32 idx = ca_os_thid_from_handle(ca_os_self_handle());

    ca_stdout_printf_n("WRITER started: idx=%u p1=%u", idx, p1);

    while(running) {
        ca_enter_critical();
        shared_counter++;
        write_count++;
        u32 sc = shared_counter;
        u32 wc = write_count;
        u32 nesting = ca_critical_nesting_level();
        ca_exit_critical();

        ca_stdout_printf_n("WRITER: counter=%u writes=%u nesting_was=%u", sc, wc
    , nesting);
        ca_os_sleep(300);
    }

    return 0;
}

// Task that reads the shared variable
static u32 task_reader(void *arg) {
    const u32 p1 = (u32)(uintptr_t)arg;
    const u32 idx = ca_os_thid_from_handle(ca_os_self_handle());

    ca_stdout_printf_n("READER started: idx=%u p1=%u", idx, p1);

    while(running) {
        ca_enter_critical();
        u32 sc = shared_counter;
        u32 wc = write_count;
        u32 rc = ++read_count;
        ca_exit_critical();

        ca_stdout_printf_n("READER: counter=%u writes=%u reads=%u", sc, wc, rc);
        ca_os_sleep(500);
    }
```

```
60
61      return 0;
62  }
63
64  void ca_os_main(void) {
65      running = 1;
66
67      ca_os_job("writer", CA_TH_LEVEL2, task_writer, (void *)(uintptr_t)1,
68                          STACK_MEDIUM, CA_JOB_STD, CA_FAULT_ASSERT);
69      ca_os_job("reader", CA_TH_LEVEL2, task_reader, (void *)(uintptr_t)2,
70                          STACK_MEDIUM, CA_JOB_STD, CA_FAULT_ASSERT);
71
72      ca_os_run(true);
73  }
```

31.1.4 Architecture

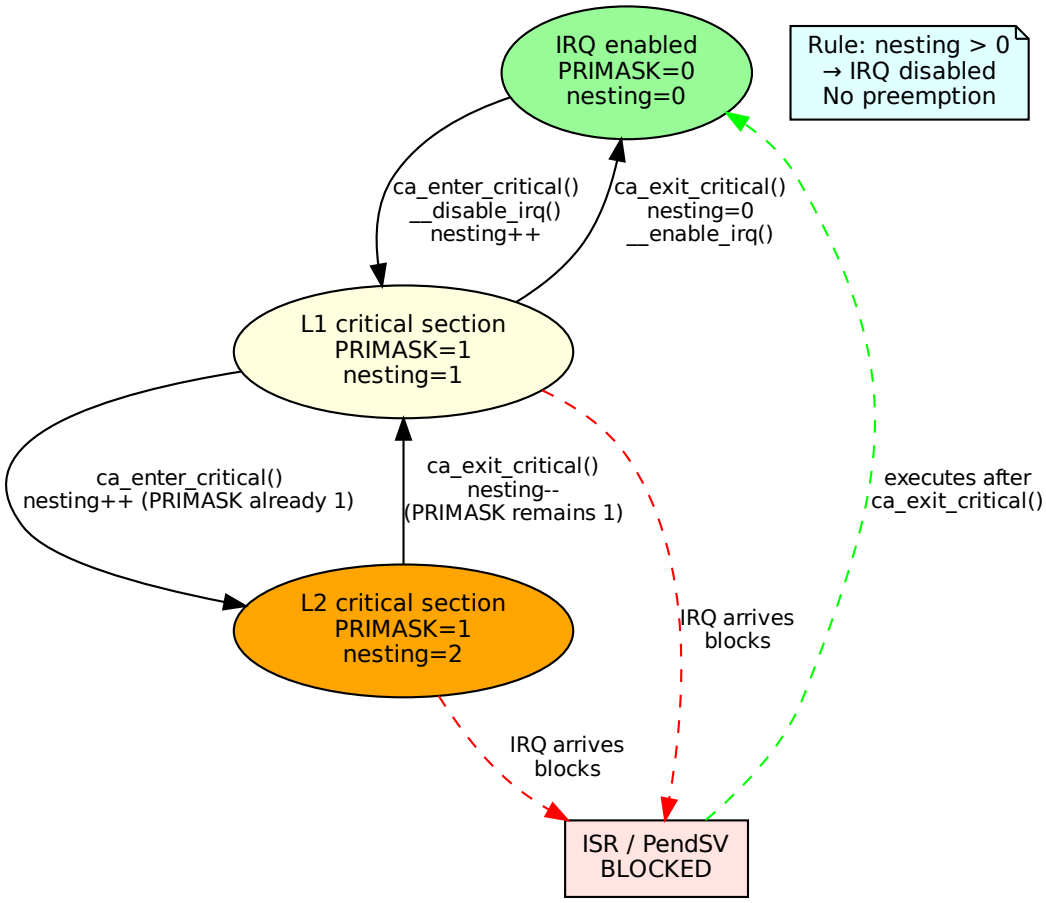

Figure 31.1: Critical section states — PRIMASK nesting

The diagram shows the management of critical section nesting. Each `ca_enter_critical` increments the nesting counter and disables interrupts (PRIMASK=1). Each `ca_exit_critical` decrements the counter; only when the counter returns to zero are interrupts re-enabled. This allows

nesting critical sections without the risk of re-enabling interrupts prematurely.

31.1.5 Detailed analysis

Shared variables

```
static u32 shared_counter = 0;
static u32 write_count = 0;
static u32 read_count = 0;
```

These three variables are shared between the two tasks:

- `shared_counter`: Counter incremented by the writer and read by the reader
- `write_count`: Total number of writes performed
- `read_count`: Total number of reads performed

Note that, unlike the previous examples, **there is no need to declare or initialize any synchronization structure**. The critical sections do not require objects: they operate directly on the processor's PRIMASK register.

Writer task

```
static u32 task_writer(void *arg) {
    (void)arg;
    // ...
    while(running) {
        ca_enter_critical();
        shared_counter++;
        write_count++;
        u32 sc = shared_counter;
        u32 wc = write_count;
        u32 nesting = ca_critical_nesting_level();
        ca_exit_critical();

        ca_stdout_printf_n("WRITER: counter=%u writes=%u nesting_was=%u", sc, wc
    , nesting);
        ca_os_sleep(300);
    }
    // ...
}
```

The writer task:

1. **Enters the critical section** with `ca_enter_critical()`: interrupts are disabled
2. **Updates shared variables** safely: no other task can interrupt this sequence
3. **Copies values into local variables** to be able to print them after releasing the critical section
4. **Queries the nesting level** with `ca_critical_nesting_level()` to show the internal counter
5. **Exits the critical section** with `ca_exit_critical()`: interrupts are re-enabled
6. **Prints the results** outside the critical section, because I/O is a slow operation

Reader task

```
static u32 task_reader(void *arg) {
    (void)arg;
    // ...
    while(running) {
        ca_enter_critical();
        u32 sc = shared_counter;
```

```
        u32 wc = write_count;
        u32 rc = ++read_count;
        ca_exit_critical();

        ca_stdout_printf_n("READER: counter=%u writes=%u reads=%u", sc, wc, rc);
        ca_os_sleep(500);
    }
    // ...
}
```

The reader task:

1. **Enters a critical section** to ensure a consistent read
2. **Reads all related variables** in a single atomic operation: `shared_counter`, `write_count` and `read_count` will always be consistent with each other
3. **Increments the read counter** inside the critical section
4. **Exits the critical section** and prints the results

Consistent reading is the key point: without a critical section, the writer could modify `shared_counter` between the reading of `shared_counter` and that of `write_count`, producing inconsistent values.

Critical section nesting

The implementation in caOS supports nesting via a global counter:

```
static volatile u32 g_critical_nesting = 0;
static volatile u32 g_saved_primask = 0;
```

- The first `ca_enter_critical()` saves the PRIMASK state and disables IRQs
- Subsequent ones only increment the counter
- Each `ca_exit_critical()` decrements the counter
- Only when the counter returns to zero are IRQs re-enabled

This means it is safe to call `ca_enter_critical()` from a function already inside a critical section, without the risk of prematurely re-enabling interrupts.

Initialization

```
void ca_os_main(void) {
    running = 1;

    ca_os_job("writer", CA_TH_LEVEL2, task_writer, (void *)(uintptr_t)1,
                        STACK_MEDIUM, CA_JOB_STD, CA_FAULT_ASSERT);
    ca_os_job("reader", CA_TH_LEVEL2, task_reader, (void *)(uintptr_t)2,
                        STACK_MEDIUM, CA_JOB_STD, CA_FAULT_ASSERT);

    ca_os_run(true);
}
```

We note the absence of any initialization call for critical sections. Unlike mutexes (`ca_mutex_init`), semaphores (`ca_sem_init`), and condition variables (`ca_cond_init`), critical sections do not require initialization: they are ready for use immediately.

31.1.6 API

The functions for critical sections are:

- `ca_enter_critical()`: Enters a critical section (disables IRQs, supports nesting)
- `ca_exit_critical()`: Exits a critical section (re-enables IRQs only when the nesting count returns to 0)
- `ca_critical_nesting_level()`: Returns the current nesting level

31.1.7 Critical sections vs other primitives

Feature	Critical section	Mutex	IRQ Spinlock
Initialization	None	`ca_mutex_init`	`ca_spinlock_irq_init`
Blocks other tasks	No (disables IRQs)	Yes (wait queue)	No (disables IRQs)
Overhead	Minimal	Medium	Low
Nesting	Yes (global counter)	No (deadlock)	No
Recommended duration	Very short	Any	Short (<100µs)
Use from ISR	Yes	No	Yes

Critical sections are the right choice when:

1. The code to be protected is **very short** (a few instructions)
2. There is no need to **block** other tasks, only to prevent context switching
3. Protection from **interrupt handlers** is also required
4. The **lightest mechanism possible** is desired

31.1.8 Warning: fundamental rules

- **Never perform slow operations** inside a critical section: no I/O, no sleep, no allocations. Interrupts are disabled, so the entire system is halted.
- **Always balance** calls: every `ca_enter_critical` must have its own `ca_exit_critical`. A failure to release leaves interrupts permanently disabled.
- **Prefer mutexes** when the protected section is long or when it is necessary to block other tasks while waiting.

31.1.9 What this example teaches us

1. **Minimal protection**: How to use critical sections for short atomic operations without synchronization overhead
2. **Consistent reading**: How to ensure that a set of related variables is read consistently
3. **Safe nesting**: How critical sections can be nested without the risk of premature interrupt re-enabling
4. **Printing outside the critical section**: How to copy data into local variables and print only after releasing the protection
5. **Zero initialization**: Unlike other primitives, critical sections are ready for use without setup

31.1.10 Example output

Below is the output produced by the example on the debug serial port:

```
================================================
 -- c.a.O.S --
   build : 77af553c+dev - 2026-02-15 22:28:56
   MCU : STM 32 F:H7xx T:753
================================================
   System Clock: 480000000 Hz
```

```
   SysTick: 47999 clocks per tick
   Debug UART3 Baudrate: 4000000 bps
================================================
WRITER started: idx=3 p1=1
WRITER: counter=1 writes=1 nesting_was=1
READER started: idx=4 p1=2
READER: counter=1 writes=1 reads=1
WRITER: counter=2 writes=2 nesting_was=1
READER: counter=2 writes=2 reads=2
WRITER: counter=3 writes=3 nesting_was=1
WRITER: counter=4 writes=4 nesting_was=1
```

Chapter 32

Task Notification: Lightweight Inter-Task Signaling

32.1 Example 9 — Task Notification: lightweight signaling between tasks

32.1.1 Introduction

In the previous examples, we have seen various synchronization primitives: mutexes for mutual exclusion, semaphores for resource control, condition variables for producer-consumer coordination, and critical sections for fast data protection. All these primitives require the declaration and initialization of dedicated data structures.

However, there is a very common scenario where a task simply needs to **signal something to another task**: "data is ready", "work is completed", "an event has arrived". For these cases, caOS offers **task notifications**, the lightest signaling mechanism available.

Task notifications do not require any additional data structures: they use a `notify_value` field already present in the context of each task. This makes them faster than queues and semaphores, with zero memory overhead. The constraint is that each task has only one `u32` value for notifications.

32.1.2 What is a task notification?

A task notification is a direct task-to-task signaling mechanism that:

- Uses a **single u32 value** already present in the task context
- Requires **no additional data structures** (no mutexes, semaphores, or queues)
- Is **faster** than any other synchronization primitive
- Supports different **actions** on the value: overwrite, increment, bit set/clear
- Can also be used by **ISRs** (interrupt handlers)

Task notifications are particularly useful for:

1. **"Data ready" signaling**: A task notifies another that data is ready
2. **Event counters**: Incrementing a counter for every event
3. **Status flags**: Setting specific bits to signal different conditions

32.1.3 The source code

The file is located in `examples/example_9/ca_os_ex9.c`:

```c
#include "caos.h"

/*
 * Example of task notification usage
 *
 * Notifications are the lightest signalling mechanism in caOS:
 * zero memory overhead (they use the notify_value field of the task context)
 * and they are faster than queues and semaphores for simple signalling.
 *
 * In this example a sender task sends notifications to a receiver task,
 * showing the different actions available: overwrite, increment and set bits.
 */

static u32 running;
static u32 receiver_idx;  // receiver task index, saved for the sender

// Receiver task: waits for notifications from the sender
static u32 task_receiver(void *arg) {
    const u32 p1 = (u32)(uintptr_t)arg;
    const u32 idx = ca_os_thid_from_handle(ca_os_self_handle());

    ca_stdout_printf_n("RECEIVER started: idx=%u p1=%u", idx, p1);

    // save its own index for the sender
    receiver_idx = idx;

    while(running) {
        // attende notification con clear automatico, timeout 2000ms
        u32 value = ca_notify_take(2000);

        if (value != 0) {
            ca_stdout_printf_n("RECEIVER: notification received value=0x%08X",
    value);
        } else {
            ca_stdout_printf_n("RECEIVER: timeout, no notification");
        }
    }

    return 0;
}

// Sender task: sends notifications to the receiver with different actions
static u32 task_sender(void *arg) {
    const u32 p1 = (u32)(uintptr_t)arg;
    const u32 idx = ca_os_thid_from_handle(ca_os_self_handle());

    ca_stdout_printf_n("SENDER started: idx=%u p1=%u", idx, p1);

    u32 cycle = 0;

    while(running) {
        ca_os_sleep(500);

        switch(cycle % 3) {
        case 0:
            // overwrite: writes a value directly
            ca_notify_give(receiver_idx, 0xAA00 + cycle);
            ca_stdout_printf_n("SENDER: overwrite value=0x%08X", 0xAA00 + cycle)
    ;
            break;

        case 1:
            // increment: increments the receiver's counter
```

```
            ca_notify_give_inc(receiver_idx);
            ca_stdout_printf_n("SENDER: increment");
            break;

        case 2:
            // set bits: imposta bit specifici
            ca_notify_send(receiver_idx, (1 << 0) | (1 << 4),
    CA_NOTIFY_ACTION_SET_BITS);
            ca_stdout_printf_n("SENDER: set bits 0x%08X", (1 << 0) | (1 << 4));
            break;
        }

        cycle++;
    }

    return 0;
}

void ca_os_main(void) {
    running = 1;

    // receiver created first so that its idx is available
    ca_os_job("receiver", CA_TH_LEVEL2, task_receiver, NULL,
                          STACK_MEDIUM, CA_JOB_STD, CA_FAULT_ASSERT);
    ca_os_job("sender",   CA_TH_LEVEL3, task_sender, NULL,
                          STACK_MEDIUM, CA_JOB_STD, CA_FAULT_ASSERT);

    ca_os_run(true);
}
```

32.1.4 Architecture

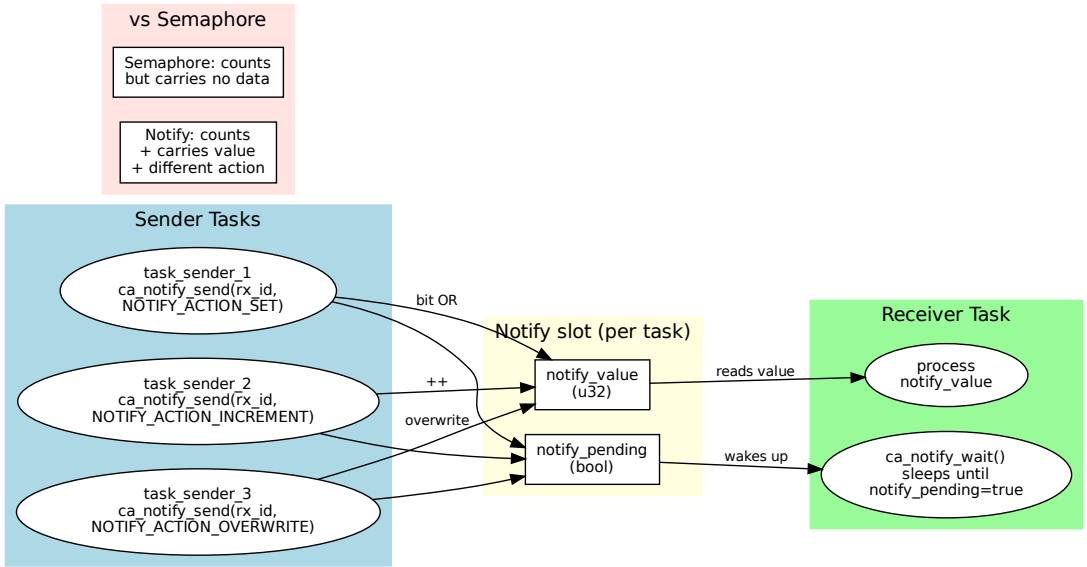

Figure 32.1: Task notification sequence — direct signaling between tasks

The diagram shows how sender tasks send notifications to the receiver with different actions: `SET` (OR bits), `INCREMENT` (counter), `OVERWRITE` (direct value). The receiver wakes up automatically when a notification arrives. Unlike a semaphore, the notification also carries a u32 value and allows encoding additional information within the action itself.

32.1.5 Detailed analysis

Destination task addressing

```
static u32 receiver_idx;  // receiver task index, saved for the sender
```

Unlike mutexes and semaphores, where tasks access a shared structure, notifications are **direct**: the sender must know the index of the destination task. In this example, the receiver saves its own index (received as parameter `idx`) in a global variable, so the sender can use it.

The index `idx` is the one assigned by the scheduler at the time of task creation with `ca_os_job`. It is the first parameter of the task function.

Task receiver

```
static u32 task_receiver(void *arg) {
    const u32 idx = ca_os_thid_from_handle(ca_os_self_handle());
    (void)arg;
    // ...
    receiver_idx = idx;

    while(running) {
        u32 value = ca_notify_take(2000);

        if (value != 0) {
            ca_stdout_printf_n("RECEIVER: notification received value=0x%08X",
    value);
        } else {
            ca_stdout_printf_n("RECEIVER: timeout, no notification");
        }
    }
    // ...
}
```

The receiver task:

1. **Saves its own index** in `receiver_idx` to make it accessible to the sender
2. **Waits for a notification** with `ca_notify_take(2000)`: it blocks for up to 2000ms
3. **Checks the received value**: if it is not 0, the notification has arrived; if it is 0, the timeout has expired
4. **The clear is automatic**: `ca_notify_take` resets the `notify_value` after reading, so the receiver is ready for the next notification

Sender task

```
static u32 task_sender(void *arg) {
    (void)arg;
    // ...
    u32 cycle = 0;

    while(running) {
        ca_os_sleep(500);

        switch(cycle % 3) {
        case 0:
```

```
            ca_notify_give(receiver_idx, 0xAA00 + cycle);
            break;
        case 1:
            ca_notify_give_inc(receiver_idx);
            break;
        case 2:
            ca_notify_send(receiver_idx, (1 << 0) | (1 << 4),
    CA_NOTIFY_ACTION_SET_BITS);
            break;
        }
        cycle++;
    }
    // ...
}
```

The sender task demonstrates three different notification actions, cycling through them:

1. **Overwrite** (`ca_notify_give`): Overwrites the receiver's `notify_value` with a direct value. This is the most common action, ideal for passing simple data.
2. **Increment** (`ca_notify_give_inc`): Increments the receiver's `notify_value` by 1. Useful as an event counter: the receiver reads how many events have accumulated.
3. **Set bits** (`ca_notify_send` with `CA_NOTIFY_ACTION_SET_BITS`): Performs an OR operation between the current value and the provided bitmask. It allows signaling multiple conditions: each bit represents a different event.

The five available actions

Action	Constant	Operation	Typical use
None	`CA_NOTIFY_ACTION_NONE`	No modification, wake-up only	Pure wake-up
Set bits	`CA_NOTIFY_ACTION_SET_BITS`	`value |= param`	Multiple flags
Clear bits	`CA_NOTIFY_ACTION_CLEAR_BITS`	`value &= ~param`	Reset specific flags
Overwrite	`CA_NOTIFY_ACTION_OVERWRITE`	`value = param`	Data passing
Increment	`CA_NOTIFY_ACTION_INCREMENT`	`value++`	Event counter
Set if empty	`CA_NOTIFY_ACTION_SET_IF_EMPTY`	`value = param` only if `value == 0`, otherwise `false`	Data that must not overwrite an unread one

Priority and creation order

```
ca_os_job("receiver", CA_TH_LEVEL2, task_receiver, NULL,
                      STACK_MEDIUM, CA_JOB_STD, CA_FAULT_ASSERT);
ca_os_job("sender",   CA_TH_LEVEL3, task_sender, NULL,
                      STACK_MEDIUM, CA_JOB_STD, CA_FAULT_ASSERT);
```

The receiver is created with a higher priority (`CA_TH_LEVEL2`) than the sender (`CA_TH_LEVEL3`). This ensures that the receiver is scheduled first and can save its `idx` in `receiver_idx` before the sender starts sending notifications.

No initialization

As with critical sections (example 8), task notifications do not require any initialization call. The `notify_value` field in the task context is initialized to zero by the scheduler at the time of task creation.

32.1.6 API

The main functions for task notifications are:

- `ca_notify_send(task_idx, value, action)`: Send notification with specified action
- `ca_notify_give(task_idx, value)`: Send notification with overwrite (inline helper)
- `ca_notify_give_inc(task_idx)`: Send notification with increment (inline helper)
- `ca_notify_take(timeout_ms)`: Wait for notification with automatic clear (inline helper)
- `ca_notify_peek(timeout_ms)`: Wait for notification without clear (inline helper)
- `ca_notify_wait(clear_on_exit, timeout_ms)`: Wait for notification (base function)
- `ca_notify_get(task_idx)`: Read value without blocking
- `ca_notify_clear(task_idx)`: Clear value
- `ca_notify_send_isr(task_idx, value, action)`: Send notification from ISR
- `ca_notify_give_isr(task_idx, value)`: Send notification from ISR with overwrite (inline helper)

32.1.7 Notifications vs other primitives

Feature	Notification	Queue	Semaphore
Additional memory	Zero	Buffer + structure	Structure
Initialization	None	`ca_queue_static_init`	`ca_sem_init`
Transferable values	1 x u32	N messages	Counter
Directionality	Task-to-task	Any	Any
Use from ISR	Yes (`_isr`)	Limited	Yes (`_post`)
Overhead	Minimal	Medium	Low

Notifications are the right choice when:

1. You need to signal a **single event** or pass a **single value**
2. Communication is **direct** between two specific tasks
3. You want the **fastest and lightest** mechanism possible
4. You are operating from an **ISR** and need to signal a task with minimal overhead

32.1.8 When not to use notifications

- If you need **multiple values** in a queue: use queues
- If **multiple tasks** need to wait for the same signal: use semaphores or condition variables
- If you need **mutual exclusion**: use mutexes
- If the receiver is not a specific task but **anyone interested**: use other mechanisms

32.1.9 What this example teaches us

1. **Direct signaling**: How to send notifications to a specific task via its handle
2. **Multiple actions**: How to use overwrite, increment, and set bits for different scenarios
3. **Zero setup**: How notifications require no data structures or initialization
4. **Waiting with timeout**: How the receiver blocks waiting with a timeout and automatic clear

5. **Informed trade-offs**: Notifications are extremely fast but limited to a single u32 value per task ## Example output

Below is the output produced by the example on the debug serial port:

```
================================================
 -- c.a.O.S --
   build : 77af553c+dev - 2026-02-15 22:34:58
   MCU : STM 32 F:H7xx T:753
================================================
   System Clock: 480000000 Hz
   SysTick: 47999 clocks per tick
   Debug UART3 Baudrate: 4000000 bps
================================================
SENDER started: idx=4 p1=0
RECEIVER started: idx=3 p1=0
SENDER: overwrite value=0x0000AA00
RECEIVER: notifica ricevuta value=0x0000AA00
SENDER: increment
RECEIVER: notifica ricevuta value=0x00000001
SENDER: set bits 0x00000011
RECEIVER: notifica ricevuta value=0x00000011
SENDER: overwrite value=0x0000AA03
RECEIVER: notifica ricevuta value=0x0000AA03
SENDER: increment
RECEIVER: notifica ricevuta value=0x00000001
SENDER: set bits 0x00000011
RECEIVER: notifica ricevuta value=0x00000011
SENDER: overwrite value=0x0000AA06
RECEIVER: notifica ricevuta value=0x0000AA06
```

32.1.10 Verification of waits with timeout (`twait`)

Since 09/27, a task waiting for a notification **with timeout** (`ca_notify_take()`) registers in the same wait list as those waiting without a timeout, parked in `SLEEP` until expiration, and the signaler wakes it up immediately (S2_02 §8.8). Previously, it performed polling every 10 ms outside the list: it would wake up up to 10 ms after the signal.

The command `twait [sec]` (default 3 s) measures it with a peer task created at the first call. The wait runs in the command task:

1. **latency** — 300 loops: the peer performs `ca_notify_send_handle()` to the waiting task after a random 1..8 ms; the waiter, with a 20 ms timeout, must obtain it (`lost=0`), not before the signal (`spur=0`), and be running within 2 ms (`lat_max` limit, in ticks);
2. **timeout** — no one notifies; for `sec` seconds, T = 1..20 ms: the return never arrives **before** T (`early=0`), at most 2 ms after (`late=0`), and always with `false` (`got=0`).

One line, closed by `PASS` or `FAIL`. On H753 (tick 200 µs):

```
TW notify : rounds=300 lat_max=0/10 lost=0 spur=0 | tmo n=291 early=0 late=0 got
   =0 over_max=0/10  PASS
```

On the previous kernel: FAIL, `lat_max=50/10`.

In the bank, it is case `timed_wait` of `test_ex09.cpp` (helper `test/hw_test/inc/caosTimedWait.h`). Manually:

```
caos_shell -e 9 -q -t 40 -u "TW .*(PASS|FAIL)" -g "^TW" "twait 3"
```

Chapter 33

Watchdog

33.1 Example 10 — Watchdog Timer (WDT)

33.1.1 Introduction

In the previous examples, we saw how tasks can be protected from software faults using the Safeguard module. However, there is another fundamental protection in embedded systems: the **Watchdog Timer (WDT)**.

The watchdog is a hardware timer that, if not periodically "reloaded" by the software, **resets the MCU**. It protects the system from hangs, infinite loops, and tasks that stop performing their duties.

A watchdog that is configured but never triggers is indistinguishable from one that is working, until the day it is needed: for this reason, the example does not just configure it, but **actually triggers it** and, upon reboot, reports what caused the reset.

In this example, we will see how to: 1. configure the watchdog (IWDG or WWDG) and know its maximum timeout; 2. reload it from a dedicated task; 3. reconfigure an **already running** IWDG (new timeout, the watchdog remains active); 4. read the **cause of the last reset** with `ca_wdt_reset_cause()`.

33.1.2 What is the Watchdog Timer?

IWDG (Independent Watchdog)

Feature	Description
Clock	LSI (~32 kHz, ~40 kHz on F1) - independent of the system clock
Timeout	from 1 ms to the maximum of the family (table below)
Once started	**CANNOT be stopped**, only reconfigured

The LSI is not a crystal: on some parts, it deviates from the nominal value by tens of percentage points, so IWDG timeouts are **nominal**.

WWDG (Window Watchdog)

Feature	Description
Clock	PCLK divided by 4096 × 2^WDGTB
Timeout	from about 0.1 ms to a few tens/hundreds of ms

Feature	Description
Window	the reload must occur within a window (in caOS the window is open: 0x7F)

33.1.3 Driver API (`wdt.h`)

```
bool ca_wdt_init(u32 timeout_ms, ca_wdt_mode_t mode, ca_wdt_type_t type);
bool ca_wdt_enable(void);              /* starts and reloads */
void ca_wdt_reload(void);
u32  ca_wdt_get_timeout_ms(void);      /* effective timeout after HW rounding */
bool ca_wdt_is_enabled(void);
u32  ca_wdt_max_timeout_ms(ca_wdt_type_t type);
ca_wdt_reset_t ca_wdt_reset_cause(bool clear);   /* NONE | IWDG | WWDG */
```

- The timeout ranges from `CA_WDT_TIMEOUT_MIN_MS` (1 ms) to `ca_wdt_max_timeout_ms(type)`, the **actual** maximum for the family.
- A **running IWDG** accepts a new `ca_wdt_init()`: prescaler and reload change, and the subsequent `ca_wdt_enable()` reloads the counter with the new value. This is what `ca_os_reset()` and the `reboot` command (1 ms timeout) do, and it is what is needed for an image started by a bootloader that left the IWDG enabled. A running WWDG, or a change of type, is rejected.
- With a **debugger connected**, the watchdogs stop while the core is in halt (freeze in DBGMCU, written only if `DHCSR.C_DEBUGEN` is active: without a debugger, the DBGMCU is not touched).
- RCC reset flags remain at 1 until they are cleared: `ca_wdt_reset_cause(true)` clears **all** of them (power-on, pin, software…), so those who need the others must read them first.

Maximums per family

Values printed by the boards at boot (`E10: max IWDG ... WWDG ...`), 10/21/2026:

Board	IWDG max	WWDG max	PCLK1
NUCLEO-F446ZE	32768 ms	49 ms	42 MHz, WDGTB up to /8
NUCLEO-F767ZI	32768 ms	38 ms	54 MHz, /8
NUCLEO-H753ZI	32768 ms	279 ms	120 MHz, /128
NUCLEO-H563ZI	131072 ms	134 ms	250 MHz, /128
NUCLEO-U575ZI-Q	131072 ms	419 ms	80 MHz, /128

F1xx (LSI 40 kHz) reaches ~26 s of IWDG; it is not on the test bench.

33.1.4 The source code

The file is located in `examples/example_10/ca_os_ex10.c`. The example remains **stopped at boot** and works on command.

Only one task reloads the watchdog, and only when told to do so:

```
static u32 task_feeder(void *arg)
{
    (void)arg;
    while (1) {
        if (s_feed) ca_wdt_reload();
        ca_os_sleep(E10_FEED_MS);          /* 200 ms */
    }
    return 0;
}
```

At boot, first of all, the cause of the last reset is read and the flags are cleared:

```
s_boot_cause = ca_wdt_reset_cause(true);
PRINTF_N(buf, sizeof(buf), "E10: last reset by watchdog: %s", s_cause_name[
    s_boot_cause]);
```

The heart of `e10 start` is phases 3 and 4: an IWDG at 20 s, then the **same IWDG in operation** brought to 5 s. Surviving 6 s after reconfiguration proves that the new value has been taken and that the task is keeping it alive:

```
bool p3 = ca_wdt_init(E10_LONG_MS, CA_WDT_MODE_RESET, CA_WDT_TYPE_IWDG);
u32 t3 = ca_wdt_get_timeout_ms();
s_feed = true;
p3 = p3 && near(t3, E10_LONG_MS) && ca_wdt_enable() && ca_wdt_is_enabled();
ca_os_sleep(3000);

bool p4 = ca_wdt_init(E10_RECONF_MS, CA_WDT_MODE_RESET, CA_WDT_TYPE_IWDG);
u32 t4 = ca_wdt_get_timeout_ms();
p4 = p4 && near(t4, E10_RECONF_MS) && ca_wdt_enable();
ca_os_sleep(E10_RECONF_MS + 1000U);
```

`e10 bite` configures the watchdog and stops reloading it:

```
static void bite(ca_wdt_type_t type, u32 ms)
{
    if (!ca_wdt_init(ms, CA_WDT_MODE_RESET, type)) { ... }
    s_feed = false;
    if (!ca_wdt_enable()) { ... }
    CLI_PRINTF_N("E10: starving %s, %u ms - a reset must follow", ...);
}
```

33.1.5 Architecture

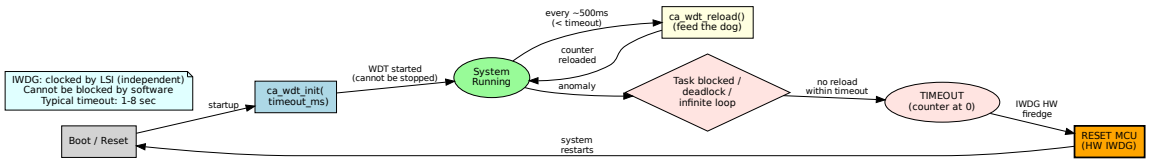

Figure 33.1: Watchdog Timer state machine

The diagram shows the watchdog lifecycle: after initialization, the system must periodically reload the counter (`ca_wdt_reload`) within the configured timeout. If the task hangs or enters an infinite loop, the reload does not occur and, upon timeout expiration, the IWDG generates a hardware reset independent of the software. The watchdog cannot be stopped after it has been started.

33.1.6 CLI Commands

Command	Description
`e10 start`	single pass, no reset, closed by `RUN RESULT : OK (4/4)`
`e10 bite iwdg [ms]`	IWDG at `ms` (default 2000), reload task stopped: reset

Command	Description
`e10 bite wwdg`	WWDG at its maximum, never reloaded: reset. Rejected if `start` has already enabled the IWDG
`e10 early wwdg`	WWDG with early warning: the callback leaves a mark in the last backup register, then reset; the next boot prints `E10: early warning before the reset: WWDG, 1 call(s)`
`e10 early iwdg [ms]`	same with IWDG on H5/U5; on other families the mode must be rejected: `E10: no early warning for IWDG here, mode refused`
`e10 info`	reset cause at boot, maximums, driver status
`wdt info`	driver node (`EN_CLI_WDT=1`), registered by `ca_wdt_init()`
`reboot`	`cli.c` command: arms the IWDG at 1 ms and stops reloading it

The four phases of `e10 start`:

1. `ca_wdt_init(0)` and `ca_wdt_init(max + 1)` rejected;
2. IWDG maximum reaches at least 20 s on every family;
3. IWDG at 20 s: effective timeout within 5%, started, kept alive for 3 s;
4. IWDG **running** set to 5 s: accepted, and the board survives for 6 s.

From the end of the pass, the IWDG remains on (it cannot be turned off) and the task reloads it.

33.1.7 Expected Output

On the NUCLEO-H563ZI:

```
================================================
       TEST 10: Watchdog Timer (WDT)
================================================
E10: last reset by watchdog: none
E10: max IWDG 131072 ms, WWDG 134 ms
E10: early warning before the reset: none
E10: idle - e10 start | bite | early | info

c.a.O.S > e10 start
E10: start - 4 phases
WDT: timeout out of range
WDT: timeout out of range
E10: phase 1 OK - 0 ms and max+1 ms refused
E10: max IWDG 131072 ms, WWDG 134 ms
E10: phase 2 OK - IWDG reaches 20 s
E10: IWDG 20000 ms -> effective 20000 ms, running
E10: phase 3 OK - IWDG at 20 s enabled and fed
E10: running IWDG set to 5000 ms -> effective 5000 ms
E10: phase 4 OK - running IWDG reconfigured, still alive
  RUN RESULT : OK  (4/4)

c.a.O.S > e10 bite iwdg 2000
E10: starving IWDG, 2000 ms - a reset must follow
[RESET AFTER ~2 SECONDS]
...
E10: last reset by watchdog: IWDG
```

The two `WDT: timeout out of range` are the driver rejecting the phase 1 values: they are expected. The driver writes them directly to the UART, not from the stdout queue, so they may appear broken or mixed with the task lines.

A `e10 bite wwdg` on the NUCLEO-H753ZI (after a `reset`, because the IWDG enabled by `start` rejects it):

```
c.a.O.S > e10 bite wwdg
E10: starving WWDG, 275 ms - a reset must follow
...
E10: last reset by watchdog: WWDG
```

33.1.8 The bench test

`test/hw_test/src/test_ex10.cpp` executes, in this order:

Phase	Expected
boot	cause, maximums, `E10: idle`
`e10 start`	`RUN RESULT : OK (4/4)`, no reset during the pass
`wdt info`	`wdt: ENABLED type=IWDG`
`e10 bite iwdg 2000`	no banner in the first 600 ms, banner within 8 s, cause `IWDG`
`e10 bite wwdg`	banner within 4 s, cause `WWDG`
`e10 early wwdg`	banner within 4 s, cause `WWDG`, early warning sign
`e10 early iwdg 2000`	H5/U5: no banner in the first 600 ms, banner within 8 s, cause `IWDG` and sign; elsewhere `mode refused` and no reset
`reboot`	banner within 4 s, cause `IWDG`
`reset`	cause `none`: the previous boot cleared the flags

The order matters: the WWDG comes before `reboot` because an enabled IWDG (left by `start`) rejects the WWDG, and only a reset turns off the IWDG.

Bench result, 21/10/2026: 7/7 on NUCLEO-H563ZI, H753ZI, F446ZE, F767ZI and U575ZI-Q (Release). **22/10/2026**, with the two early warning phases: 9/9 on NUCLEO-H563ZI, H753ZI, F767ZI, U575ZI-Q and F446ZE.

33.1.9 Differences between Families

Family	Reset flag register	Notes
F1xx / F4xx / F7xx / U5xx	`RCC->CSR` (`IWDGRSTF`, `WWDGRSTF`, `RMVF`)	
H5xx	`RCC->RSR` (`IWDGRSTF`, `WWDGRSTF`, `RMVF`)	IWDG with 4-bit PR (/1024)

Family	Reset flag register	Notes
H7xx	`RCC->RSR` (`IWDG1RSTF`, `WWDG1RSTF`, `RMVF`)	instances `IWDG1`/`WWDG1`; WWDG1 resets the system only with `RCC_GCR.WW1RSC = 1` (RM0433 §7.7.35), which the driver sets

33.1.10 Best Practices

1. Only one task reloads

Reloading scattered across multiple tasks hides the blocked task: it is enough for just one to continue reloading. It is better to have a dedicated task that reloads only if the others have shown signs of life.

2. Timeout well above the reload period

```
ca_wdt_init(2000, CA_WDT_MODE_RESET, CA_WDT_TYPE_IWDG);  /* 2 s */
/* reload every 200-500 ms */
```

With the LSI potentially deviating significantly from the nominal value, a margin of 4-10 times is reasonable.

3. Reading the reset cause at boot

```
ca_wdt_reset_t why = ca_wdt_reset_cause(true);
```

A watchdog reset in the field is information: it must be recorded, not lost at the next reset.

33.1.11 Summary

1. **The watchdog protects against software hangs** by resetting the MCU if it is not reloaded in time.
2. **IWDG** is independent of the system clock and can reach tens of seconds (131 s on H5/U5); **WWDG** has millisecond timeouts.
3. **An enabled IWDG cannot be turned off**, but it can be reconfigured: `ca_wdt_init()` + `ca_wdt_enable()`.
4. `ca_wdt_reset_cause()` indicates whether the last reset was caused by a watchdog; use `clear = true` to clear the flags.
5. **The real test is the reset**: the example triggers it and verifies the cause upon reboot.

Chapter 34

CPU Temperature

34.1 Example 11 — Core Temperature Monitor with Watchdog Protection

34.1.1 Introduction

In embedded systems, MCU overheating can cause malfunctions, performance degradation, or permanent damage. This example demonstrates how to use the **internal temperature sensor** to monitor the core temperature and trigger automatic protections.

In this example, we will see how to:

1. Initialize the internal temperature sensor
2. Create a temperature monitoring task
3. Implement a two-threshold protection:
   - **75°C**: core clock reduction
   - **85°C**: stop watchdog reload → system reset
4. Manage recovery when the temperature drops

34.1.2 Thermal Protection Architecture

The system implements a **two-threshold** protection with hysteresis:

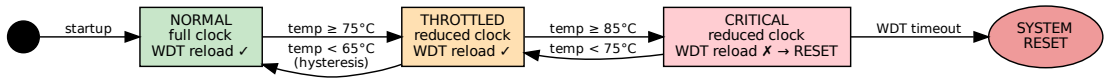

Figure 34.1: Thermal protection state machine

Why Two Thresholds?

1. **75°C Threshold (Clock Reduction)**: First level of protection. By reducing the clock, power consumption and thermal dissipation are decreased, allowing the system to cool down without interrupting operations.
2. **85°C Threshold (WDT Reset)**: Second level of protection. If the temperature continues to rise despite the clock reduction, the system is forced to reset to prevent permanent damage.

3. **Hysteresis (65°C)**: The recovery temperature is lower than the activation temperature to avoid frequent state oscillations when the temperature is near the threshold.

34.1.3 Source Code

The file is located in `examples/example_11/ca_os_ex11.c`:

```
#include "caos.h"
#include "temp_sensor.h"

/* Configurazione */
#define TEMP_CLOCK_THRESHOLD      75      // 75 C  - soglia riduzione clock
#define TEMP_WDT_RESET_THRESHOLD  85      // 85 C  - soglia reset WDT
#define TEMP_RECOVERY_THRESHOLD   65      // 65 C  - soglia di ripristino
#define TEMP_READ_PERIOD_MS       500     // 500ms
#define WDT_TIMEOUT_MS            2000    // 2 secondi

/* Stati del sistema termico */
typedef enum {
    THERM_STATE_NORMAL = 0,       // T < 65 C
    THERM_STATE_CLOCK_REDUCE,     // 75 C  <= T < 85 C
    THERM_STATE_WDT_RESET,        // T >= 85 C      reset inevitabile
} thermal_state_t;

static volatile thermal_state_t g_thermal_state = THERM_STATE_NORMAL;
static volatile bool g_wdt_stopped = false;
static volatile bool g_clock_reduced = false;

/* Task di monitoraggio temperatura */
static u32 task_temp_monitor(void *arg) {
    (void)arg;
    while (1) {
        i32 current_temp = ca_temp_read();

        /* Determina stato in base alla temperatura */
        if (current_temp >= TEMP_WDT_RESET_THRESHOLD) {
            new_state = THERM_STATE_WDT_RESET;
        } else if (current_temp >= TEMP_CLOCK_THRESHOLD) {
            new_state = THERM_STATE_CLOCK_REDUCE;
        } else if (current_temp <= TEMP_RECOVERY_THRESHOLD) {
            new_state = THERM_STATE_NORMAL;
        } else {
            new_state = g_thermal_state;
        }

        /* Gestisci transizione di stato */
        if (new_state != g_thermal_state) {
            g_thermal_state = new_state;

            switch (g_thermal_state) {
                case THERM_STATE_WDT_RESET:
                    g_wdt_stopped = true;
                    /* Riduci anche il clock se non ancora ridotto */
                    if (!g_clock_reduced) {
                        ca_os_clock_reduce_freq(50);
                        g_clock_reduced = true;
                    }
                    break;

                case THERM_STATE_CLOCK_REDUCE:
                    if (!g_clock_reduced) {
                        ca_os_clock_reduce_freq(50);
                        g_clock_reduced = true;
```

```
                    }
                    break;

                case THERM_STATE_NORMAL:
                    if (g_wdt_stopped)
                        g_wdt_stopped = false;
                    if (g_clock_reduced) {
                        ca_os_clock_restore_freq();
                        g_clock_reduced = false;
                    }
                    break;
            }
        }

        ca_os_sleep(TEMP_READ_PERIOD_MS);
    }
}

/* Task di reload watchdog */
static u32 task_wdt_reload(void *arg) {
    (void)arg;
    while (1) {
        /* Se g_wdt_stopped    true, NON ricaricare     reset sistema */
        if (!g_wdt_stopped) {
            ca_wdt_reload();
        }
        ca_os_sleep(WDT_TIMEOUT_MS / 2);
    }
}

char buf[DEFAULT_MSG_SIZE];
void ca_os_main(void) {
    /* 1. Inizializza sensore temperatura */
    if (!ca_temp_init()) {
        PRINTF_N(buf,sizeof(buf),"ERROR: Temperature sensor init FAILED!");
        return;
    }

    /* 2. Inizializza WDT */
    if (!ca_wdt_init(WDT_TIMEOUT_MS, CA_WDT_MODE_RESET, CA_WDT_TYPE_IWDG)) {
        PRINTF_N(buf,sizeof(buf),"ERROR: WDT initialization FAILED!");
        return;
    }

    /* 3. Crea task */
    ca_os_job("temp_mon", CA_TH_LEVEL3, task_temp_monitor, NULL,
              STACK_MEDIUM, CA_JOB_STD, CA_FAULT_ASSERT);
    ca_os_job("wdt_reload", CA_TH_LEVEL2, task_wdt_reload, NULL,
              STACK_SMALL, CA_JOB_STD, CA_FAULT_ASSERT);

    /* 4. Abilita WDT */
    if (!ca_wdt_enable()) {
        PRINTF_N(buf,sizeof(buf),"ERROR: WDT enable FAILED!");
        return;
    }

    /* 5. Avvia scheduler */
    ca_os_run(true);
}
```

34.1.4 CLI Commands

`ca_wdt_init()` automatically registers the WDT driver CLI node (if `EN_CLI_WDT=1`). In this example, the watchdog is initialized in `ca_os_main`, so the command is available as soon as the scheduler starts.

Command	Description
`wdt info`	Shows status, type, mode, and configured timeout
`sensor`	Shows the current core temperature (built-in `cli.c`); on the H563, it also shows the DTS temperature
`dts`	H563: DTS versus ADC sensor, with `DTS CMP PASS/FAIL` verdict
`dts alarm`	H563: DTS threshold alarm test, `DTS ALARM PASS/FAIL` verdict

Typical output during operation:

```
c.a.O.S > wdt info
wdt: ENABLED  type=IWDG  mode=RESET  timeout=2000 ms

c.a.O.S > sensor
Core temperature : 47 Celsius
```

Useful for monitoring the running system without interrupting the thermal protection cycle.

34.1.5 The digital DTS sensor (H563)

The H563 has a second sensor, the **DTS** (RM0481 ch. 27), independent of the ADC: an oscillator whose frequency increases with temperature, measured by counting PCLK cycles. The calibration is factory-written in the block registers (frequency at 30 °C and slope in Hz/°C), so it does not depend on VREF+ or VREFINT and does not occupy ADC1. It is not present on other families: the functions indicate this and the rest of the example remains unchanged.

```
bool ca_temp_dts_present(void);
i32  ca_temp_read_dts(void);     /* centi-degC, average of 16 measurements */
bool ca_temp_set_alarm(i32 cold_c, i32 hot_c, ca_temp_alarm_cb_t cb);
void ca_temp_retune(void);       /* after a core clock change */
```

- **Reading**: a measurement oscillates by about 1 °C; `ca_temp_read_dts` averages 16 of them in about 2 ms (each measurement recalibrates itself). On the bench, the DTS reads 1-2 °C above the ADC sensor, within the sum of the two datasheet errors (DS14258: DTS from -7 to +2 °C, ADC 3 °C linearity).
- **Alarm**: the DTS compares each measurement with two hardware thresholds and generates an interrupt, without a task reading it. The callback runs **in the interrupt** and receives the side exceeded (`hot` true above `hot_c`, false below `cold_c`). Each side triggers **once** and then remains off until the next `ca_temp_set_alarm`; `cb` to `NULL` turns off the alarm.
- **Clock**: the thresholds are PCLK counts. By halving the clock, the same heat would give half the count, i.e., a "hotter" die, and the alarm would trigger falsely. `ca_pwr_set_freq` /`ca_pwr_restore_freq` call `ca_temp_retune()`, which reconstructs the thresholds; `therm_set_clock()` of this example also does this.

The reference is PCLK and not the LSE because, over 15 LSE periods, the count moves by about 1 unit per °C against the ~15 of PCLK. Calibration would require a clock under 1 MHz

and the divider stops at 127, so at 250 MHz it works at about 2 MHz: measured on 24/10/2026, the readings remain within 1-2 °C of the ADC sensor.

`dts alarm` tests three cases: a high threshold below the current temperature must trigger (hot side, only once); a window around the temperature must remain silent; the same window must also remain silent with the clock halved.

```
c.a.O.S > dts
DTS temp   29.87 C
DTS adc   28 C   read 2106 us
DTS CMP PASS (DTS-ADC 1 C, window -10..5)

c.a.O.S > dts alarm
DTS alarm -1..26 C at 29 C: hot 1 cold 0 (want 1 0)
DTS alarm -1..59 C at 29 C: hot 0 cold 0 (want 0 0)
DTS alarm across half clock: hot 0 cold 0 (want 0 0)
DTS ALARM PASS
```

34.1.6 Detailed analysis

Threshold Configuration

```
#define TEMP_CLOCK_THRESHOLD      75      // 75 C  - soglia riduzione clock
#define TEMP_WDT_RESET_THRESHOLD  85      // 85 C  - soglia reset WDT
#define TEMP_RECOVERY_THRESHOLD   65      // 65 C  - soglia di ripristino
```

- `TEMP_CLOCK_THRESHOLD`: When the temperature reaches 75°C, the core clock is halved to reduce thermal dissipation.
- `TEMP_WDT_RESET_THRESHOLD`: When the temperature reaches 85°C, the watchdog reload is stopped, causing a system reset after ~2 seconds.
- `TEMP_RECOVERY_THRESHOLD`: When the temperature drops below 65°C, all protections are deactivated and the system returns to normal configuration.

Thermal System States

```
typedef enum {
    THERM_STATE_NORMAL = 0,       // T < 65 C  - funzionamento normale
    THERM_STATE_CLOCK_REDUCE,     // 75 C  <= T < 85 C  - clock ridotto
    THERM_STATE_WDT_RESET,        // T >= 85 C  - reset inevitabile
} thermal_state_t;
```

Note: once the 85°C threshold is exceeded, a reset is inevitable. The WDT is no longer reloaded and the system resets after the timeout (~2s). There is no recovery from this state — the protection is intentionally irreversible.

Temperature Monitoring Task

```
static u32 task_temp_monitor(void *arg) {
    (void)arg;
    while (1) {
        i32 current_temp = ca_temp_read();

        /* Determina stato in base alla temperatura */
        if (current_temp >= TEMP_WDT_RESET_THRESHOLD) {
            new_state = THERM_STATE_WDT_RESET;
        } else if (current_temp >= TEMP_CLOCK_THRESHOLD) {
            new_state = THERM_STATE_CLOCK_REDUCE;
        } else if (current_temp <= TEMP_RECOVERY_THRESHOLD) {
            new_state = THERM_STATE_NORMAL;
```

```
        } else {
            new_state = g_thermal_state;
        }

        /* Gestisci transizione di stato */
        if (new_state != g_thermal_state) {
            // ... applica protezioni ...
        }

        ca_os_sleep(TEMP_READ_PERIOD_MS);
    }
}
```

The task: 1. Reads the temperature every 500ms via `ca_temp_read()` 2. Determines the new state based on the thresholds 3. Manages state transitions by activating/deactivating protections

Watchdog Reload Task

```
static u32 task_wdt_reload(void *arg) {
    (void)arg;
    while (1) {
        /* Se g_wdt_stopped    true, NON ricaricare     reset sistema */
        if (!g_wdt_stopped) {
            ca_wdt_reload();
        }
        ca_os_sleep(WDT_TIMEOUT_MS / 2);
    }
}
```

This task checks the `g_wdt_stopped` variable: - If **false**: reloads the watchdog normally - If **true** (T >= 85°C): does **NOT** reload the watchdog → the system is reset after `WDT_TIMEOUT_MS`

Clock Reduction Functions

```
/* Da hw/<famiglia>/common/clock.c */
u32 ca_os_clock_reduce_freq(u16 scale);    // Riduce clock al X% (es: 50 = 50%)
u32 ca_os_clock_restore_freq(void);        // Ripristina clock originale
```

These functions are implemented in the `clock.c` file specific to the MCU family.

The functions are implemented in `hw/<famiglia>/common/clock.c` for each MCU family. They operate on the AHB prescaler (HPRE) for F1xx/F4xx/F7xx, HPRE in CFGR2 for H5xx, and D1CPRE for H7xx. They select the hardware divisor closest to the requested percentage among those available (1, 2, 4, 8, 16, 64, 128, 256, 512).

`ca_os_clock_reduce_freq(50)` reduces the clock to 50% of the nominal frequency (defined by `SYSCLK_FREQ_HZ` in `objmap.h`). The PLL remains unchanged — no clock glitches.

34.1.7 Expected Output

```
================================================
  TEST 11: Core Temperature Monitor + WDT
================================================

Initializing temperature sensor...
Temperature sensor initialized

Initializing WDT:
  - Timeout: 2000 ms
  - Type: IWDG
  - Mode: RESET
WDT initialized successfully
```

```
13
14 TEMP Monitor started
15   - Clock reduce threshold: 75 C
16   - WDT reset threshold: 85 C
17   - Recovery threshold: 65 C
18   - Read period: 500 ms
19
20 WDT Reload task started
21 WDT ENABLED - system protected
22 Temperature monitoring active
23 Clock reduce threshold: 75 C
24 WDT reset threshold: 85 C
25 Recovery threshold: 65 C
26
27 NORMAL: Temp=45 C  - System OK
28 Temp=46 C , State=0, Clk=0, WDT=0
29 Temp=47 C , State=0, Clk=0, WDT=0
30 ...
31 WARNING: Temp=75 C  - Reducing clock
32   -> Core clock: REDUCED (50%)
33 Temp=76 C , State=1, Clk=1, WDT=0
34 ...
35 NORMAL: Temp=64 C  - System OK          <-- recupero sotto 65 C
36   -> Core clock: RESTORED
37 ...
38 !!! WDT RESET: Temp=85 C  - Stopping WDT reload!
39   -> Core clock: REDUCED (50%)
40   -> WDT reload: STOPPED (reset incoming!)
41 [RESET DELLA MCU DOPO ~2 SECONDI]
```

34.1.8 Test Variants

Test 1: Normal Operation

Keep the temperature below 65°C (controlled environment or cold MCU).

Expected result: No protection activated, system stable.

Test 2: Clock Reduction Activation

Heat the MCU up to 75-84°C (e.g., execute intensive code, increase clock, hot environment).

Expected result: - Print “WARNING: Temp=XX°C - Reducing clock” - Clock halved (if implemented) - System continues to operate

Test 3: WDT Reset Activation

Heat the MCU above 85°C.

Expected result: - Print “!!! WDT RESET: Temp=XX°C - Stopping WDT reload!” - MCU reset after ~2 seconds - Flag `RCC_CSR.IWDGRSTF` set after reset

Test 4: Recovery from Clock Reduce

After clock reduction activation (75-84°C), cool the MCU below 65°C.

Expected result: - Print “NORMAL: Temp=XX°C - System OK” - Original clock restored - System returns to full frequency operation

Note: If the temperature has exceeded 85°C (WDT_RESET), recovery is not possible — the system is reset by the watchdog.

34.1.9 Threshold Considerations

MCU Family	Max Operating Temp	Max Junction Temp	Recommended Threshold
STM32F1xx	85°C	150°C	70°C / 80°C
STM32F4xx	105°C	150°C	75°C / 85°C
STM32F7xx	105°C	150°C	75°C / 85°C
STM32H5xx	125°C	150°C	80°C / 90°C
STM32H7xx	125°C	150°C	80°C / 90°C

Note: Thresholds can be adjusted based on the specific application and expected operating conditions.

34.1.10 Thermal System Debugging

Variable Monitoring

In STM32CubeIDE, add the following variables to the "Expressions" view:

- `g_thermal_state`: Current state (0=normal, 1=clock, 2=wdt)
- `g_wdt_stopped`: true if WDT is not reloaded
- `g_clock_reduced`: true if clock is reduced
- `g_clock_events`: Number of clock reduction activations
- `g_wdt_events`: Number of WDT reset activations

Post-Reset Diagnostics

After a reset caused by overheating:

```
if (RCC->CSR & RCC_CSR_IWDGRSTF) {           /* F1, F4, F7, U5 */
    ca_stdout_put_n("Reset caused by IWDG (possible overheating)");
}
```

The example does not do this by itself; the register changes with the family (`RCC->RSR` on the H5 and on the H7), as explained in example 10.

34.1.11 Best Practices

1. Choosing Appropriate Thresholds

```
/* Per applicazioni automotive (temperature elevate) */
#define TEMP_CLOCK_THRESHOLD      80      // 80 C
#define TEMP_WDT_RESET_THRESHOLD  95      // 95 C

/* Per applicazioni consumer (temperature moderate) */
#define TEMP_CLOCK_THRESHOLD      70      // 70 C
#define TEMP_WDT_RESET_THRESHOLD  80      // 80 C
```

2. Verify Clock Implementation

The `ca_os_clock_reduce_freq()` and `ca_os_clock_restore_freq()` functions are already implemented in `hw/<famiglia>/common/clock.c`.

For families that do not support them, implement the functions in the specific clock file.

3. Logging Thermal Events

```
case THERM_STATE_WDT_RESET:
    g_wdt_events++;
    ca_stdout_printf_n("!!! WDT RESET: Temp=%dC - Stopping WDT reload!",
                       current_temp);
```

4. Testing in Real-World Conditions

- Perform tests in a thermal chamber
- Verify system response times
- Validate thresholds with real workloads

34.1.12 Summary

1. **The internal temperature sensor** provides accurate core temperature readings (±1°C after calibration).

2. **The two-threshold protection** allows for gradual overheating management:

   - 75°C: clock reduction (first cooling attempt)
   - 85°C: system reset (extreme protection)

3. **Hysteresis** (65°C recovery) prevents frequent oscillations when the temperature is near the thresholds.

4. **The watchdog timer** is used as a controlled reset mechanism: when the temperature is critical, the reload is stopped, causing a reset after the configured timeout.

5. **The `ca_os_clock_reduce_freq()` and `ca_os_clock_restore_freq()` functions** are implemented in `hw/<famiglia>/common/clock.c` and manage the MCU clock reduction/restoration.

6. **Integrated CLI**: `wdt info` shows the watchdog status; `sensor` shows the current temperature. Both are available without additional application code.

Chapter 35

Extending the System Command Line

35.1 Example 12 — Extending the CLI with user commands

35.1.1 Introduction

caOS includes a system CLI (Command Line Interface) accessible via UART/USB_CDC. Built-in commands provide generic diagnostic tools: task status, memory usage, stack, MPU. Each application can add its own commands by registering a node in the CLI's **chain of responsibility**.

In this example, we will see how to:

1. Define a CLI handler with the correct signature
2. Register it in the chain with `ca_cli_register()`
3. Respond with application output (task statistics and shared counters)
4. Coexist correctly with built-in commands and other handlers in the chain

The application context is intentionally simple: three concurrent tasks contending for a mutex with `ca_mutex_trylock`. The educational focus is entirely on the CLI.

35.1.2 The system CLI

The caOS CLI is a dedicated task that receives characters via STDIN (uart, usb_cdc, etc.) byte by byte, accumulates the line, and, upon receiving `\r` or `\n`, sends the command to the internal queue. The CLI thread processes each command through the chain of registered handlers.

Built-in commands

Command	Description
`help`	List commands from all handlers in the chain
`top`	CPU + memory + stack usage
`sched`	CPU breakdown since last call: context switch, task, idle, free
`taskall`	All tasks (status, priority, stack)
`task <n>`	Specific task detail
`free`	Available heap memory
`canary`	Stack canary status (if MPU is present)
`mpu`	Configured MPU regions
`stack <n>`	Address and stack map of a task

Command	Description
`memlist`	Allocated heap blocks
`hexdump <addr> [lines]`	Memory dump in hexadecimal

Chain of Responsibility

The CLI uses the **chain of responsibility** pattern: each registered handler receives the command and decides whether to handle it or pass it to the next one.

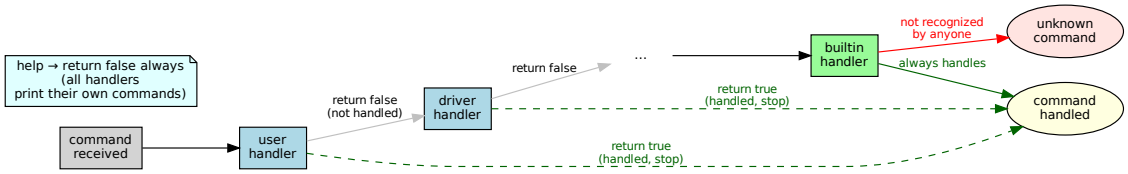

Figure 35.1: CLI Chain of Responsibility

Rules: - `return true` — command handled, the chain stops - `return false` — command not recognized, pass to the next handler - `help` — must always return `false` to allow all handlers to show their commands

`ca_cli_register()` inserts the node **at the head** of the chain (prepend), so the last one registered is queried first.

API

```
typedef struct ca_cli_node {
    bool (*handler)(c_str *cmd);   /* true = command handled */
    struct ca_cli_node *next;
} ca_cli_node_t;

void ca_cli_register(ca_cli_node_t *node);  /* prepend to the chain */
```

The node must be **static** (duration for the entire execution). Registration must be done **before** `ca_os_run()`, typically in `ca_os_main()`.

35.1.3 Source code

The file is located in `examples/example_12/ca_os_ex12.c`:

```
#include "caos.h"

static u32 killer;
static u32 shared_counter;
static u32 counter_t1;
static u32 counter_t2;
static u32 counter_t3;
static ca_mutex_t mtx;

static u32 task_1_exec(void *arg) {
    const u32 p1 = (u32)(uintptr_t)arg;
    const u32 idx = ca_os_thid_from_handle(ca_os_self_handle());
    ca_os_sleep(700);
    ca_stdout_printf_n("TASK t1_w1 started: idx=%u p1=%u", idx, p1);
```

```
    while(killer) {
        counter_t1++;
        if (ca_mutex_trylock(&mtx)) {
            shared_counter++;
            ca_mutex_unlock(&mtx);
        }
        ca_os_sleep(500);
    }
    return 0;
}

static u32 task_2_exec(void *arg) {
    const u32 p1 = (u32)(uintptr_t)arg;
    const u32 idx = ca_os_thid_from_handle(ca_os_self_handle());
    ca_os_sleep(700);
    ca_stdout_printf_n("TASK t1_w2 started: idx=%u p1=%u", idx, p1);
    while(killer) {
        counter_t2++;
        if (ca_mutex_trylock(&mtx)) {
            shared_counter++;
            ca_mutex_unlock(&mtx);
        }
        ca_os_sleep(700);
    }
    return 0;
}

static u32 task_3_exec(void *arg) {
    const u32 p1 = (u32)(uintptr_t)arg;
    const u32 idx = ca_os_thid_from_handle(ca_os_self_handle());
    ca_stdout_printf_n("TASK t1_w3 started: idx=%u p1=%u", idx, p1);
    while(killer) {
        counter_t3++;
        if (ca_mutex_trylock(&mtx)) {
            shared_counter++;
            ca_mutex_unlock(&mtx);
        }
        ca_os_sleep(900);
    }
    return 0;
}

static bool user_cli_handler(c_str *pcmd)
{
    c_str cmd = *pcmd;
    const char *p = ca_skip_sp(cmd->data);

    if (ca_strncmp(p, "help", 4) == 0) {
        CLI_PUT_N("show : show task counters");
        return false;   /* continue the chain: show the other help too */
    }
    if (ca_strncmp(p, "show", 4) == 0) {
        CLI_PUT_N("--- task counters ---");
        CLI_PRINTF_N("shared  : %u", (u32)shared_counter);
        CLI_PRINTF_N("t1_w1   : %u", (u32)counter_t1);
        CLI_PRINTF_N("t1_w2   : %u", (u32)counter_t2);
        CLI_PRINTF_N("t1_w3   : %u", (u32)counter_t3);
        return true;
    }
    return false;
}

111     ca_os_job("t1_w2", CA_TH_LEVEL2, task_2_exec, (void *)(uintptr_t)3,
    STACK_MEDIUM, CA_JOB_STD, CA_FAULT_ASSERT);
112     ca_os_job("t1_w3", CA_TH_LEVEL2, task_3_exec, (void *)(uintptr_t)5,
    STACK_MEDIUM, CA_JOB_STD, CA_FAULT_ASSERT);
113 #endif
114
115     EVAL_CLI( ca_cli_register(&s_user_cli_node); )
116     ca_os_run(true);
117 }
```

Note: the `ca_os_configure()` function is documented in detail in chapter `S2_07_00_ca_os_configure.md`.

35.1.4 Detailed analysis

CLI Handler `user_cli_handler`

```
1 static bool user_cli_handler(c_str *pcmd)
2 {
3     c_str cmd = *pcmd;
4     const char *p = ca_skip_sp(cmd->data);
5
6     if (ca_strncmp(p, "help", 4) == 0) {
7         CLI_PUT_N("show : show task counters");
8         return false;   /* let the other handlers add their help */
```

```
    }
    if (ca_strncmp(p, "show", 4) == 0) {
        CLI_PUT_N("--- task counters ---");
        CLI_PRINTF_N("shared  : %u", (u32)shared_counter);
        CLI_PRINTF_N("t1_w1   : %u", (u32)counter_t1);
        CLI_PRINTF_N("t1_w2   : %u", (u32)counter_t2);
        CLI_PRINTF_N("t1_w3   : %u", (u32)counter_t3);
        return true;    /* command handled, stop the chain */
    }
    return false;       /* not recognized, pass to the next handler */
}
```

Key points:

- **Signature**: `bool (*handler)(c_str *pcmd)` — pointer to pointer, no copy
- `ca_skip_sp`: skips any leading spaces before comparing
- `help` → `return false`: mandatory to allow all handlers in the chain to print their commands
- **Output via `CLI_PUT_N` / `CLI_PRINTF_N`**: these macros include `ca_os_yield()` and `ca_os_sleep(1)` — **never call them while holding a mutex**
- `return true`: stops the chain; the command is not propagated to subsequent handlers

Static node and registration

```
static ca_cli_node_t s_user_cli_node = { user_cli_handler, NULL };

EVAL_CLI( ca_cli_register(&s_user_cli_node); )
```

- The node must be **static**: `ca_cli_register` inserts it into the linked list without copying it
- `NULL` in the `next` field is updated by `ca_cli_register` at the time of insertion
- `EVAL_CLI(...)` compiles the code only if `ENABLE_CLI=1`, making it a no-op otherwise

Application context: mutex trylock

The three tasks contend for a mutex with `ca_mutex_trylock`, which is **non-blocking**: if the mutex is occupied, the task does not suspend but continues the loop.

```
counter_t1++;                       /* always incremented */
if (ca_mutex_trylock(&mtx)) {       /* only if the mutex is free */
    shared_counter++;
    ca_mutex_unlock(&mtx);
}
ca_os_sleep(500);
```

The `show` command allows you to observe at runtime how many times each task has executed its loop and how many times the mutex has been acquired.

Stack per MCU family

```
#if ( MCU==F1xx && MCU_ID==103 )
    ca_os_job(..., STACK_SMALL, ...);   /* F103: 20 KB SRAM in total */
#else
    ca_os_job(..., STACK_MEDIUM, ...);  /* H753 and others */
#endif
```

35.1.5 Adding more commands

To add commands, extend the handler with additional comparisons:

```
static bool user_cli_handler(c_str *pcmd)
{
    c_str cmd = *pcmd;
    const char *p = ca_skip_sp(cmd->data);

    if (ca_strncmp(p, "help", 4) == 0) {
        CLI_PUT_N("show : show task counters");
        CLI_PUT_N("reset : stop the tasks");
        return false;
    }
    if (ca_strncmp(p, "show", 4) == 0) {
        /* ... print statistics ... */
        return true;
    }
    if (ca_strncmp(p, "reset", 5) == 0) {
        killer = 0;
        CLI_PUT_N("tasks stopped");
        return true;
    }
    return false;
}
```

For applications with many separate commands on different modules, you can register **multiple nodes** in the chain — each one handles its own commands independently of the others:

```
static ca_cli_node_t s_net_cli_node   = { net_cli_handler,   NULL };
static ca_cli_node_t s_sensor_cli_node = { sensor_cli_handler, NULL };

ca_cli_register(&s_net_cli_node);
ca_cli_register(&s_sensor_cli_node);
```

35.1.6 Expected output

Startup:

```
TASK t1_w3 started: idx=0 p1=5
TASK t1_w1 started: idx=0 p1=1
TASK t1_w2 started: idx=0 p1=3
```

By typing `help` on the UART (all handlers in the chain contribute):

```
c.a.O.S > help
show : show task counters
top        : cpu + mem + stack usage
sched      : cpu split since last call: switch, tasks, idle, free
banner     : show os banner
taskall    : show all tasks
task <n>   : show task N
free       : Show global memory usage
...
```

By typing `show`:

```
c.a.O.S > show
--- task counters ---
shared  : 47
t1_w1   : 22
t1_w2   : 16
t1_w3   : 12
```

By typing an unknown command (no handler recognizes it):

```
c.a.O.S > xyz
xyz:3 huh!
```

35.1.7 Required configuration in `os_config.h`

```
#define ENABLE_CLI       1    /* the CLI must be enabled */
#define ENABLE_DBG_UART 1    /* UART needed as the I/O channel */
```

Without `ENABLE_CLI 1`, `EVAL_CLI(...)` becomes a no-op and `ca_cli_register` does nothing.

35.1.8 Summary

1. `ca_cli_register(&node)` inserts a static node with handler `bool (*)(c_str *pcmd)` at the head of the chain.
2. `return true` stops the chain — the command has been handled.
3. `return false` propagates to the next handler — command not recognized or `help`.
4. `help` **must always return** `false` to allow all handlers to print their commands.
5. **Output via** `CLI_PUT_N` / `CLI_PRINTF_N` — never under mutex, they include `yield` + `sleep`.
6. **Multiple nodes** can be registered independently: each module handles its own commands without knowing about the others.

Chapter 36

Execution Time Profiling with DWT CYCCNT

36.1 Example 13 — Profiling and task watchdog

36.1.1 Introduction

This example demonstrates two features of the caOS scheduler module:

1. **Execution time profiling** via `ca_measure_start`/`ca_measure_stop`, based on clock cycles consumed by the task (not real time).
2. **Individual task watchdog**: a task that does not call `ca_os_thread_reset_watchdog` within the set limit is automatically terminated by the scheduler.

36.1.2 The `measure` module

API (`caos/inc/measure.h`)

```
void ca_measure_start(u32 *p_snap);
void ca_measure_stop(volatile u32 *p);
```

Behavior

`ca_measure_start` saves the current value of the task's `runtime_total` (clock cycles accumulated since the task started). `ca_measure_stop` calculates the difference and writes it to the same pointer. The result is the number of clock cycles spent by the task between `start` and `stop`.

```
// Implementazione
void ca_measure_start(u32 *p) {
    if (p) *p = ca_scheduler_get_runtime_total();
}

void ca_measure_stop(volatile u32 *p) {
    u32 res = 0;
    if (p) res = ca_scheduler_get_runtime_total() - (*p);
    *p = res;
}
```

Difference compared to the direct DWT approach

Aspect	Direct DWT→CYCCNT	`ca_measure` (runtime_total)
Unit	wall-clock cycles	task-only cycles
Preemption	included in the measurement	excluded (task cycles only)
Interrupts	included	excluded
Initialization	`ca_measure_init()` (deprecated)	automatic (caOS init)
Nested measurements	no	yes (independent local variables)

The main advantage: the measurement is **deterministic** and does not depend on how much other tasks or IRQs have interrupted the task during the profiled section.

Conversion to microseconds

The result of `ca_measure_stop` is in clock cycles. Conversion to ms:

```
u32 time_ms = (u32)((elapsed * 1000) / ca_os_clock_get_freq());
```

`ca_os_clock_get_freq()` returns `SystemCoreClock` in Hz.

Nested measurements

Since `p_snap` is a local variable, independent measurements can also be performed in recursive calls or in different functions:

```
u32 snap_outer, snap_inner;
ca_measure_start(&snap_outer);
    ca_measure_start(&snap_inner);
    inner_function();
    ca_measure_stop(&snap_inner);   // inner_function cycles
outer_function();
ca_measure_stop(&snap_outer);       // total cycles (inner + outer)
```

36.1.3 Task watchdog

API

```
void ca_os_thread_set_watchdog(u32 clock_cycles);   // set the threshold
void ca_os_thread_reset_watchdog(void);              // reset runtime_total
```

Mechanism

The scheduler accumulates the task's active clock cycles in `runtime_total`. At each context switch, it verifies:

```
if (runtime_wdt > 0 && runtime_total > runtime_wdt)
    task->status = CA_ST_TH_SIG_WDT;  // the task is terminated
```

`ca_os_thread_set_watchdog(N)` sets `runtime_wdt = N`. The task must call `ca_os_thread_reset_watchdog()` periodically (which resets `runtime_total`) to avoid termination.

Note: the limit is in active task clock cycles (not real time). A task that sleeps with `ca_os_sleep` does not consume cycles and does not advance towards the threshold. The value must be calibrated experimentally, taking into account the expected load.

36.1.4 Source code

```c
#include "caos.h"

#if EN_MEASURE

static u32 g_elapsed_us;
static volatile u32 g_run_count;

static void work_function(void)
{
    volatile u32 x = 1U;
    for (u32 i = 0U; i < 50000U; i++) {
        x = x * 3U + 1U;
    }
    (void)x;
}

static u32 task_measure_exec(void *arg)
{
    (void)arg;
    u32 elapsed;
    while (1) {
        ca_measure_start(&elapsed);
        work_function();
        ca_measure_stop(&elapsed);
        g_elapsed_us = elapsed;
        g_run_count++;
        ca_os_sleep(1000);
    }
    return 0U;
}

static u32 task_loop_fail(void *arg)
{
    const u32 p1 = (u32)(uintptr_t)arg;
    ca_os_thread_set_watchdog(p1);   // p1 = 16000000 cycles
    while (1) {
        while (1) {
            ca_os_sleep(10);         // never resets the watchdog
        }
        ca_os_thread_reset_watchdog();
    }
    return 0U;
}

static bool user_cli_handler(c_str *pcmd)
{
    const char *p = ca_skip_sp((*pcmd)->data);
    if (ca_strncmp(p, "help", 4) == 0) {
        CLI_PUT_N("show : elapsed time by example_13");
        return false;
    }
    if (ca_strncmp(p, "show", 4) == 0) {
        u32 time_ms = (u32)((g_elapsed_us * 1000) / ca_os_clock_get_freq());
        CLI_PRINTF_N("run count : %u", g_run_count);
        CLI_PRINTF_N("last us   : %u clocks %u ms", g_elapsed_us, time_ms);
        return true;
    }
    return false;
}
static ca_cli_node_t s_user_cli_node = { user_cli_handler, NULL };

```

```
#endif /* EN_MEASURE */

void ca_os_configure(void)
{

    EVAL_STDOUT(
        ca_stdout_init();
        ca_stdout_set_sender(STDOUT);
        ca_stdout_create_thread();
    )
    EVAL_CLI(
        ca_cli_init(4096);
        ca_cli_set_sender(STDOUT);
        ca_cli_create_thread();
    )
    EVAL_USB_CDC_STD(ca_usb_dev_mng_cdc_cli();)

}

void ca_os_main(void)
{
    EVAL_MEASURE(
        g_elapsed_us = 0U;
        g_run_count  = 0U;
        ca_os_job("measure", CA_TH_LEVEL2, task_measure_exec, NULL,
                  STACK_SMALL, CA_JOB_STD, CA_FAULT_ASSERT);
        ca_os_job("loop", CA_TH_LEVEL4, task_loop_fail, (void *)(uintptr_t)
    16000000,
                  STACK_SMALL, CA_JOB_STD, CA_FAULT_ASSERT);
        EVAL_CLI( ca_cli_register(&s_user_cli_node); )
    )
    ca_os_run(true);
}
```

36.1.5 Detailed analysis

`task_measure_exec`

The task measures the clock cycles consumed by `work_function()` (50000 iterations of a volatile calculation). The variable `elapsed` is local: `ca_measure_start` saves the snapshot of `runtime_total` into it, and `ca_measure_stop` writes the difference to it. The result is directly in clock cycles (not microseconds). The CLI converts to ms via `ca_os_clock_get_freq()`.

`task_loop_fail` — watchdog demonstration

```
ca_os_thread_set_watchdog(16000000);   // 16M cycles     ~95ms on H753@480MHz
while (1) {
    while (1) { ca_os_sleep(10); }     // internal endless loop
    ca_os_thread_reset_watchdog();     // never reached
}
```

The internal loop never terminates, so `ca_os_thread_reset_watchdog()` is never called. When the task accumulates 16 million active cycles, the scheduler terminates it with `CA_ST_TH_SIG_WDT` and prints an error message.

Note: `ca_os_sleep` does not consume active cycles — the task sleeps and the scheduler does not increment `runtime_total`. The watchdog triggers only when active cycles exceed the threshold, not the elapsed real time.

Watchdog trigger time estimation

The real time before triggering depends on how many cycles the task consumes per iteration of the `ca_os_sleep(10)`. The sleep is negligible; active cycles are consumed mainly in the scheduler overhead during context switches. The 16M cycle threshold must therefore be calibrated experimentally.

EVAL_MEASURE

The `EVAL_MEASURE` guard enables both tasks and state variables only if `EN_MEASURE` is defined in `os_config.h`. Unlike older examples with `EVAL_F103`/`EVAL_F407`, here the selection is by functionality, not by family — `measure` works identically on all supported MCUs.

36.1.6 Expected output

show command via CLI

```
show
run count : 47
last us   : 284521 clocks  0 ms
```

The value in cycles depends on the frequency and the core pipeline. The conversion to ms will be 0 for short `work_function`; for longer functions, the correct value will appear.

top -r command

```
top -r
task[00] 'idle      ' RUNNING  L1   CPU= 0.0% Clk:      0 Stack= 3.4%  total
    :12345678 wdt=0
task[01] 'stdout    ' BLOCKED  L2   CPU= 0.0% Clk:      0 Stack=12.0%  total
    :456789 wdt=0
task[02] 'measure   ' BLOCKED  L2   CPU= 0.1% Clk: 284521 Stack=18.0%  total
    :9876543 wdt=0
task[03] 'loop      ' REMOVED  L4   CPU= 0.0% Clk:      0 Stack= 0.0%  total
    :16000123 wdt=16000000
```

The task `loop` appears as REMOVED with `total` having exceeded `wdt`.

Watchdog message

```
ERROR : Task[3] 'loop':task watchdog on! 12345
```

36.1.7 Required configuration in os_config.h

```
#define EN_MEASURE  1    // abilita modulo measure + task watchdog
#define ENABLE_STDOUT   1
#define ENABLE_CLI      1    // optional: 'show' command
```

36.1.8 Summary

1. `ca_measure_start(u32 *p)` / `ca_measure_stop(volatile u32 *p)`: the measurement uses `runtime_total` of the task — it counts only active cycles, immune to preemption and IRQs.
2. **Nested measurements**: each local variable is an independent snapshot.
3. `ca_os_thread_set_watchdog(N)`: sets the threshold in active clock cycles. The task must call `ca_os_thread_reset_watchdog()` periodically.

4. **Watchdog vs sleep**: `ca_os_sleep` does not consume active cycles — the watchdog measures only the actual work of the task.

5. `EVAL_MEASURE`: portable guard, works on all supported MCU families.

Chapter 37

Streams

37.1 Example 14 — Stream Buffer with interactive CLI

37.1.1 Introduction

The **Stream Buffer** is a FIFO circular buffer for byte streams. Unlike the Message Buffer (which preserves message boundaries), the Stream treats data as a continuous flow of bytes, similar to a pipe.

In this example: - A **writer** task sends data into the stream (production) - A **reader** task receives data from the stream (consumption) - A **monitor** task displays the stream status in real-time - The **CLI** allows controlling prints and viewing statistics

Demonstrated features

Function	Description
`CA_STREAM_STATIC_DEFINE()`	Static buffer declaration in .bss
`ca_stream_send()` / `ca_stream_receive()`	Send/receive with timeout
`ca_stream_bytes_available()`	Bytes available for reading
`ca_stream_space_available()`	Free space for writing
`ca_stream_set_trigger()`	Minimum threshold for receiver wake-up
`ca_stream_reset()`	Clear the buffer
`ca_stream_is_empty()` / `ca_stream_is_full()`	Buffer status query

CLI Commands

Command	Description
`start`	Enable task prints
`stop`	Disable task prints
`show`	Show stream statistics
`clear`	Reset stream buffer
`help`	List available commands

37.1.2 Example architecture

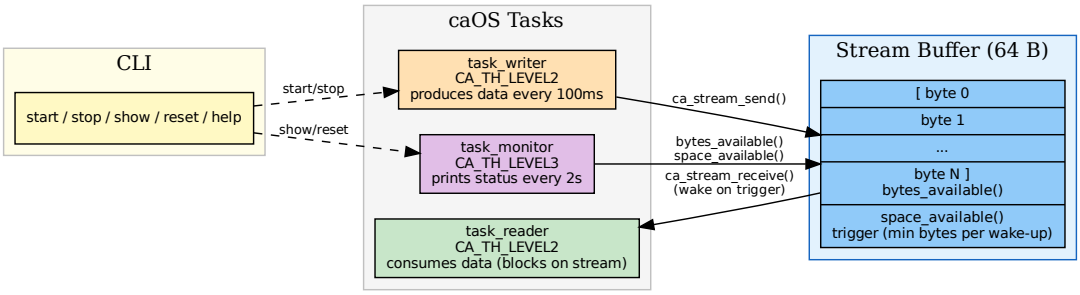

Figure 37.1: Stream Buffer architecture

37.1.3 Source code

The file is located in `examples/example_14/ca_os_ex14.c`:

```c
#include "caos.h"

#define STREAM_SIZE 64  // Dimensione buffer stream in byte

/* Stream buffer statico (allocazione in .bss) */
CA_STREAM_STATIC_DEFINE(data_stream, STREAM_SIZE);

static u32 running;
static u32 bytes_sent;
static u32 bytes_received;
static u32 writer_cycles;
static u32 reader_cycles;
static volatile u8 print_enabled;  // 0 = prints disabled, 1 = enabled

/* ============================================================================
 * TASK: Writer - sends data into the stream
 * ============================================================================
    */

static u32 task_writer(void *arg) {
    const u32 p1 = (u32)(uintptr_t)arg;
    const u32 idx = ca_os_thid_from_handle(ca_os_self_handle());

    if (print_enabled) {
        ca_stdout_printf_n("WRITER started: idx=%u p1=%u", idx, p1);
    }

    u8 sequence = 0;
    char tx_buffer[16];
    int tx_len;

    while (running) {
        // Prepare a block of data to send
        tx_len = ca_snprintf(tx_buffer, sizeof(tx_buffer), "DATA_%03d", sequence
   );

        // Send data into the stream (timeout 500ms)
        u32 written = ca_stream_send(&data_stream, (u8*)tx_buffer, tx_len, 500);
```

```
37
38          if (written > 0) {
39              bytes_sent += written;
40              writer_cycles++;
41              sequence++;
42
43              if (print_enabled) {
44                  ca_stdout_printf_n("WRITER: sent %u bytes (seq=%d)", written,
    sequence - 1);
45              }
46          } else {
47              if (print_enabled) {
48                  ca_stdout_printf_n("WRITER: timeout (stream full?)");
49              }
50          }
51
52          // Wait before the next send
53          ca_os_sleep(200);
54      }
55
56      return 0;
57  }
58

37.1.4 Detailed analysis

Static Stream Buffer

```
#define STREAM_SIZE 64
CA_STREAM_STATIC_DEFINE(data_stream, STREAM_SIZE);
```

The macro expands to:

```
static u8 data_stream_buf[64];
static ca_stream_buffer_t data_stream = {
    .buffer = data_stream_buf,
    .size = 64,
    .head = 0, .tail = 0, .count = 0,
    .lock = CA_SPINLOCK_IRQ_INIT,
    .waiting_task = 0xFFFFFFFF,
    .trigger_level = 1
};
```

Advantages: - Allocation in .bss (zero heap overhead) - Compile-time initialization - No risk of fragmentation

Trigger level

```
ca_stream_set_trigger(&data_stream, 8);
```

The **trigger level** sets the minimum byte threshold to wake up the waiting receiver task. Default: 1 byte.

When to use it: - If the receiver needs to process multiple blocks of bytes - To reduce the number of context switches - To optimize throughput vs latency

Print control with `print_enabled`

```
static volatile u8 print_enabled;  // 0 = disabled, 1 = enabled

// Nei task:
if (print_enabled) {
    ca_stdout_printf_n("...");
}
```

Prints are **disabled by default** (`print_enabled = 0` in `ca_os_main()`). They can be enabled with the `start` command from the CLI.

> **Note**: It is not possible to send prints with `ca_stdout_*` before `ca_os_run(true)`, because the output system (stdout thread) is not yet active.

CLI Hook

The CLI node handles 5 commands: - `start`: enable prints (`print_enabled = 1`) - `stop`: disable prints (`print_enabled = 0`) - `show`: statistics + print status - `clear`: flush stream buffer - `help`: adds the line `start | stop | show | clear` to the system help and returns `false`, so the chain goes on to the other nodes

The handler returns `true` if it handled the command, `false` to pass it to the next node. The node is registered with `ca_cli_register()`.

37.1.5 Expected output

At startup

The scheduler is started with `ca_os_run(true)`. Task prints are disabled by default. Type `help` to view the available commands.

Command `help`

```
c.a.O.S > help
internal commands:
top       : cpu + mem + stack usage
sched     : cpu split since last call: switch, tasks, idle, free
banner    : show os banner
taskall   : show all tasks
task <n>  : show task N
free      : Show global memory usage
canary    : show stack canary status
mpu       : show mpu regions
sensor    : show core temperature
stack <n> : show stack x task N usage
memlist   : show all memory allocated blocks
hexdump <addr hex> [lines] : classic hexdump

c.a.O.S > user commands:
start | stop | show | clear
```

`show` command (with prints disabled)

```
c.a.O.S > show

--- Stream Buffer Statistics:
   Bytes sent    : 1840
   Bytes received: 1840
```

```
   Writer cycles : 230
   Reader cycles : 230
   Available     : 0
   Free space    : 64
   Print status  : DISABLED
```

Enabling prints

```
c.a.O.S > start

Print ENABLED - task output active
READER: recv 8 bytes: 'DATA_045'
WRITER: sent 8 bytes (seq=46)
READER: recv 8 bytes: 'DATA_046'
WRITER: sent 8 bytes (seq=47)
...
```

Disabling prints

```
c.a.O.S > stop

Print DISABLED - task output silenced
```

Tasks continue to execute (they write/read from the stream), but they do not print.

37.1.6 Stream vs Message Buffer

Feature	Stream Buffer	Message Buffer
Data unit	Byte	Message
Boundaries	Not preserved	Preserved
Use case	Continuous stream (UART, TCP)	Distinct packets
Overhead	Minimal (head/tail only)	Length per message

Example:

```
// Stream: "ABC" + "DEF"      "ABCDEF" (merged)
ca_stream_send(sb, "ABC", 3, 100);
ca_stream_send(sb, "DEF", 3, 100);
ca_stream_receive(sb, buf, 6, 100);  // buf = "ABCDEF"

// Message: "ABC" + "DEF"      two separate messages
ca_message_send(mb, "ABC", 3, 100);
ca_message_send(mb, "DEF", 3, 100);
ca_message_receive(mb, buf, &len, 100);  // buf = "ABC", len = 3
ca_message_receive(mb, buf, &len, 100);  // buf = "DEF", len = 3
```

37.1.7 Required configuration in `os_config.h`

```
#define ENABLE_CLI      1    // CLI needed for user commands
#define ENABLE_DBG_UART 1    // UART for output
#define ENABLE_STDOUT      1    // Log system for ca_stdout_*
```

37.1.8 Summary

1. **Stream Buffer** is a FIFO circular buffer for byte streams, ideal for continuous communication between tasks.
2. **Main APIs**:
   - `ca_stream_send()` / `ca_stream_receive()`: blocking with timeout
   - `ca_stream_bytes_available()` / `ca_stream_space_available()`: status query
   - `ca_stream_set_trigger()`: receiver wake-up threshold
   - `ca_stream_reset()`: flush buffer
3. **CLI hook** allows adding user commands (`start`, `stop`, `show`, `clear`, `help`).
4. **Print control** with variable `print_enabled`: prints are disabled by default to avoid saturating the UART.
5. **Static vs Heap**: `CA_STREAM_STATIC_DEFINE()` allocates the buffer in .bss, zero heap overhead.
6. **Trigger level**: optimizes the trade-off between latency (low trigger) and throughput (high trigger).

37.1.9 Verification of waits with timeout (`twait`)

Since 09/27, a task waiting for the stream buffer **with timeout** (`ca_stream_receive()`) registers itself in the same wait list as those waiting without a timeout, parked in `SLEEP` until expiration, and the signaler wakes it up immediately (S2_02 §8.8). Previously, it performed polling every 10 ms outside the list: it would wake up up to 10 ms after the signal.

The command `twait [sec]` (default 3 s) measures this with a peer task created at the first call. The wait runs in the command task:

1. **latency** — 300 cycles: the peer sends a byte after 1..8 ms randomly; the waiter, with a 20 ms timeout, must obtain it (`lost=0`), not before the signal (`spur=0`), and be running within 2 ms (`lat_max` limit, in ticks);
2. **timeout** — no one sends; for `sec` seconds, T = 1..20 ms: the return never arrives **before** T (`early=0`), at most 2 ms after (`late=0`), and always with `false` (`got=0`).

One line, closed by `PASS` or `FAIL`. On H753 (tick 200 µs):

```
TW stream : rounds=300 lat_max=0/10 lost=0 spur=0 | tmo n=291 early=0 late=0 got
   =0 over_max=0/10  PASS
```

On the previous kernel: FAIL, `lat_max=45/10` and `late=140` out of 200: the old code compared ticks with milliseconds.

In the test bench, it is case `timed_wait` of `test_ex14.cpp` (helper `test/hw_test/inc/caosTimedWait.h`). Manually:

```
caos_shell -e 14 -q -t 40 -u "TW .*(PASS|FAIL)" -g "^TW" "twait 3"
```

Chapter 38

Messages

38.1 Example 15 — Message Buffer with heap allocation

38.1.1 Introduction

The **Message Buffer** is a message buffer with framing that preserves message boundaries. Unlike the Stream Buffer (which treats data as a continuous stream of bytes), every send/receive operation is atomic:

- **Send**: writes `[lunghezza][payload]` as an indivisible unit
- **Receive**: reads a complete message or nothing at all

This ensures message integrity during communication between tasks.

In this example: - A **writer** task sends structured messages - A **reader** task receives the messages - A **monitor** task displays the buffer status in real-time - The **CLI** allows controlling prints and viewing statistics

Demonstrated features

Function	Description
`ca_message_init()`	Initialization with heap allocation
`ca_message_destroy()`	Free memory (not used in this example)
`ca_message_send()` / `ca_message_receive()`	Atomic send/receive with timeout
`ca_message_peek_size()`	Reads size of next message (without removing)
`ca_message_count()`	Number of messages present in the buffer
`ca_message_space_available()`	Free space in the buffer
`ca_message_reset()`	Resets the buffer
`ca_message_is_empty()`	Query buffer status

CLI Commands

Command	Description
`start`	Enables task prints
`stop`	Disables task prints
`show`	Shows message buffer statistics
`clear`	Resets message buffer
`help`	List of available commands

38.1.2 Example architecture

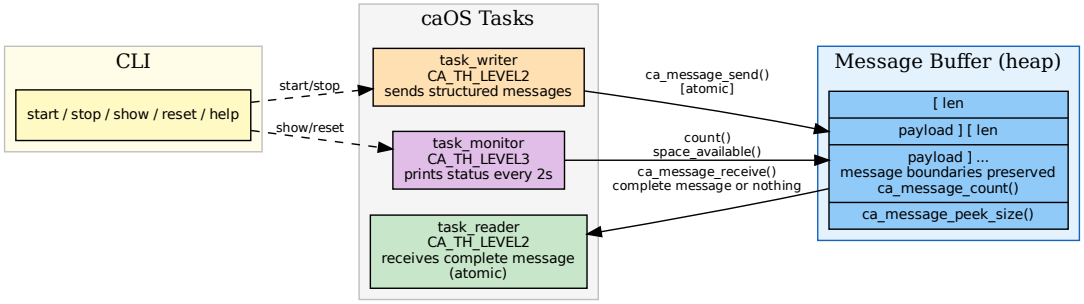

Figure 38.1: Message Buffer architecture

```

38.1.4 Detailed analysis

Initialization with heap allocation

```
#define MSG_BUFFER_SIZE     660U  // 10 messages    (2-byte header + 64-byte
    payload)

ca_message_buffer_t msg_buffer;  // Dichiarazione

void ca_os_main(void) {
    // Initialization with heap allocation
    if (!ca_message_init(&msg_buffer, MSG_BUFFER_SIZE)) {
        // Error handling
        while (1) { __NOP(); }
    }
```

```
    // ...
}
```

Heap advantages: - Flexibility in size - Memory allocated only when needed
Disadvantages: - Possible fragmentation - Allocation overhead - Need to handle errors

Message structure

```
typedef struct {
    u32 id;              /* Sender ID */
    u32 sequence;        /* Sequence number */
    char payload[64];    /* Application data */
} Message_t;
```

Total size: `4 + 4 + 64 = 72 byte`
Message Buffer Overhead: 2 bytes per header (length)
Occupancy per message: `72 + 2 = 74 byte`

Buffer size calculation

```
#define MSG_PAYLOAD_SIZE    64U
#define MSG_MAX_COUNT       10U
#define MSG_BUFFER_SIZE     (MSG_MAX_COUNT * (CA_MSG_HEADER_SIZE +
    MSG_PAYLOAD_SIZE))
                          // = 10 * (2 + 64) = 660 byte
```

Message size peek

```
u16 peek_size = ca_message_peek_size(&msg_buffer);

if (peek_size > 0) {
    ca_stdout_printf_n("READER: peek size=%u", peek_size);
}
```

`ca_message_peek_size()` reads the size of the next message **without removing it** from the buffer. Useful for: - Allocating buffers of the correct size - Debugging and statistics - Size-based decision making

Print control with `print_enabled`

```
static volatile u8 print_enabled;  // 0 = disabled, 1 = enabled

// Nei task:
if (print_enabled) {
    ca_stdout_printf_n("...");
}
```

Prints are **disabled by default** (`print_enabled = 0` in `ca_os_main()`). They can be enabled with the `start` command from the CLI.

> **Note**: It is not possible to send prints with `ca_stdout_*` before `ca_os_run(true)`, because the output system (stdout thread) is not yet active.

CLI Hook

The CLI node handles 5 commands: - `start`: enable prints (`print_enabled = 1`) - `stop`: disable prints (`print_enabled = 0`) - `show`: statistics + print status - `clear`: flush message buffer - `help`: adds the line `start | stop | show | clear` to the system help and returns `false`, so the chain goes on to the other nodes

The handler returns `true` if it handled the command, `false` to pass it to the next node. The node is registered with `ca_cli_register()`.

38.1.5 Expected output

At startup

The scheduler is started with `ca_os_run(true)`. Task prints are disabled by default. Type `help` to view the available commands.

Command `help`

```
c.a.O.S > help
internal commands:
top       : cpu + mem + stack usage
sched     : cpu split since last call: switch, tasks, idle, free
banner    : show os banner
taskall   : show all tasks
task <n>  : show task N
free      : Show global memory usage
canary    : show stack canary status
mpu       : show mpu regions
sensor    : show core temperature
stack <n> : show stack x task N usage
memlist   : show all memory allocated blocks
hexdump <addr hex> [lines] : classic hexdump

c.a.O.S > user commands:
start | stop | show | clear
```

`clear` command

```
c.a.O.S > clear

Message buffer cleared!
```

`show` command (with prints disabled)

```
c.a.O.S > show

--- Message Buffer Statistics:
   Messages sent    : 192
   Messages received: 192
   Writer cycles    : 192
   Reader cycles    : 192
   Messages in queue: 0
   Free space       : 660 bytes
   Print status     : DISABLED
```

Enabling prints

```
c.a.O.S > start

Print ENABLED - task output active
WRITER: sent msg seq=214 (size=72)
READER: recv msg from ID=1 seq=214 payload='Hello from Writer #214'
WRITER: sent msg seq=215 (size=72)
READER: recv msg from ID=1 seq=215 payload='Hello from Writer #215'

READER: recv msg from ID=1 seq=221 payload='Hello from Writer #221'
WRITER: sent msg seq=222 (size=72)
READER: recv msg from ID=1 seq=222 payload='Hello from Writer #222'
WRITER: sent msg seq=223 (size=72)
READER: recv msg from ID=1 seq=223 payload='Hello from Writer #223'
=== MESSAGE BUFFER STATUS ===
Messages in queue : 0 / 10
Free space        : 660 / 660 bytes
Empty             : YES
Next message size : 0 bytes
Total sent        : 224 messages (224 cycles)
Total recv        : 224 messages (224 cycles)
============================
WRITER: sent msg seq=224 (size=72)
READER: recv msg from ID=1 seq=224 payload='Hello from Writer #224'
```

Disabling prints

```
c.a.O.S > stop

Print DISABLED - task output silenced
```

Tasks continue to execute (send/receive messages), but do not print.

38.1.6 Stream vs Message Buffer

Feature	Stream Buffer	Message Buffer
Data unit	Byte	Message
Boundaries	Not preserved	Preserved
Use case	Continuous stream (UART, TCP)	Distinct packets
Overhead	Minimal (head/tail only)	2-byte header per message
API count	Available bytes	Number of messages
API peek	No	`ca_message_peek_size()`
Atomicity	No	Yes (atomic send/receive)

Practical example:

```
// Stream: "ABC" + "DEF"      "ABCDEF" (fusi in un unico flusso)
ca_stream_send(sb, "ABC", 3, 100);
ca_stream_send(sb, "DEF", 3, 100);
ca_stream_receive(sb, buf, 6, 100);  // buf = "ABCDEF"

// Message: "ABC" + "DEF"      two separate messages
ca_message_send(mb, "ABC", 3, 100);
ca_message_send(mb, "DEF", 3, 100);

// First receive
len = ca_message_receive(mb, buf1, max, 100);  // buf1 = "ABC", len = 3

// Second receive
len = ca_message_receive(mb, buf2, max, 100);  // buf2 = "DEF", len = 3
```

38.1.7 Required configuration in `os_config.h`

```
#define ENABLE_CLI       1    // CLI needed for user commands
#define ENABLE_DBG_UART 1    // UART for output
#define ENABLE_STDOUT      1    // Log system for ca_stdout_*
```

38.1.8 Heap memory management

Allocation

```
bool ca_message_init(ca_message_buffer_t *mb, u32 size);
```

- Allocate `size` bytes from the heap
- Initialize internal structure
- Return `true` on success, `false` if out of memory

Destruction (not used in this example)

```
void ca_message_destroy(ca_message_buffer_t *mb);
```

- Free allocated memory
- To be called if the buffer is no longer needed

Best practice

```
// In ca_os_main():
if (!ca_message_init(&mb, SIZE)) {
    // Error handling: not enough memory
    while (1) { __NOP(); }
}

// In a cleanup task (optional):
ca_message_destroy(&mb);
```

38.1.9 Summary

1. **Message Buffer** preserves message boundaries, ideal for communication of distinct packets between tasks.
2. **Heap allocation**: `ca_message_init()` dynamically allocates memory, offering flexibility but requiring error management.

3. **Main API**:
   - `ca_message_send()` / `ca_message_receive()`: atomic operations with timeout
   - `ca_message_peek_size()`: reads size of next message without removing it
   - `ca_message_count()`: number of messages in queue
   - `ca_message_space_available()`: free space
   - `ca_message_reset()`: clears buffer
4. **Overhead**: 2 bytes per message (length header).
5. **CLI hook** allows adding user commands (`start`, `stop`, `show`, `clear`, `help`).
6. **Print control** with variable `print_enabled`: prints are disabled by default to avoid saturating the UART.
7. **Message structure**: the example uses a `{id, sequence, payload}` struct, but the application can define any format.
8. **Atomicity**: every `send` writes a complete message, every `receive` reads a complete message. No partial or merged messages.

38.1.10 Verification of waits with timeout (`twait`)

Since 09/27, a task waiting for the message buffer **with timeout** (`ca_message_receive()`) registers in the same wait list as those waiting without timeout, parked in `SLEEP` until expiration, and the signaler wakes it up immediately (S2_02 §8.8). Previously, it performed polling every 10 ms outside the list: it would wake up up to 10 ms after the signal.

The `twait [sec]` command (default 3 s) measures it with a peer task created at the first call. The wait runs in the command task:

1. **latency** — 300 cycles: the peer sends a message after 1..8 ms randomly; the waiter, with a timeout of 20 ms, must obtain it (`lost=0`), not before the signal (`spur=0`), and be running within 2 ms (`lat_max` limit, in ticks);
2. **timeout** — no one sends; for `sec` seconds, T = 1..20 ms: the return never arrives **before** T (`early=0`), at most 2 ms later (`late=0`), and always with `false` (`got=0`).

One line, closed by `PASS` or `FAIL`. On H753 (tick 200 µs):

```
TW message : rounds=300 lat_max=0/10 lost=0 spur=0 | tmo n=291 early=0 late=0
    got=0 over_max=0/10  PASS
```

On the previous kernel: FAIL, `lat_max=50/10` and `late=140` out of 200: the old code compared ticks with milliseconds.

In the test bench, it is case `timed_wait` of `test_ex15.cpp` (helper `test/hw_test/inc/caosTimedWait.h`). Manually:

```
caos_shell -e 15 -q -t 40 -u "TW .*(PASS|FAIL)" -g "^TW" "twait 3"
```

Chapter 39

Thread Pool with RNG and SHA-256

39.1 Example 16 — Thread Pool with RNG and SHA-256

39.1.1 Introduction

The **Thread Pool** is a set of pre-allocated threads that remain active for the entire life of the system, ready to execute dynamically assigned jobs. Compared to creating one-shot threads for every operation, the pool eliminates allocation overhead and ensures a fixed number of concurrent tasks.

In this example, a **producer** task periodically generates random byte buffers via the hardware RNG and sends the SHA-256 calculation to the pool. The **worker threads** perform the cryptographic calculation asynchronously, without blocking the producer.

The pattern is **fire-and-forget**: the producer does not wait for the result; the calculation happens in the background.

> **Availability**: this example requires `EN_RNG=1`, `EN_HASH=1`, `EN_POOL=1`. On platforms that do not support these features (F1xx, F4xx, F7xx with default configuration) the code compiles but only displays an informative message.

Demonstrated Features

Function	Description
`ca_pool_init()`	Creates N pre-allocated worker threads
`ca_pool_submit()`	Sends a job to the pool (fire-and-forget)
`ca_pool_stats()`	Real-time statistics: busy/free/queued
`ca_rng_fill()`	Fills a buffer with HW random data
`ca_hash_compute()`	Calculates SHA-256 on buffer (one-shot)

CLI Commands

Command	Source	Description
`start`	application	Enables SHA-256 digest printing
`stop`	application	Disables printing
`show`	application	Shows pool statistics and counters
`rng get`	driver `rng.c`	Generates and prints a single 32-bit random value

Command	Source	Description
`help`	chain	Lists all commands (driver + application)

The CLI uses the **chain of responsibility** pattern: `ca_rng_init()` registers the driver node, the application code registers its own node with `ca_cli_register()`. The `rng get` commands are handled by the driver without code in the application.

39.1.2 Example Architecture

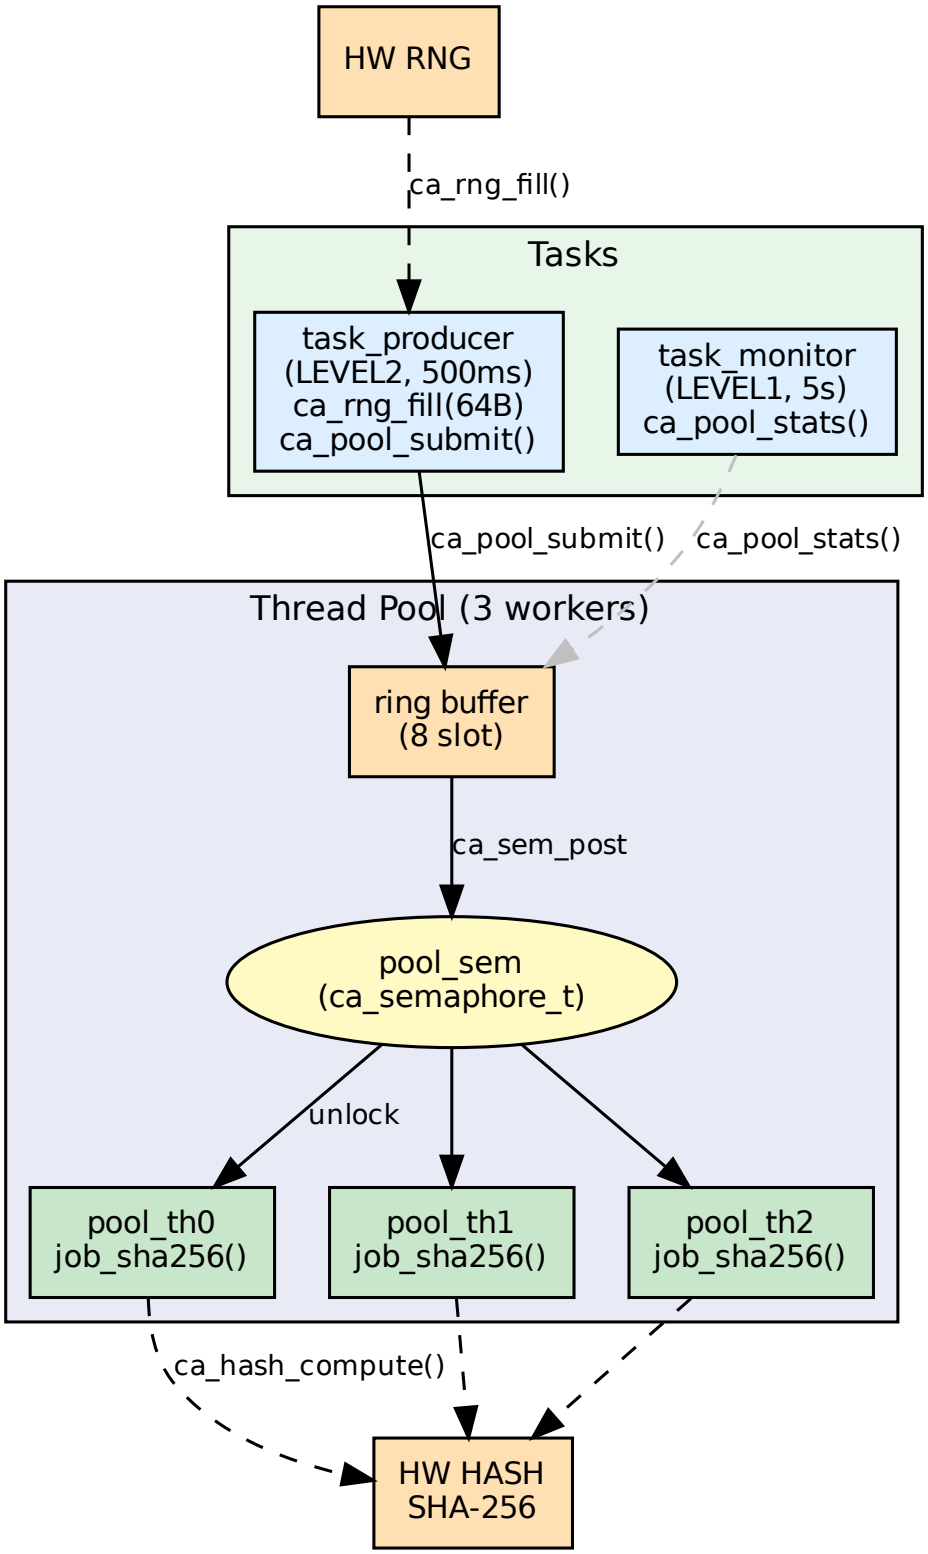

Figure 39.1: Example 16 Architecture — Thread Pool + RNG + SHA-256

39.1.3 Source Code

The file is located in `examples/example_16/ca_os_ex16.c`:

```c
#include "caos.h"

#if EN_RNG == 1 && EN_HASH == 1 && EN_POOL == 1

114     };
115     ca_pool_init(&pool_cfg);
116
117     ca_os_job("producer", CA_TH_LEVEL2, task_producer, NULL,
118               STACK_SMALL, CA_JOB_STD, CA_FAULT_ASSERT);
119
```

```
120     ca_os_job("monitor", CA_TH_LEVEL1, task_monitor, NULL,
121               STACK_SMALL, CA_JOB_STD, CA_FAULT_ASSERT);
122
123     EVAL_CLI( ca_cli_register(&s_user_cli_node); )
124
125     ca_os_run(true);
126 }
```

39.1.4 Detailed analysis

Pool initialization

```
1 ca_pool_cfg_t pool_cfg = {
2     .n_threads  = 3,
3     .stack_size = STACK_MEDIUM,
4     .priority   = CA_TH_LEVEL1,
5 };
6 ca_pool_init(&pool_cfg);
```

`ca_pool_init()` creates 3 permanent threads with names `pool_th0`, `pool_th1`, `pool_th2`. Each thread executes a loop:

```
1 while (1) {
2     ca_sem_wait(&pool_sem);        // sleeps until work arrives
3     ca_pool_job_t job = pop();     // takes the job from the queue
4     pool_busy++;
5     job.func(idx, job.p1);         // esegue
6     pool_busy--;
7 }
```

The semaphore `pool_sem` is the synchronization mechanism: it counts the available jobs. When it is zero, threads sleep without consuming CPU.

Sending a job

```
1 i32 res = ca_pool_submit(job_sha256, b);
```

`ca_pool_submit()`: 1. Inserts `{func, p1}` into the queue's ring buffer (mutex-protected) 2. Calls `ca_sem_post()` to wake up a worker 3. If the queue is full, it creates a one-shot thread as a fallback

The buffer pointer is passed as `u32` — valid on Cortex-M33/M7 where pointers are 32-bit.

Static round-robin buffer pool

```
1 #define N_BUFS  (POOL_THREADS + 2)   /* = 5 buffer */
2
3 static ex16_buf_t buf_pool[N_BUFS];
4 static volatile u8 buf_idx;
5
6 /* In task_producer: */
7 u8 bi = buf_idx;
8 buf_idx = (u8)((bi + 1u) % N_BUFS);
9 ex16_buf_t *b = &buf_pool[bi];
```

Buffers are static in `.bss`, reused in round-robin. With `N_BUFS = POOL_THREADS + 2 = 5` buffers and a producer sending a job every 500ms while workers complete in a few µs, there is no risk of overwriting while a worker is reading the buffer.

> **Rule**: `N_BUFS` must be at least `POOL_THREADS + 1` to ensure that the producer does not overwrite a buffer that is still being processed.

Hardware SHA-256 calculation

```
bool ok = ca_hash_compute(CA_HASH_ALGO_SHA256, b->data, BUF_SIZE, digest, &dlen)
    ;
```

`ca_hash_compute()` uses the **hardware HASH peripheral** present on H5/H7: - On H563: HASH with context swap (CSR), protected by a mutex for concurrent use - On H753: identical, with automatic register save/restore

The digest is 32 bytes (SHA-256). The example prints only the first 8 bytes as a visual identifier.

Pool statistics

```
void ca_pool_stats(u8 *busy, u8 *free_th, u8 *queued);
```

Field	Meaning
`busy`	Thread currently executing a job
`free_th`	Thread waiting (`pool_n - busy`)
`queued`	Job in queue yet to be assigned

`busy` is a `volatile u8` counter, incremented/decremented before/after `job.func()`. It is accurate for visualization; a delta of ±1 during context switching is acceptable.

CLI — Chain of Responsibility

The CLI follows the **chain of responsibility** pattern: each node receives the command and can handle it (returns `true`) or pass it to the next node (returns `false`). `help` always returns `false` to show the output of all nodes in the chain.

```
static bool user_cli_handler(c_str *pcmd)
{
    c_str cmd = *pcmd;
    const char *p = ca_skip_sp(cmd->data);

    if (ca_strncmp(p, "help", 4) == 0) {
        CLI_PUT_N("ex16: start | stop | show  (rng get - driver)");
        return false;           /* propagate: show the other nodes' help too */
    }
    if (ca_strncmp(p, "start", 5) == 0) {
        print_digest = 1;
        CLI_PUT_N("verbose ON");
        return true;
    }
    if (ca_strncmp(p, "stop", 4) == 0) {
        print_digest = 0;
        CLI_PUT_N("verbose OFF");
        return true;
    }
    if (ca_strncmp(p, "show", 4) == 0) {
        u8 busy, free_th, queued;
        ca_pool_stats(&busy, &free_th, &queued);
        CLI_PRINTF_N("submitted=%u  done=%u  failed=%u  rejected=%u  "
                     "busy=%u/%u  queued=%u/%u",
                     jobs_submitted, jobs_done, jobs_failed, jobs_rejected,
                     (u32)busy, (u32)POOL_THREADS,
                     (u32)queued, (u32)POOL_QUEUE_SIZE);
        return true;
    }
```

```
    return false;
}

static ca_cli_node_t s_user_cli_node = { user_cli_handler, NULL };
```

Registration in `ca_os_main`:

```
EVAL_CLI( ca_cli_register(&s_user_cli_node); )
```

The RNG driver node (`rng get`) is automatically registered by `ca_rng_init()` in `ca_os_configure`. The application must not handle `rng`.

`print_digest` is `volatile u8` written by the CLI and read by the workers — atomic read/write on 32-bit ARM, no need for mutexes.

39.1.5 Expected output

At startup — automatic statistics every 5s

The monitor wakes up after 2 seconds and then every 5 seconds. Digest prints are disabled by default.

```
=== POOL STATS ===
  submitted : 106
  done      : 106
  failed    : 0
  rejected  : 0
  busy      : 0 / 3
  free      : 3
  queued    : 0 / 8
==================
=== POOL STATS ===
  submitted : 114
  done      : 114
  failed    : 0
  rejected  : 0
  busy      : 0 / 3
  free      : 3
  queued    : 0 / 8
==================
```

`submitted == done` and `failed == 0` confirm that all jobs have been executed correctly. `busy = 0` indicates that the workers are waiting on the semaphore (no jobs in flight at the time of the snapshot).

The four counters

The distinction between `failed` and `rejected` is the didactic point of the example, not a printing detail:

counter	meaning
`submitted`	jobs **accepted** by the pool
`done`	of those, hash successful
`failed`	of those, hash failed
`rejected`	**never entered** the pool: RNG failed, or queue full

`rejected` is deliberately **outside** of `submitted`: the pool cannot be held responsible for a job that was never delivered to it. Hence the invariant that holds at every real instant:

```
submitted == done + failed + busy + queued
```

Keeping the two categories in a single counter makes the accounting unreadable: `submitted - done - failed` would go negative as soon as the queue fills up.

`show` Command

```
c.a.O.S > show
submitted=106  done=106  failed=0  rejected=0  busy=0/3  queued=0/8
```

`rng get` command (driver)

```
c.a.O.S > rng get
rng: 0xA3F12C7B  (2751987835)
```

Command `start` — digest enablement

```
c.a.O.S > start

Verbose ON     digest stampati
SHA256 seq=131 w=6 : 4c275ad7e07eba44...
SHA256 seq=132 w=7 : 32b0e47b92d63ddd...
SHA256 seq=133 w=5 : 5f552c9aafae4838...
=== POOL STATS ===
  submitted : 134
  done      : 134
  ...
SHA256 seq=134 w=6 : 095a9baa872a1d8a...
SHA256 seq=135 w=7 : 57eec8a2dfa3b7ca...
```

The worker IDs (`w=5`, `w=6`, `w=7`) are the scheduler indices of the 3 pool threads, assigned at the time of `ca_pool_init()`. The sequence number is strictly increasing and assigned by the producer; the completion order may vary slightly between workers.

Command `stop` — with CLI/output interleaving

```
stSHA256 seq=136 w=5 : 61c5f7cd6ad674b0...
SHA256 seq=137 w=6 : 18f7252d0c1329e1...
opSHA256 seq=138 w=7 : a19d55be77cae44f...

Verbose OFF
```

The characters `st` and `op` appear in the middle of SHA256 prints. This is normal behavior: the CLI receives typed characters (`s`, `t`, `o`, `p`) asynchronously, while the log system sends worker strings over the same output channel. This is not an error.

39.1.6 Required configuration in `os_config.h`

```
#define EN_RNG          1    /* Hardware RNG     F4/F7/H5/H7 */
#define EN_HASH         1    /* Hardware SHA-256     H5/H7 only */
#define EN_POOL         1    /* Thread pool     MAX_TASK >= 50 */
#define POOL_QUEUE_SIZE 8    /* Job queue depth (default) */

#define ENABLE_CLI      1    /* CLI for user commands */
#define ENABLE_STDOUT      1    /* Log system for ca_stdout_* */
```

39.1.7 Created threads

With the configuration of this example, the system creates:

Thread	Name	Priority	Role
idle	`idle`	0	Scheduler idle task
log	`log`	—	Asynchronous output
CLI	`cli`	—	Command reception
USB CDC	`usb_cdc`	—	I/O channel
pool_th0	`pool_th0`	LEVEL1	SHA-256 worker
pool_th1	`pool_th1`	LEVEL1	SHA-256 worker
pool_th2	`pool_th2`	LEVEL1	SHA-256 worker
producer	`producer`	LEVEL2	Generates RNG buffers
monitor	`monitor`	LEVEL1	Prints statistics

39.1.8 Summary

1. **Thread Pool** pre-allocates N permanent threads. No runtime creation/destruction, minimal overhead.

2. **Synchronization mechanism**: counting semaphore `pool_sem`. Workers sleep on `ca_sem_wait()`, the producer wakes them up with `ca_sem_post()` after each `ca_pool_submit()`.

3. **Fire-and-forget**: the producer does not wait for the SHA-256 calculation result. If the result is needed, the application must use a separate channel (event, notify, global variable).

4. **Round-robin buffer**: `N_BUFS = POOL_THREADS + 2` static buffers ensure that the producer does not overwrite a buffer still being processed, without dynamic allocations.

5. **One-shot fallback**: if the queue is full (all workers busy and `POOL_QUEUE_SIZE` jobs waiting), `ca_pool_submit()` creates a temporary one-shot thread. In this example, this never happens (slow producer, fast workers).

6. **CLI/output interleaving**: normal with an asynchronous log system. Typed characters may appear in the middle of task prints on the shared channel.

7. **Hardware HASH**: the SHA-256 calculation uses the dedicated H5/H7 peripheral. Multiple workers can use it simultaneously thanks to the CSR register context swap, managed internally by `ca_hash_compute()` with a mutex.

Chapter 40

Event Group: Synchronization on Bit Patterns

40.1 Example 17 — Event Group: bit pattern synchronization

40.1.1 Introduction

The **Event Group** is a synchronization primitive based on a set of 32 boolean flags (bits). Multiple tasks can wait for one or more bits to be set, using two modes:

- **WAIT_ANY**: the task wakes up when *at least one* of the requested bits is set.
- **WAIT_ALL**: the task wakes up when *all* requested bits are set simultaneously.

Compared to semaphores, event groups allow expressing composite conditions without introducing auxiliary state variables. The `ca_event_set()` function is ISR-safe and can be called from interrupt handlers.

In this example, three simulated sensors (temperature, pressure, humidity) produce samples asynchronously. An **aggregator** task waits for all three to have published their data (WAIT_ALL) before processing the result. A **watchdog** task instead waits for any error bit (WAIT_ANY) with a 3-second timeout.

Demonstrated features

Function	Description
`ca_event_init()`	Initializes an event group
`ca_event_set()`	Sets one or more bits (OR) — ISR-safe
`ca_event_wait_all()`	Waits for ALL bits to be set
`ca_event_wait_any()`	Waits for AT LEAST ONE bit to be set, with timeout
`ca_event_get()`	Reads the current value of the bits without blocking
`CA_EVENT_BIT(n)`	Helper for the n-th bit mask

CLI Commands

Command	Description
`err_t`	Injects a temperature error (sets BIT_ERR_TEMP)
`err_p`	Injects a pressure error (sets BIT_ERR_PRES)
`show`	Shows aggregation counters, watchdog alerts, and current bits

Command	Description
`help`	Lists available commands

40.1.2 Example architecture

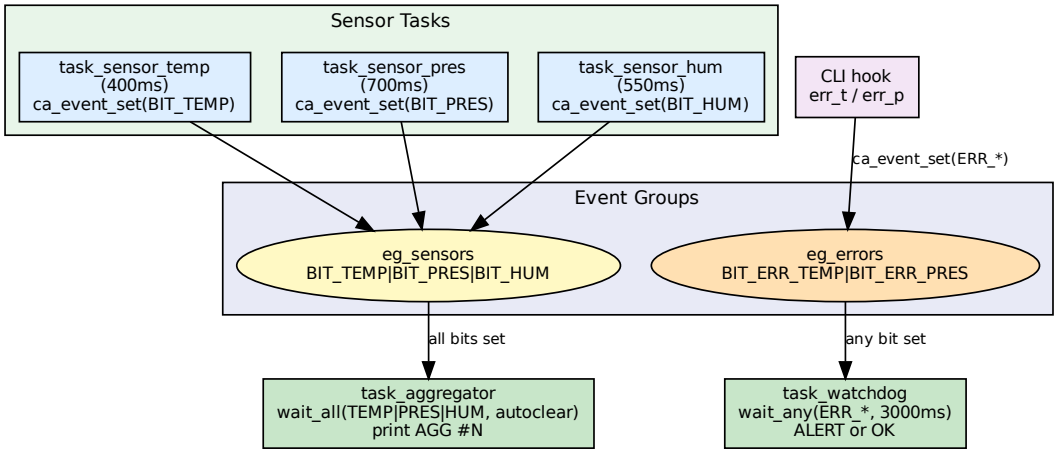

Figure 40.1: Example 17 Architecture — Event Groups

40.1.3 Source code

The file is located in `examples/example_17/ca_os_ex17.c`:

```c
#include "caos.h"

/* Sensor bit map */
#define BIT_TEMP    CA_EVENT_BIT(0)
#define BIT_PRES    CA_EVENT_BIT(1)
#define BIT_HUM     CA_EVENT_BIT(2)

    ca_os_run(true);
}
```

40.1.4 Detailed analysis

Two independent event groups

The example uses **two** separate `ca_event_group_t` structures:

```
static ca_event_group_t eg_sensors;   /* bits 0-2: data ready */
static ca_event_group_t eg_errors;    /* bits 8-9: errors */
```

Separating the two groups is a design choice: it avoids ambiguity in the bitmask and allows for different waiting policies (WAIT_ALL for sensors, WAIT_ANY for errors). A single event group with 32 bits would be technically sufficient, but less readable.

WAIT_ALL with auto-clear

```
u32 bits = ca_event_wait_all(&eg_sensors, BITS_ALL, true, CA_WAIT_FOREVER);
```

Parameter	Value	Meaning
`bits_to_wait`	`BITS_ALL` = 0x07	Wait for bits 0, 1, and 2 simultaneously
`auto_clear`	`true`	Clear bits 0, 1, 2 after match
`timeout_ms`	`0`	Infinite wait — only WAIT_ALL makes sense without timeout

Auto-clear ensures that each sample is processed *only once*: after aggregation, the bits return to zero and the sensors must set them again in the next cycle.

Why `CA_WAIT_FOREVER`? It makes no sense for the aggregator to have a timeout: if data is missing, it simply waits. The timeout is, however, fundamental for the watchdog.

WAIT_ANY with timeout

```
u32 bits = ca_event_wait_any(&eg_errors, BITS_ERR, true, 3000);
```

The watchdog wakes up in two cases:

1. **Injected error** (bits != 0): `ca_event_set` immediately wakes up the task, the bits are read and cleared. The watchdog prints the alert and returns to waiting.
2. **3s timeout** (bits == 0): no error in 3 seconds — the watchdog prints "OK" and re-arms the timeout.

This pattern is equivalent to a *software watchdog*: periodic verification of the system's health status with immediate reaction to events.

Internal wake-up mechanism

Internally, `ca_event_wait` with `timeout_ms > 0` uses the task's **SLEEP** state:

```
ca_event_wait_any(timeout_ms=3000)
           ca_os_sleep(3000)      SLEEP state, svegliato da SysTick countdown
                                or by ca_os_wake_up() called by ca_event_set()
```

When `ca_event_set(&eg_errors, BIT_ERR_TEMP)` is called from the CLI:

1. Sets the bit in `eg_errors.bits`
2. `wakeup_waiters()` checks the queue: the watchdog has a satisfied condition
3. Saves `meta->result = BIT_ERR_TEMP` *before* the auto-clear
4. Calls `ca_scheduler_signal_wake_up()` (for BLOCKED tasks) and `ca_os_wake_up()` (for SLEEP tasks)

5. The watchdog wakes up from the `ca_os_sleep()` and reads `meta->result`

With `timeout_ms = 0` (aggregator), the state used is **BLOCKED**, woken up exclusively by `ca_scheduler_signal_wake_up`.

auto-clear and race condition

The `result` field in the internal structure `ca_event_waiter_meta_t` resolves a subtle race condition: the auto-clear clears the bits *before* the woken-up task can read them, so the matched value is saved in `meta->result` and returned directly to the task upon wake-up.

Error injection from CLI

```
static bool user_cli_handler(c_str *pcmd)
{
    const char *p = ca_skip_sp((*pcmd)->data);
    ...
    if (ca_strncmp(p, "err_t", 5) == 0) {
        ca_event_set(&eg_errors, BIT_ERR_TEMP);
        CLI_PUT_N("Injected ERR_TEMP");
        return true;
    }
```

`ca_event_set()` is thread-safe (it uses `ca_spinlock_irq_t`): it can be called from the CLI task, from user tasks, or from an ISR without risk of corruption. The watchdog will be woken up immediately, regardless of how much time is left before the 3s expiration.

40.1.5 Expected output

Normal operation

```
AGG #142  T=28.6  P=101813  H=71.9
AGG #143  T=28.9  P=101818  H=71.9
AGG #144  T=28.8  P=101820  H=72.4
AGG #145  T=28.9  P=101827  H=72.5
WDG: OK (no errors in 3s)
AGG #146  T=29.1  P=101831  H=72.8
AGG #147  T=29.4  P=101832  H=73.0
AGG #148  T=29.3  P=101838  H=73.3
WDG: OK (no errors in 3s)
```

Aggregations trigger ~7 times per watchdog cycle (3s). The rate is determined by the slowest sensor: pressure at 700ms is the bottleneck. All 3 bits must be set *simultaneously*, so they aggregate approximately `3000 / 700  4.3` times every 3 seconds (in practice 6-8 due to sensor phase shifting).

The sensor bits shown by `show` are always 0x00 because they are reset by the auto-clear immediately after each aggregation.

With error injection

```
c.a.O.S > err_t

Iniettato ERR_TEMP
WDG: ALERT - temperature error! (#1)

c.a.O.S > err_p

Iniettato ERR_PRES
WDG: ALERT - pressure error! (#2)
```

The watchdog wakes up immediately after `ca_event_set()`, well before the 3s expiration. After the alert, it returns to waiting with a 3s timeout restarted from zero.

`show` command output

```
c.a.O.S > show

--- Example 17 ---
  Aggregazioni   : 181
  WDG alerts     : 2
  Sensor bits    : 0x00 (T=0 P=0 H=1)
  Error bits     : 0x00
```

`Sensor bits` may show 0x00 (all cleared after aggregation) or a partial value if read between one set and another. `Error bits` is 0x00 after the watchdog has consumed the alerts with auto-clear.

40.1.6 Required configuration in `os_config.h`

```
#define ENABLE_CLI       1    /* CLI for user commands */
#define ENABLE_STDOUT      1    /* Log system for ca_stdout_* */
```

No special flags are required: `ca_event_group_t` is always available (not conditioned by the `EN_` flag).

40.1.7 Created threads

Thread	Name	Priority	Role
idle	`idle`	0	Scheduler idle task
log	`log`	—	Asynchronous output
CLI	`cli`	—	Command reception
USB CDC	`usb_cdc`	—	I/O channel
`temp`	`temp`	LEVEL2	Temperature sensor (400ms)
`pres`	`pres`	LEVEL2	Pressure sensor (700ms)
`hum`	`hum`	LEVEL2	Humidity sensor (550ms)
`aggr`	`aggr`	LEVEL1	WAIT_ALL aggregator
`wdog`	`wdog`	LEVEL1	Watchdog WAIT_ANY + timeout

40.1.8 Summary

1. **Two wait modes**: WAIT_ALL synchronizes on a set of events that must all occur; WAIT_ANY reacts to the first event in a set, with an optional timeout.

2. **auto_clear**: matched bits are atomically cleared after the match, ensuring that each event is processed only once without an explicit reset.

3. **SLEEP timeout vs BLOCKED infinite wait**: `ca_event_wait` uses distinct task states. With `timeout_ms=0` the task is BLOCKED (only a signal wakes it up); with `timeout_ms>0` it is SLEEP (it wakes up due to a countdown or an early signal).

4. **ISR-safe**: `ca_event_set()` uses spinlocks with IRQ disabling — safe from interrupt handlers and any task.

5. **Software watchdog pattern**: WAIT_ANY with a periodic timeout is the standard pattern for supervision tasks: it reacts to errors instantly but also verifies the absence of errors every N seconds.

6. **Scalability**: with 32 bits available, a single event group can coordinate up to 32 independent conditions without additional data structures.

40.1.9 Verification of waits with timeout (`twait`)

Since 09/27, a task waiting for the event group **with timeout** (`ca_event_wait_any()`) registers in the same wait list as those waiting without a timeout, parked in `SLEEP` until expiration, and the signaler wakes it up immediately (S2_02 §8.8). Previously, it performed polling every 10 ms outside the list: it would wake up up to 10 ms after the signal.

The command `twait [sec]` (default 3 s) measures it with a peer task created at the first call. The wait runs in the command task:

1. **latency** — 300 cycles: the peer sets the bit after 1..8 ms randomly; the waiter, with a 20 ms timeout, must obtain it (`lost=0`), not before the signal (`spur=0`), and be running within 2 ms (`lat_max` limit, in ticks);
2. **timeout** — no one sets it; for `sec` seconds, T = 1..20 ms: the return never arrives **before** T (`early=0`), at most 2 ms after (`late=0`), and always with `false` (`got=0`).

One line, closed by `PASS` or `FAIL`. On H753 (tick 200 µs):

```
TW event : rounds=300 lat_max=0/10 lost=0 spur=0 | tmo n=291 early=0 late=0 got
   =0 over_max=0/10  PASS
```

On the previous kernel: PASS: the waiter with timeout was already in the list. Here `twait` is a regression; the fix (parking inside the lock) has a window that is too narrow for this test.

In the bench it is case `timed_wait` of `test_ex17.cpp` (helper `test/hw_test/inc/caosTimedWait.h`). Manually:

```
caos_shell -e 17 -q -t 40 -u "TW .*(PASS|FAIL)" -g "^TW" "twait 3"
```

Chapter 41

SW Timer: One-Shot and Periodic

41.1 Example 18 — SW Timer: one-shot and periodic

41.1.1 Introduction

The **Software Timer** is a mechanism that allows executing a callback function after a predefined delay, without occupying a dedicated task for each timing. The caOS timer system manages up to 16 simultaneous timers through a single daemon task (`tmr`), which updates their counters at every tick and calls the callbacks upon expiration.

There are two modes:

- **One-shot**: the callback is executed only once, then the timer enters the EXPIRED/STOP state.
- **Periodic**: the callback is executed periodically, restarting automatically after each expiration.

Callbacks are executed in the context of the daemon task `tmr`, **not** from an ISR. They must be short and must not block with sleep or wait calls.

In this example, three timers are created: - **LED** periodic at 500ms — simulates a LED toggle - **Stats** periodic at 2000ms — prints counters - **One-shot** at 3000ms — triggers once, rearmable via CLI

Demonstrated features

Function	Description
`ca_sw_timer_init()`	Initializes the timer system and creates the daemon task `tmr`
`ca_sw_timer_create()`	Creates a timer (one-shot or periodic) with a callback
`ca_sw_timer_start()`	Starts the counting
`ca_sw_timer_stop()`	Stops the timer (STOP state)
`ca_sw_timer_reset()`	Resets the counter and restarts
`ca_sw_timer_get_state()`	Reads the state: RUNNING / STOPPED / EXPIRED
`ca_sw_timer_get_remaining()`	Remaining milliseconds before expiration
`ca_sw_timer_count_active()`	Number of timers currently running

CLI Commands

Command	Description
`arm`	(Re)arms the one-shot timer (3s) — restart from zero
`stop`	Stops the periodic stats timer
`start`	Restarts the periodic stats timer
`show`	Shows fire counters and timer status
`help`	List of available commands

41.1.2 Example architecture

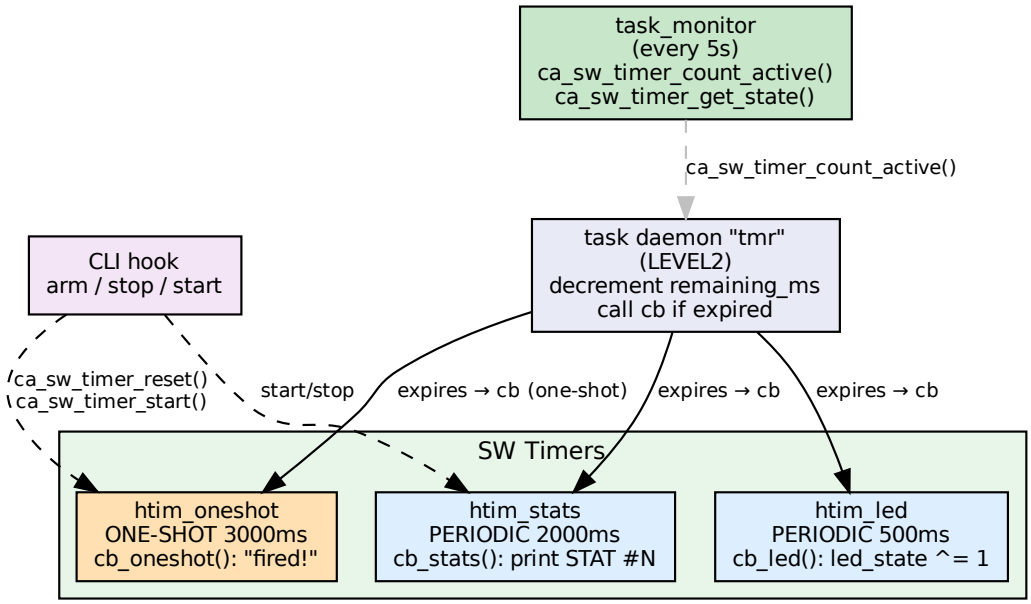

Figure 41.1: Example 18 Architecture — SW Timers

41.1.3 Source code

The file is located in `examples/example_18/ca_os_ex18.c`:

```
#include "caos.h"

#if EN_SW_TIMER == 1

static ca_sw_timer_handle_t htim_led;
static ca_sw_timer_handle_t htim_stats;
static ca_sw_timer_handle_t htim_oneshot;

static volatile u32 led_ticks;
static volatile u32 stats_ticks;
static volatile u32 oneshot_fired;
static volatile u8  led_state;

```

```
14 /* Callbacks run by the "tmr" daemon task */
15 static void cb_led(void *arg) {
16     (void)arg;
17     led_state ^= 1u;
18     led_ticks++;
19 }

71     ca_os_job("monitor", CA_TH_LEVEL1, task_monitor, NULL,
72               STACK_SMALL, CA_JOB_STD, CA_FAULT_ASSERT);
73
```

```
    EVAL_CLI( ca_cli_register(&s_user_cli_node); )
    ca_os_run(true);
}
```

41.1.4 Detailed analysis

System timer initialization

```
ca_sw_timer_init();
```

Create the daemon task `tmr` with stack `CA_TIMER_TASK_STACK` (512B default) and priority `CA_TIMER_TASK_PRIO` (2 = LEVEL2). The daemon executes a loop:

```
while (1) {
    ca_os_sleep(1);                    /* 1ms resolution */
    for (each active timer) {
        timer.remaining_ms -= elapsed;
        if (timer.remaining_ms == 0) {
            timer.cb(timer.cb_arg);    /* calls the callback */
            if (PERIODIC) rimpiazza; else EXPIRED;
        }
    }
}
```

The minimum resolution is **1ms** (one SysTick tick). Overhead: the daemon is active once per tick, but it sleeps almost immediately if no timer expires.

Timer creation and start

```
ca_sw_timer_handle_t htim_led = ca_sw_timer_create(500, CA_TIMER_PERIODIC,
    cb_led, NULL);
ca_sw_timer_start(htim_led);
```

`ca_sw_timer_create()` allocates a slot in the internal array `ca_sw_timer_t[CA_TIMER_MAX]` and returns a handle (index + 1, 0 = `CA_TIMER_INVALID`). The timer does not start until `ca_sw_timer_start()` is called.

`ca_sw_timer_handle_t` is a `u8` — simple index, zero overhead.

Difference between ONE-SHOT and PERIODIC

Type	Behavior after expiration
`CA_TIMER_ONE_SHOT`	Enters the EXPIRED/STOP state, does not restart
`CA_TIMER_PERIODIC`	Automatically restarts with the same period

To rearm the one-shot:

```
ca_sw_timer_reset(htim_oneshot);   /* reset remaining_ms = period_ms */
ca_sw_timer_start(htim_oneshot);   /* rimette in RUNNING */
```

Golden rule of callbacks

Callbacks are called **in the context of the daemon task** `tmr`. Rules:

1. **Do not call** `ca_os_sleep()` — it blocks the daemon and delays all other timers
2. **Do not call blocking** `ca_mutex_lock()` — same issue
3. **Fast operations**: incrementing counters, GPIO toggling, `ca_sem_post()`, `ca_event_set()` — OK

4. **The callback itself must not create or modify timers** — risk of internal deadlock

If you need to perform a long operation upon timer expiration, the callback must *signal* a task (using a semaphore or event group) that will perform the work.

```
/* Correct pattern for long operations */
static ca_semaphore_t sem_timer_work;

static void cb_trigger(void *arg) {
    ca_sem_post(&sem_timer_work);   /* signals, does not block */
}

static u32 task_worker(void *arg) {
    (void)arg;
    while (1) {
        ca_sem_wait(&sem_timer_work);
        /* long work here: OK, we are in a normal task */
    }
}
```

Timer states

```
                  ca_sw_timer_start()
    STOPPED

    RUNNING

           ca_sw_timer_stop()                scadenza

                                                 (PERIODIC: torna a RUNNING)

                                      EXPIRED (ONE-SHOT only)
           ca_sw_timer_start()
```

`ca_sw_timer_reset()` reports `remaining_ms = period_ms` but does not change the state — if it was STOPPED, it remains STOPPED until `start()` is called.

`ca_sw_timer_get_remaining()`

```
u32 rem3 = ca_sw_timer_get_remaining(htim_oneshot);
```

Returns the remaining milliseconds before expiration. It is 0 if the timer is STOPPED or EXPIRED. Useful for diagnostics and visualization (such as in monitor printing).

41.1.5 Expected output

At startup — automatic statistics

The stats timer triggers every 2s, the monitor every 5s. At startup, the one-shot starts and triggers after 3s.

```
STAT #1  LED=4  OS=0
STAT #2  LED=8  OS=0
ONE-SHOT fired! (#1)
STAT #3  LED=12  OS=1
=== TIMER STATUS (active=1) ===
```

```
  led    : RUN (fires=10)
  stats  : RUN (fires=5)
  oneshot: STOP rem=0ms (fires=1)
================================
```

`active=1` after the one-shot triggers (only the LED remains active because the monitor shows the state *before* stats triggers again in the monitor loop — the two periodicities of 2s and 5s overlap randomly).

Command `arm` — one-shot rearm

```
c.a.O.S > arm

One-shot armed (3s)
=== TIMER STATUS (active=2) ===
  led    : RUN (fires=394)
  stats  : STOP (fires=32)
  oneshot: RUN rem=2679ms (fires=3)
================================
ONE-SHOT fired! (#4)
=== TIMER STATUS (active=1) ===
  led    : RUN (fires=399)
  stats  : STOP (fires=32)
  oneshot: STOP rem=0ms (fires=4)
================================
```

The monitor shows the one-shot in RUN with 2679ms remaining — the print occurred ~321ms after the rearm. Three seconds later, "ONE-SHOT fired! (#4)" confirms the expiration; the timer returns to STOP.

Commands `stop` / `start`

```
c.a.O.S > stop

Timer stats stopped

c.a.O.S > start

Timer stats avviato
=== TIMER STATUS (active=2) ===
  led    : RUN (fires=410)
  stats  : RUN (fires=32)
  oneshot: STOP rem=0ms (fires=4)
================================
```

After `stop` the stats timer enters STOPPED and no longer calls `cb_stats`. After `start` it resumes; `fires=32` remains unchanged until the next 2s expiration.

Interleaving CLI/output

```
st=== TIMER STATUS (active=1) ===
  led    : RUN (fires=405)
op
Timer stats stopped
```

The characters `st` and `op` appear in the middle of the monitor output — this is normal behavior for asynchronous logging on a shared USB CDC channel (the same observed in example 16).

41.1.6 Created tasks

Thread	Name	Priority	Role
idle	`idle`	0	Scheduler idle task
log	`audit`	—	Asynchronous output
CLI	`cli`	—	Command reception
USB CDC	`usb cdc`	—	I/O channel
timer daemon	`tmr`	LEVEL2	Timer expiration management
monitor	`monitor`	LEVEL1	Print timer status every 5s

41.1.7 Configuration required in `os_config.h`

```
#define EN_SW_TIMER      1    /* Software timer system */
#define CA_TIMER_MAX     16   /* Maximum number of timers (default) */

#define ENABLE_CLI       1
#define ENABLE_STDOUT       1
```

41.1.8 Summary

1. **Single daemon task**: a single `tmr` task manages all timers. The overhead is proportional to the number of active timers, not the number of callbacks.

2. **One-shot vs Periodic**: one-shot triggers once and stops; periodic restarts automatically. Re-arming a one-shot requires `reset()` + `start()`.

3. **Lightweight callbacks**: callbacks run in the daemon task — they must be very short. For heavy work, use the signal-task pattern: the callback performs `ca_sem_post()`, and a normal task executes the work.

4. **1ms resolution**: the minimum granularity is the SysTick tick (`OS_TICK_US` in `objmap.h`: 200 µs on H753). Very short periods (< 5ms) may accumulate jitter due to daemon overhead.

5. **Handle as index**: `ca_sw_timer_handle_t` is a `u8`. Slots exhausted → `CA_TIMER_INVALID` (0). Always verify the return of `ca_sw_timer_create()` in production code.

6. `ca_sw_timer_get_remaining()`: useful for debugging and implementing software watchdogs: if a periodic timer does not trigger within `remaining + tolerance`, the system is locked.

Chapter 42

RW Lock and Barrier

42.1 Example 19 — RW Lock and Barrier

42.1.1 Introduction

This example presents two complementary synchronization primitives:

Read-Write Lock (`ca_rwlock_t`): allows multiple tasks to read a shared resource *simultaneously*, while ensuring exclusive access only during writing. It is the optimal solution for data that is read frequently and written rarely: it avoids the bottleneck of a simple mutex (which would block readers from each other as well).

Barrier (`ca_barrier_t`): an N-task synchronization point. All participants call `ca_barrier_wait()` and block until the last one arrives. The system resets automatically, allowing for repeated use in a loop (auto-reset barrier).

Demonstrated Features

Function	Description
`ca_rwlock_init()`	Initializes the RW lock
`ca_rwlock_read_lock()`	Acquires read lock (shared)
`ca_rwlock_read_unlock()`	Releases read lock
`ca_rwlock_write_lock()`	Acquires write lock (exclusive)
`ca_rwlock_write_unlock()`	Releases write lock, wakes up waiting tasks
`ca_barrier_init()`	Initializes barrier with N participants
`ca_barrier_wait()`	Waits at the barrier, returns `true` only to the last one

CLI Commands

Command	Description
`show`	Statistics: reads, writes, barrier phases, CFG version
`help`	List commands

111 }
```

42.1.4 Detailed analysis

RW Lock — write-preferring strategy

`ca_rwlock_t` implements the **write-preferring** policy: a waiting writer blocks the entry of *new* readers, even if there are already active readers. This prevents writer starvation in scenarios with very frequent readers.

Typical sequence:

```
1 Time:    0ms     200ms   400ms   600ms   800ms   1000ms  ...  2000ms
2 reader0:      R     D                   R     D                    R     D
            R  D
3 reader1:           R      D                        R      D
          R     D
4 reader2:                R        D
            R        D                                 R  D
5 writer:                                                        W     R     WR
6                                                      (esclusivo)
```

During the reading phase, multiple readers enter in parallel (`readers` counter > 0). When the writer calls `ca_rwlock_write_lock()`, it waits for `readers == 0` before proceeding. In the meantime, new readers find the writer waiting and block themselves in turn.

Read/write ratio

With 3 readers every 200-300ms and 1 writer every 2000ms:

```
1 Rate lettori      3    (1/250ms) = 12 letture/s
2 Rate writer   = 1 write every 2s = 0.5 writes/s
3 Ratio atteso      24:1
```

The output shows ~12-14 readings for each CFG update (2s / ~150ms average per reader), confirming the behavior:

```
1 CFG update v8  (reads so far: 95)
2 CFG update v9  (reads so far: 106)        11 letture in 2s
3 CFG update v10 (reads so far: 119)        13 letture in 2s
4 CFG update v11 (reads so far: 130)        11 letture in 2s
```

Barrier — trigger determinism

```
BARRIER phase 17     trigger=worker11
BARRIER phase 18     trigger=worker11
...
BARRIER phase 30     trigger=worker11
```

The trigger is **always** `worker11` (the scheduler index assigned to `worker2`). This is deterministic: the sleep times are fixed (100ms, 180ms, 260ms), so worker2 *always* arrives last at the barrier.

The number "11" is not the `idx=2` parameter passed to the task, but the **global scheduler index** assigned to that task at the moment of `ca_os_job()`. The index depends on the order of task creation in the example.

```
worker0: sleep 100ms     arrives FIRST
worker1: sleep 180ms     arrives SECOND
worker2: sleep 260ms     arrives LAST = trigger     true
```

The barrier resets automatically (`phase` is incremented) after each cycle, so workers can execute infinite phases without reinitialization.

Coordinator via semaphore

The coordinator does not participate in the barrier — it is an *external* task that receives notification via semaphore:

```
/* Trigger worker (last to arrive) */
bool trigger = ca_barrier_wait(&bar);
if (trigger) {
    barrier_phases++;
    ca_sem_post(&sem_phase_done);   /* notify the coordinator */
}

/* Coordinatore */
ca_sem_wait(&sem_phase_done);   /* waits for every phase */
```

This pattern decouples the internal synchronization of workers from the coordination logic. The coordinator can start the next processing phase, save data, or communicate with peripherals — without blocking the workers.

Comparison: RW Lock vs Simple Mutex

Scenario	Mutex (ca_mutex_t)	RW Lock (ca_rwlock_t)
3 readers, 1 writer	Readers block each other	Parallel readers
Read throughput	~1/3 (serialized)	~1 (parallel)
Write latency	Low	Can increase with many readers
Implementation	Simple	More complex
When to use	Frequently modified data	Frequently read, rarely written data

Required configuration in `os_config.h`

```
#define EN_RWLOCK    1    /* Read-Write Lock */
#define EN_BARRIER   1    /* Barrier N task */

#define ENABLE_CLI   1
#define ENABLE_STDOUT  1
```

42.1.5 Expected output

Normal operation

```
CFG update v8 (reads so far: 95)
BARRIER phase 17     trigger=worker11
COORD: fase 17 completata, reads=100 writes=8
BARRIER phase 18     trigger=worker11
COORD: fase 18 completata, reads=106 writes=8
CFG update v9 (reads so far: 106)
BARRIER phase 19     trigger=worker11
COORD: fase 19 completata, reads=111 writes=9
```

The barriers trigger every ~260ms (the rate of the slowest worker). CFG updates occur every 2s. The two patterns are independent and interleave in the output.

Command `show`

```
c.a.O.S > show

--- Example 19 ---
  Reads ok        : 153
  Writes ok       : 12
  Barrier phases : 26
  CFG version     : 12
```

`CFG version == Writes ok` confirms that every write increments the version by 1. `Barrier phases` grows approximately 8 times faster than `Writes ok` (2000ms / 260ms 7.7).

Interleaving CLI/output

```
sBARRIER phase 25     trigger=worker11
howBARRIER phase 26     trigger=worker11
```

Characters `s`, `how` of command `show` appear in the middle of task output — normal with asynchronous logging on a shared channel.

42.1.6 Created threads

Thread	Name	Priority	Role
idle	`idle`	0	Scheduler idle
log	`audit`	—	Asynchronous output
CLI	`cli`	—	Command reception
USB CDC	`usb cdc`	—	I/O channel
`reader0`	`reader0`	LEVEL2	RW reader (200ms)
`reader1`	`reader1`	LEVEL2	RW reader (250ms)
`reader2`	`reader2`	LEVEL2	RW reader (300ms)
`writer`	`writer`	LEVEL3	RW writer (2000ms)
`worker0`	`worker0`	LEVEL2	Barrier worker (100ms)
`worker1`	`worker1`	LEVEL2	Barrier worker (180ms)
`worker2`	`worker2`	LEVEL2	Barrier worker (260ms)
`coord`	`coord`	LEVEL1	Barrier coordinator

42.1.7 Summary

1. **RW Lock**: allows parallel reads between tasks with shared access. The writer blocks only when writing, not during all reads. Ideal for configuration structures or frequently read caches.

2. **Write-preferring**: a waiting writer blocks new readers, preventing its starvation in high read-traffic systems.

3. **Barrier auto-reset**: after each synchronization, the barrier is ready for the next cycle without reinitialization. The internal `phase` field ensures that delayed wake-ups do not interfere with the next cycle.

4. **Unique trigger**: only the last task to arrive at the barrier receives `true`. Using this return value for post-synchronization actions (starting the next phase, signaling the coordinator) avoids duplication.

5. **Coordinator pattern**: the trigger must not perform long operations — use `ca_sem_post()` to delegate to the coordinator. Workers restart immediately in the next cycle.

6. **Trigger determinism**: with fixed sleeps, the same worker always arrives last. In real algorithms, the workload varies and the trigger changes at each phase — the barrier handles both cases correctly.

Chapter 43

Block Pool, sleep_until and Timed Primitives

43.1 Example 20 — Block Pool, sleep_until and Timed Primitives

43.1.1 Introduction

This example integrates three advanced caOS mechanisms into a single program:

Block Pool (`ca_block_pool_t`): fixed-size block allocator. No heap, zero fragmentation, O(1) allocation time, and ISR-safe. Ideal for embedded systems with deterministic memory requirements.

`ca_os_sleep_until`: anti-drift variant of `ca_os_sleep`. A periodic task maintains the exact frequency even if the loop body takes variable time, by accumulating the delay and compensating autonomously.

Timed primitives (`ca_mutex_timedlock`, `ca_sem_timedwait`): mutex and semaphore acquisition with explicit timeout. The caller can handle the "resource not available within N milliseconds" case without blocking indefinitely.

Demonstrated Features

Function	Description
`ca_block_pool_init()`	Initializes the pool on a static buffer
`ca_block_alloc()`	Allocates a block in O(1)
`ca_block_free()`	Returns a block to the pool in O(1)
`ca_block_pool_free_count()`	Number of free blocks
`ca_os_sleep_until()`	Periodic sleep with cumulative anti-drift
`ca_mutex_timedlock()`	Acquires mutex with timeout; `true`=OK, `false`=timeout
`ca_sem_timedwait()`	Acquires semaphore with timeout; `true`=OK, `false`=timeout

CLI Commands

Command	Description
`show`	Full statistics: alloc/consumed, drift, timedlock/timedwait
`twait [sec]`	Mutex verification with timeout: wake-up latency and deadline precision
`twkill [sec]`	Verification of direct mutex and semaphore handover to a waiter removed while waiting
`help`	Command list

43.1.2 Example Architecture

43.1.4 Detailed analysis

Block Pool — structure and allocation

```c
ca_block_pool_init(&block_pool, pool_buf, sizeof(pool_buf), sizeof(DataBlock));
```

`ca_block_pool_init()` divides `pool_buf` into `N_BLOCKS = sizeof(pool_buf)/sizeof(DataBlock)` slots and builds an **in-place free list**: the first bytes of each free block contain the pointer to the next block.

```
pool_buf (8    40 byte = 320 byte):

    *next              *next              *next                        NULL

     (free)       (free)       (free)              (free)
```

```
5
6
7   head (pool->free_list)
```

`ca_block_alloc()` detaches the first block from the list (`head = head->next`) — O(1) operation. `ca_block_free()` reinserts the block at the head — O(1). Access is protected by `ca_spinlock_irq_t`, making both operations ISR-safe.

Passing pointers via u32 queue

```
1 u32 ptr_val = (u32)(uintptr_t)blk;
2 ca_queue_static_send(&block_queue.q, &ptr_val, CA_WAIT_FOREVER);
```

The queue is defined as a slot of `sizeof(u32)`. The pointer to the `DataBlock` is truncated to 32 bits — valid on Cortex-M33/M7 where all pointers are 32 bits. The consumer reconstructs the pointer with the reverse cast `(DataBlock *)(uintptr_t)ptr`.

Static buffer vs heap

Approach	Fragmentation	Alloc time	Worst case
`malloc`	Yes	O(N)	Indeterminate
Block Pool	No	O(1)	Deterministic

With 8 blocks and producer every 150ms: capacity $8 \times 150\text{ms} = 1.2$ seconds of buffering before overflow. If the consumer is slow, `alloc_fail` increments but the system does not hang.

`ca_os_sleep_until` — anti-drift

```
1 u32 last_wake = ca_os_tick_ms();   /* record the next expected wake-up */
2 while (1) {
3     ca_os_sleep_until(&last_wake, 100);  /* sleeps until last_wake + 100ms */
4     /* work of the cycle */
5     last_wake += 100;  /* internal to the function */
6 }
```

`ca_os_sleep_until` compares the current tick with the next expected wake-up instant. If the loop body took T ms, the subsequent sleep lasts (100 - T) ms instead of always 100ms. The cumulative drift is reset.

Comparison with `ca_os_sleep(100)`:

```
1 sleep classico:   | body(5ms) | sleep(100ms) | body(5ms) | sleep(100ms) | ...
2                   periodo effettivo = 105ms     deriva +5ms/ciclo
3
4 sleep_until:      | body(5ms) | sleep(95ms)  | body(5ms) | sleep(95ms)  | ...
5                   periodo effettivo = 100ms     deriva = 0
```

The output shows `drift_max=2ms` — residual due to the SysTick tick granularity (100µs for H753) and context switch latency.

Timed primitives — waiting in list with expiration

`ca_mutex_timedlock` and `ca_sem_timedwait` wait **in the same wait list** as `ca_mutex_lock` / `ca_sem_wait`, parked in `SLEEP` until expiration (S2_02 §8.8, S2_03 §9.2):

- whoever releases (`ca_mutex_unlock`, `ca_sem_post`) hands the resource to the first waiter in the list and wakes it up immediately, even from `SLEEP`;

- if no one releases it, the expiration wakes the task from the scheduler refresh, and the function returns `false`;
- with `timeout_ms = 0` they behave like `trylock` / `trywait`.

Until 09/27 they were a **sleep-poll** (`trylock` + `ca_os_sleep(10)` + retry): up to 10 ms delay from the release, and the resource went to whoever retried first instead of whoever had been waiting the longest. The `twait` command below measures this.

Ratio timedlock ok/timeout

`slow` cycle: 1000ms hold + 500ms free = 1500ms total. `fast` cycle: 200ms timedlock + 200ms timedwait + 50ms sleep = ~450ms total.

During the free window (500ms), `fast` can acquire the mutex multiple times: - First acquisition: trylock → OK → unlock → go to timedwait - Second: trylock → OK again (mutex free) - These occur until slow re-acquires

During the hold window (1000ms), every timedlock call does: - wait in list for 200 ms (SLEEP), then timeout

The observed ratio (`ok=66, timeout=44` 3:2) reflects the multiple acquisitions per free window against the frequent timeouts during the hold.

Ratio timedwait ok/timeout

`ca_sem_post` is called by `slow` every ~1500ms. `fast` calls `ca_sem_timedwait(200ms)` every ~450ms: - 1500ms / 450ms 3.3 calls per post → expected ratio 1 ok : 3 timeout - Output: `ok=35, timeout =141` 1:4 — `fast` is not always waiting when `slow` performs `post`: the semaphore accumulates and the next `timedwait` takes it immediately

43.1.5 Expected output

Normal operation

```
=== EX20 STATS ===
  BlockPool: alloc=153 fail=0 consumed=153 free=8/8
  Periodic : count=227 drift_max=2ms
  Timedlock: ok=45 timeout=31
  Timedwait: ok=15 timeout=61
==================
```

`alloc==consumed` and `free=8/8` confirm that no blocks were lost. `drift_max=2ms` with a 100ms period = 2% maximum jitter. `Timedlock ok > 0` confirms that `fast` acquires the mutex during the free windows of `slow`.

`show` Command

```
--- Example 20 ---
  BlockPool  alloc    : 135
  BlockPool  fail     : 0
  BlockPool  consumed : 135
  BlockPool  free     : 8 / 8
  Periodic   count    : 200
  Periodic   drift_max: 2 ms
  Timedlock  ok       : 39
  Timedlock  timeout  : 28
  Timedwait  ok       : 13
  Timedwait  timeout  : 53
```

Profile `top`

```
task 'producer  ' CPU= 0.1% Stack= 4.6% SW=   175 SL=  1381 BL=1
task 'consumer  ' CPU= 0.1% Stack= 4.6% SW=   175 SL=     0 BL=1
task 'periodic  ' CPU= 0.1% Stack= 5.0% SW=   261 SL=   903 BL=1
task 'slow      ' CPU= 0.0% Stack= 3.6% SW=    34 SL=  2037 BL=1
task 'fast      ' CPU= 1.7% Stack= 4.6% SW=  2250 SL=     0 BL=1
```

`fast` has `SW=2250` (many context switches for polling) and `CPU=1.7%` — the cost of sleep-poll every 10ms. `slow` has `SL=2037` (many sleeps: 1000ms + 500ms per cycle). `idle=97.1%` confirms that the system is well-sized.

43.1.6 Created threads

Thread	Name	Priority	Role
idle	`idle`	0	Scheduler idle task
log	`audit`	—	Asynchronous output
CLI	`cli`	—	Command reception
`producer`	`producer`	LEVEL2	Allocates blocks, sends to queue
`consumer`	`consumer`	LEVEL2	Receives blocks, verifies, frees
`periodic`	`periodic`	LEVEL2	Exact 100ms via sleep_until
`slow`	`slow`	LEVEL2	Holds mutex 1s, posts sem
`fast`	`fast`	LEVEL2	Timedlock + timedwait every 450ms
`stats`	`stats`	LEVEL1	Prints statistics every 5s

43.1.7 Required configuration in `os_config.h`

```
#define EN_BLOCK_POOL    1    /* Block Pool allocator */

#define ENABLE_CLI       1
#define ENABLE_STDOUT      1
```

43.1.8 Summary

1. **Block Pool**: O(1) allocator on a static buffer. Free list in-place within free blocks. ISR-safe via spinlock. `alloc_ok == consumed` guarantees no memory leaks.

2. **No heap**: `DataBlock` are never `malloc`-ed. The pool is statically sized with `POOL_N_BLOCKS`. In case of overflow, `alloc_fail` increments and the producer skips the cycle — no crash.

3. **Anti-drift** `ca_os_sleep_until`: automatically compensates for body duration. After N iterations, `last_wake = start + Nperiod` is exact. Essential for ADC sampling tasks, PID control, and timed protocols.

4. **Timed primitives sleep-poll**: `ca_mutex_timedlock` and `ca_sem_timedwait` use the trylock-/sleep(10ms)/retry pattern. No permanent blocking, no implicit ownership transfer. Maximum latency 10ms from resource availability.

5. **Ownership-safe**: the sleep-poll pattern avoids the "ownership transfer + timeout" bug that would occur with direct `ca_os_block()` + `ca_mutex_unlock()`: the task never receives ownership without knowing it.

6. **Producer/consumer pattern**: static queue of `u32` pointers as a channel between producer and consumer. The pool ensures that blocks are not freed while in transit in the queue.

43.1.9 Verification of waits with timeout (`twait`)

Since 09/27, a task waiting for a mutex **with timeout** (`ca_mutex_timedlock()`) registers in the same wait list as those waiting without a timeout, parked in `SLEEP` until expiration, and the signaler wakes it up immediately (S2_02 §8.8). Previously, it polled every 10 ms outside the list: it would wake up up to 10 ms after the signal.

The `twait [sec]` command (default 3 s) measures it with a peer task created at the first call. The wait runs in the command task:

1. **latency** — 300 cycles: the peer holds the mutex and releases it after 1..8 ms randomly; the waiter, with a 20 ms timeout, must obtain it (`lost=0`), not before the signal (`spur=0`), and be running within 2 ms (`lat_max` limit, in ticks);
2. **timeout** — the peer holds the mutex for the entire test; for `sec` seconds, T = 1..20 ms: the return never arrives **before** T (`early=0`), at most 2 ms after (`late=0`), and always with `false` (`got=0`).

One line, closed by `PASS` or `FAIL`. On H753 (tick 200 µs):

```
TW mutex : rounds=300 lat_max=0/10 lost=0 spur=0 | tmo n=291 early=0 late=0 got
   =0 over_max=0/10  PASS
```

On the previous kernel: FAIL, `lat_max=50/10`.

In the bank, it is case `timed_wait` of `test_ex20.cpp` (helper `test/hw_test/inc/caosTimedWait.h`). Manually:

```
caos_shell -e 20 -q -t 40 -u "TW .*(PASS|FAIL)" -g "^TW" "twait 3"
```

43.1.10 Waiter removed while waiting (`twkill`)

Mutex and semaphore **hand over** the resource to the waiter they remove from the list. A task killed while waiting is marked `REMOVE` immediately, but only freed at the next scheduler refresh: a release arriving in between would have handed it the mutex (owner dead forever) or the semaphore unit (lost). Now, the releaser skips waiters that are terminating.

`twkill [sec]` performs 10 cycles per second for the mutex and as many for the semaphore: a victim (alternating with and without timeout) waits, a survivor waits behind it, the victim is removed and the resource is released **immediately**, before the refresh. The survivor must obtain it within 100 ms (`lost=0`) and in the end, no one must possess it anymore (`owner=0`).

```
TK mutex : rounds=30/30 lost=0 owner=0  PASS
TK sem   : rounds=30/30 lost=0 owner=0  PASS
```

The first version of this test revealed a defect that was already present: the mutex remembered the owner by **index**. The survivor received the mutex, then the removal of the victim shifted it in the list, and its `ca_mutex_unlock()` no longer passed the ownership check (safeguard, then HardFault). Now the owner is a handle (S2_03 §9.2).

On the previous kernel: `lost=1` on the first round (the mutex delivered to the victim), then `SETUP_FAILED` (the victim with timeout never entered the list). In the test bench: case `kill_handoff` of `test_ex20.cpp`.

Chapter 44

Multi-Instance UART with Binary Protocol

44.1 Example 21 — Multi-instance UART with binary protocol

44.1.1 Introduction

Up to example 20, the UART has been used exclusively as a debug channel and CLI input (UART3 connected to the ST-Link VCP). This example introduces the **multi-instance** UART driver: multiple serial ports active simultaneously, each with its own reception callback and its own application role.

The practical case is communication between two nodes on the same microcontroller via a **structured binary protocol**: UART7 acts as *master* (sends commands), UART2 as *slave* (receives, processes, and responds). The CLI to monitor traffic in real-time is available on USB CDC (or UART3 ST-Link VCP depending on the configuration).

The chosen binary protocol is minimal but robust: fixed start-of-packet field (SOP), command, payload length, optional payload, and 8-bit checksum. This scheme is directly applicable to real-world communications with sensors, actuators, radio modules, or secondary microcontrollers.

Demonstrated features

Function / Concept	Description
`ca_uart_init(num, baud, cb)`	Multi-instance initialization with RX callback
`ca_uart_put(num, msg)`	Transmission on a specific instance
`ca_uart_rx_cb_t`	Byte reception callback type (ISR-safe)
RX state machine	Byte-by-byte protocol decoding in ISR context
Binary protocol SOP/CMD/LEN/PAYLOAD/CHK	Message encapsulation with integrity check
LED from ISR	GPIO toggle in RX callback for visual debugging
`ENABLE_UART`	Flag to enable the generic UART driver (independent of debug UART)

CLI Commands

Command	Description
`hello`	Manually send the HELLO command (0x10) on UART7
`status`	Manually send the STATUS command (0x20) on UART7
`show`	Master statistics (TX/RX) and slave (processed cmds, uptime)
`wire`	Continuity of jumpers on pure GPIO, verdict `WIRE RESULT : OK|FAIL (n/2)`; must be run first
`bridge`	VCP UART slave repeater: `echo`, `conv`, `baud <n>` (see VCP UART Bridge)
`help`	List of available commands and wiring diagram

44.1.2 Required Hardware

Board: Nucleo-H753ZI (STM32H753ZIT6)

Jumpers (2 wires):

```
PE8  (UART7 TX)                          PD6  (UART2 RX)
PD5  (UART2 TX)                          PE7  (UART7 RX)
```

Signal	MCU Pin	AF	Nucleo Connector
UART7 TX	PE8	7	CN10 pin 18
UART7 RX	PE7	7	CN10 pin 20
UART2 TX	PD5	7	CN9 pin 6
UART2 RX	PD6	7	CN9 pin 4

UART3 (TX: PD8, RX: PD9, AF7) is already wired to the Nucleo's ST-Link VCP and does not require jumpers.

Nucleo-H753ZI LEDs:

LED	Pin	Toggle when
LD1 green	PB0	Byte received on UART7 RX (master RX callback)
LD2 yellow	PE1	Byte received on UART2 RX (slave RX callback)
LD3 red	PB14	Checksum error detected by `rx_feed()`

> **Note on hardware conflicts:** UART4 and UART5 present conflicts on the Nucleo-H753ZI: - `PA1` (UART4 RX, AF8) is `ETH_RMII_REF_CLK`: the LAN8742A PHY generates a **continuous 50 MHz clock** on this line — UART reception is impossible. - `PC12` (UART5 TX, AF8) and `PD2` (UART5 RX, AF8) are `SDMMC1_CK` and `SDMMC1_CMD`. UART7 (PE8/PE7, AF7) and UART2 (PD5/PD6, AF7) are free pins with no conflicts with onboard peripherals.

44.1.3 The binary protocol

Each packet has the structure:

```
1
2      SOP          CMD          LEN           PAYLOAD               CHK
3     1 byte      1 byte       1 byte        0 .. 60 byte         1 byte
4
5   0xAA     command   n. bytes   optional data          all
6                      payload                        i byte
7                                                    precedenti
```

Field	Size	Description
SOP	1 byte	Always `0xAA` — marks the start of the packet
CMD	1 byte	Command identifier (see table below)
LEN	1 byte	Payload length in bytes (0 if absent)
PAYLOAD	0–60 bytes	Parameters or response data
CHK	1 byte	Checksum = mod-256 sum of SOP+CMD+LEN+PAYLOAD

Maximum packet size: 64 bytes (4 header/checksum + 60 payload).
Response: the CMD field of the response has bit 7 set (`CMD | 0x80`).

Implemented commands

Command	CMD	Response	Response CMD	Response payload
HELLO	0x10	0x90	(0x10|0x80)	none
STATUS	0x20	0xA0	(0x20|0x80)	`[cmds_lo, tick_lo, tick_hi, 0x01]` (4 bytes)

44.1.4 Example architecture

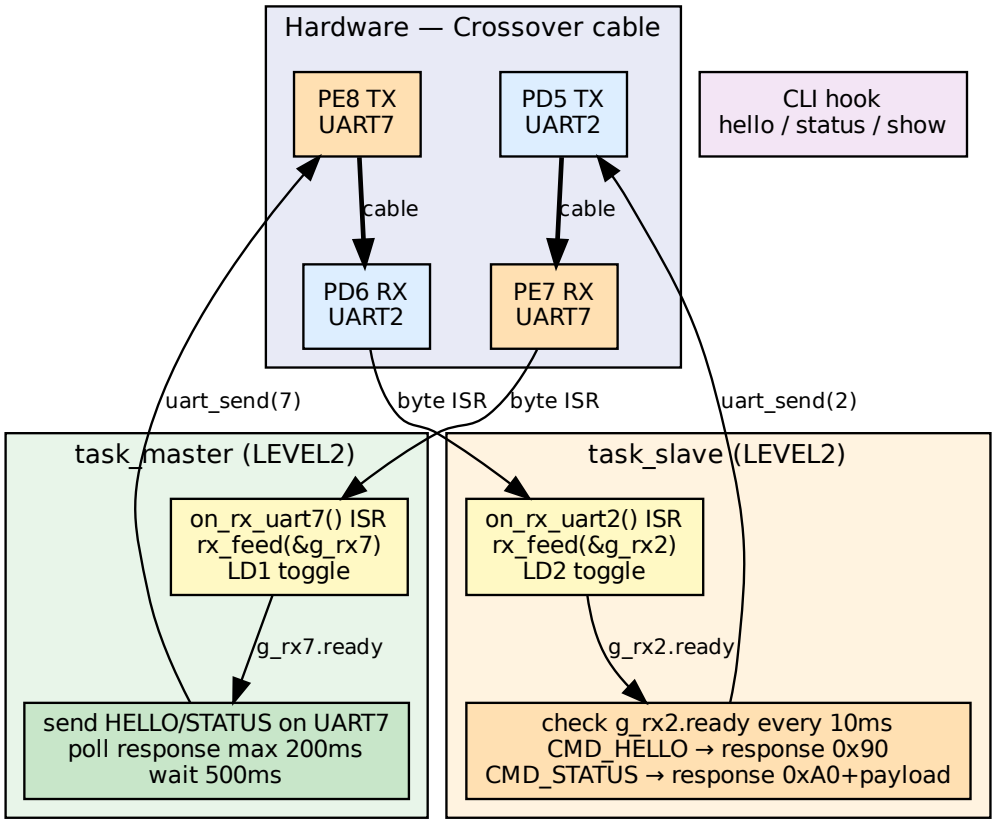

Figure 44.1: Example 21 architecture — UART master/slave

Complete data flow:

```
[task_master]                                   [task_slave]

uart_send(7, HELLO)
          PE8 TX                                                  PD6 RX

                      on_rx_uart2(byte)
                      LD2 toggle (ISR)
                      rx_feed(&g_rx2, byte)
                      g_rx2.ready = true
                                                 elabora CMD_HELLO
                                                 uart_send(2, 0x90)
          PE7 RX                                                  PD5 TX

on_rx_uart7(byte)
LD1 toggle (ISR)
rx_feed(&g_rx7, byte)
g_rx7.ready = true
poll: g_rx_hello++
```

44.1.5 The source code

The file is located in `examples/example_21/ca_os_ex21.c`.

Protocol and constants

```
#define PKT_SOP     0xAAu
#define PKT_MAX     64u
#define PKT_HDR     4u                      /* SOP + CMD + LEN + CHK */
#define PKT_MAX_PL  (PKT_MAX - PKT_HDR)  /* 60 byte payload max */

#define CMD_HELLO   0x10u
#define CMD_STATUS  0x20u
#define RESP_FLAG   0x80u
```

Reception state machine

Reception is byte-by-byte via the ISR callback. A `rx_ctx_t` structure maintains the parser state for each UART:

```
typedef enum { RX_SOP, RX_CMD, RX_LEN, RX_PAYLOAD, RX_CHK } rx_state_t;

typedef struct {
    rx_state_t   state;
    u8           cmd, len, pi, chk;
    u8           payload[PKT_MAX_PL];
    u8           pkt[PKT_MAX];
    u8           pkt_size;
    volatile bool ready;   /* true = complete packet, waiting to be consumed */
    u32          err;      /* checksum error counter */
} rx_ctx_t;
```

The `rx_feed()` function advances the state machine byte by byte. In case of an incorrect checksum, it increments `ctx->err` and toggles LD3 (red):

```
case RX_CHK:
    if (byte == ctx->chk) {
        /* valid packet */
        ctx->pkt[0] = PKT_SOP; ctx->pkt[1] = ctx->cmd;
        ctx->pkt[2] = ctx->len;
        for (u8 i = 0; i < ctx->len; i++) ctx->pkt[3+i] = ctx->payload[i];
        ctx->pkt[3 + ctx->len] = byte;
        ctx->pkt_size = PKT_HDR + ctx->len;
        ctx->ready = true;
    } else {
        ctx->err++;
        ca_gpio_toggle(CA_GPIO_PORT_B, CA_GPIO_PIN_14); /* LD3 red: chk error */
    }
    ctx->state = RX_SOP;
    break;
```

ISR Callback — one per UART

```
static rx_ctx_t g_rx7;   /* slave replies     received on UART7 RX (PE7) */
static rx_ctx_t g_rx2;   /* master commands     received on UART2 RX (PD6) */

static void on_rx_uart7(u32 byte) {
    ca_gpio_toggle(CA_GPIO_PORT_B, CA_GPIO_PIN_0);   /* LD1 green: master RX */
    rx_feed(&g_rx7, (u8)byte);
}
static void on_rx_uart2(u32 byte) {
```

```
    ca_gpio_toggle(CA_GPIO_PORT_E, CA_GPIO_PIN_1);   /* LD2 yellow: slave RX */
    rx_feed(&g_rx2, (u8)byte);
}
```

Registered at init time:

```
ca_uart_init(7, CA_UART_BAUD_115200, on_rx_uart7);
ca_uart_init(2, CA_UART_BAUD_115200, on_rx_uart2);
```

Building and sending a packet

```
static void uart_send(u32 num, u8 cmd, const u8 *pl, u8 plen) {
    string raw_s;
    p_str msg = &raw_s;
    u8   *buf = (u8 *)msg->data;

    buf[0] = PKT_SOP; buf[1] = cmd; buf[2] = plen;
    u8 chk = buf[0] + buf[1] + buf[2];
    for (u8 i = 0; i < plen; i++) { buf[3+i] = pl[i]; chk += pl[i]; }
    buf[3 + plen] = chk;
    msg->size = PKT_HDR + plen;
    ca_uart_put(num, msg);
}
```

The buffer is allocated on the stack (not on the heap): zero fragmentation, safe in task context.

Task master

The master sends each command and waits for the response (max 200 ms, poll every 10 ms) before proceeding with the next command. This avoids the race condition on the single buffer `g_rx7`:

```
static u32 task_master(void *arg) {
    (void)arg;
    ca_os_sleep(200);   /* waits for slave initialization */
    while (1) {
        /* HELLO: send and wait for the reply */
        uart_send(7, CMD_HELLO, NULL, 0);
        g_tx_hello++;
        for (u32 t = 0; t < 20; t++) {
            ca_os_sleep(10);
            if (g_rx7.ready) {
                if (g_rx7.pkt[1] == (CMD_HELLO | RESP_FLAG))
                    g_rx_hello++;
                g_rx7.ready = false;
                break;
            }
        }
        ca_os_sleep(500);

        /* STATUS: send and wait for the reply */
        uart_send(7, CMD_STATUS, NULL, 0);
        g_tx_status++;
        for (u32 t = 0; t < 20; t++) {
            ca_os_sleep(10);
            if (g_rx7.ready) {
                if (g_rx7.pkt[1] == (CMD_STATUS | RESP_FLAG))
                    g_rx_status++;
                g_rx7.ready = false;
                break;
            }
        }
```

```
        ca_os_sleep(500);
    }
    return 0;
}
```

Task slave

```
static u32 task_slave(void *arg) {
    (void)arg;
    while (1) {
        g_slave_ticks++;
        if (g_rx2.ready) {
            u8 cmd = g_rx2.pkt[1]; g_rx2.ready = false; g_slave_cmds++;
            if (cmd == CMD_HELLO) {
                uart_send(2, CMD_HELLO | RESP_FLAG, NULL, 0);
            } else if (cmd == CMD_STATUS) {
                u8 pl[4] = { (u8)(g_slave_cmds & 0xFF),
                             (u8)(g_slave_ticks & 0xFF),
                             (u8)((g_slave_ticks >> 8) & 0xFF),
                             0x01 };
                uart_send(2, CMD_STATUS | RESP_FLAG, pl, 4);
            }
        }
        ca_os_sleep(10);
    }
    return 0;
}
```

44.1.6 Detailed analysis

UART multi-instance: how it works

The `uart.c` driver maintains two static arrays indexed by UART number (1..12):

```
static USART_TypeDef* g_uart_instances[CA_UART_MAX] = {NULL};
static ca_uart_rx_cb_t     hook_on_rx[CA_UART_MAX]       = {NULL};
```

`ca_uart_init(num, baud, cb)` populates both. Each ISR `USARTx_IRQHandler` calls `ca_uart_recv_handler(N)` with the corresponding UART number, which in turn invokes `hook_on_rx[N](rx_data)`. In this way, any number of UARTs can be active simultaneously with independent callbacks.

State machine: why byte by byte

The callback `on_rx_uartN` is called **by the ISR** for every single byte received. It is not possible to block, allocate heap, or access shared structures with locks in this context. The state machine `rx_feed()` is designed exactly for this:

- No locks: a single producer (ISR) and a single consumer (task) for each `rx_ctx_t`
- No dynamic allocation: all buffers are static within the structure
- O(1) operation per byte: the switch case is deterministic

The flag `ready` is `volatile bool`: the ISR sets it to `true`, the task sets it to `false`. On Cortex-M, writing a bool is atomic — the race condition is handled correctly without mutexes.

> **Note**: the structure buffers only one complete packet. The master consumes `g_rx7.ready` within 200 ms after each transmission, well before the next packet arrives (500 ms pause). For higher rates, a circular queue of `rx_ctx_t` is used.

Race condition: single buffer and polling

A naïve implementation of the master task that sends HELLO and STATUS in sequence without waiting for the responses creates a race condition:

```
master sends HELLO       HELLO reply arrives, g_rx7.ready=true
master sends STATUS      STATUS reply arrives, overwrites pkt[], g_rx7.ready
    still true
master reads pkt[1]       sees 0xA0 (STATUS), not 0x90 (HELLO)     g_rx_hello
    stays 0
```

The solution is **blocking polling after each transmission**: the master waits up to 200 ms for the response, consumes it, and resets `ready` before sending the next command. With a 500 ms pause between commands, the timing is generous even considering the jitter of the task_slave (10 ms).

LED: visual debugging of interrupts

The three LEDs on the Nucleo provide immediate feedback without the need for a CLI or debugger:

- **Green LD1** (PB0): blinks on every byte on UART7 RX → confirms that the master is receiving
- **Yellow LD2** (PE1): blinks on every byte on UART2 RX → confirms that the slave is receiving
- **Red LD3** (PB14): turns on only on checksum error → indicator of HW/wiring issues

GPIO toggling is safe in ISR: `ca_gpio_toggle()` writes directly to the BSRR/BRR register without locks.

Checksum and error detection

```
CHK = (SOP + CMD + LEN +    PAYLOAD) mod 256
```

When the checksum does not match, `rx_ctx_t.err` is incremented, LD3 flashes, and the machine returns to `RX_SOP`. The error is visible with the `show` command:

```
RX HELLO resp : 42  (chk_err=0)
Slave cmds rx : 42  (chk_err=0)
```

STATUS response: structured payload

```
u8 pl[4] = {
    (u8)(g_slave_cmds  & 0xFF),         /* commands processed (low byte) */
    (u8)(g_slave_ticks & 0xFF),         /* uptime ticks 10ms (low byte) */
    (u8)((g_slave_ticks >> 8) & 0xFF),  /* uptime ticks 10ms (high byte) */
    0x01                                 /* status: 1=OK */
};
```

The master receives the 4 bytes in `g_rx7.pkt[3..6]` and can reconstruct the values.

44.1.7 Expected output

Startup

```
c.a.O.S >
```

The CLI appears after boot (via USB CDC). The master task waits 200 ms before sending the first HELLO. LEDs LD1 and LD2 immediately start blinking alternately with each byte exchanged.

Command `show` after ~10 seconds

```
c.a.O.S > show

--- Example 21 UART multi-istanza ---
  [MASTER  UART7 TX:PE8]
    TX HELLO      : 5
    TX STATUS     : 5
  [MASTER  UART7 RX:PE7  <-- slave UART2]
    RX HELLO resp : 5  (chk_err=0)
    RX STATUS resp: 5
  [SLAVE   UART2 RX:PD6  <-- master UART7]
    Cmds elaborati: 10  (chk_err=0)
    Slave ticks   : 987  (x10ms)
```

`TX HELLO + TX STATUS = Cmds elaborati` confirms that every command sent has been received and processed by the slave. `chk_err=0` indicates the absence of corruption on the channel.

Simulated checksum error (by disconnecting a wire)

```
c.a.O.S > show

  [MASTER  UART7 RX:PE7  <-- slave UART2]
    RX HELLO resp : 12  (chk_err=3)
```

The 3 errors indicate corrupted packets. The red LD3 flashes on every error. The state machine automatically resynchronizes at the next valid SOP (0xAA).

44.1.8 Required configuration in `os_config.h`

```
#define ENABLE_UART        1    /* generic multi-instance UART driver active */
#define STDOUT_ON_UART     1    /* STDOUT and CLI on the debug UART (VCP) */
#define STDIN_ON_UART      1
#define EN_USB             0    /* console on UART, not on USB CDC */
#define ENABLE_CLI         1    /* CLI for user commands */
#define ENABLE_STDOUT          1    /* log system for ca_stdout_* */
```

44.1.9 Bridge VCP UART

The ST-LINK VCP is the only serial port that the bench PC already has available. The `bridge` command repeats it on the **slave** UART of the example, which on the five mapped Nucleo-144 boards is always the same pair:

Board	UART	TX	RX
H753, H563, U575, F446, F767	USART2 (`USART_B` on Zio)	PD5 = **CN9-6**	PD6 = **CN9-4**

This way, the console of another board (for example the LPUART of ex62, which the VCP does not reach) can be read without a USB-to-serial adapter. The bridge uses the slave UART: the two crossed master/slave jumpers must be **removed** first.

Command	Effect
`bridge echo`	Autotest with **a single CN9-6 CN9-4 jumper**: 4 × 56 bytes are sent from the TX and must return from the RX. Prints `bridge echo: PASS|FAIL (ok/totale, sbagliati, persi)` and the `WIRE RESULT : OK|FAIL (n/1)` line. At the end of the test, the UART returns to the example's slave.
`bridge conv`	Converter: from that moment on, every byte from the VCP is sent out of the UART TX and every byte received returns to the VCP. CLI and stdout are turned off: **you can only exit by resetting**.
`bridge baud <n>`	Bridge UART speed (1200 ... 4000000, default 115200 8N1).
`bridge`	Summary of pins, speed, and rules.

Use as a converter to another board

```
board A (ex21, bridge conv)          board B (es. ex62, console LPUART)
  CN9-6  PD5  TX  ------------------>  RX of B's console
  CN9-4  PD6  RX  <------------------  TX of B's console
  GND             -------------------  GND
```

On the PC, open the VCP of board A at 115200 (or at the speed set with `bridge baud` before `bridge conv`) to communicate with the console of board B.

Implementation

Both directions pass through two 1 KB rings: the RX callbacks (in ISR) fill them, and a task empties them with `ca_uart_put()`, which waits for the UART and therefore must never be called from an ISR. In converter mode, the VCP UART (`UART_DBG_NUM`) is reinitialized with the bridge callback instead of `ca_cli_rx_byte`. This requires the driver to call the registered callback also on the console UART (`uart.c`, `ca_uart_recv_handler`): before 10/13, the console went directly to the CLI and the callback was ignored.

Measurements 10/13 on H753 (jumper CN9-6 CN9-4): `bridge echo` PASS 224/224 at 9600, 115200, and 921600; `bridge conv` in loopback, 3 lines of 105 bytes returned identical. The test bench (`test_homo_ex21`) adds 4 phases: bridge jumper, echo at the three speeds, converter in loopback, jumper removed.

44.1.10 Created Threads

Thread	Name	Priority	Role
idle	`idle`	0	Scheduler idle task
log	`log`	—	Asynchronous output on USB CDC
CLI	`cli`	—	Command reception on USB CDC
USB CDC	`usb`	—	USB Device CDC stack
`master`	`master`	LEVEL2	Sends HELLO/STATUS on UART7, processes responses
`slave`	`slave`	LEVEL2	Processes commands from UART2, responds on UART2

44.1.11 Summary

1. **UART Multi-instance**: `ca_uart_init(num, baud, cb)` registers independent callbacks for each port. The driver handles up to 12 simultaneous UARTs with arrays indexed by number.

2. **Channel separation**: USB CDC for debug/CLI, UART7/UART2 for application protocol. The callback architecture makes the channels completely independent.

3. **Pin selection**: on Nucleo-H753ZI use UART7 (PE8/PE7, AF7) and UART2 (PD5/PD6, AF7) to avoid conflicts with ETH (PA1) and SDMMC (PC12/PD2).

4. **ISR-safe state machine**: protocol parsing occurs byte-by-byte in the callback, without locks, without heap, in O(1) per byte. The `volatile bool ready` flag ensures zero-cost synchronization between ISR and task.

5. **Blocking polling post-send**: the master waits for the response (max 200 ms) before sending the next command. This prevents overwriting the single buffer `g_rx7` when response times are in the 10–20 ms range.

6. **LED from ISR**: GPIO toggle in `on_rx_uart7/2` and in `rx_feed` for checksum error. Immediate visual confirmation of interrupt operation without additional tools.

7. **Robust binary protocol**: SOP as a synchronization marker, LEN for variable payload (0–60 bytes), CHK for error detection. Response with `CMD | 0x80` allows distinguishing commands from responses on the same link.

8. **Scalability**: adding a new command only requires a `case` in `task_slave` and the corresponding constant `CMD_xxx`. The protocol framework (SOP/LEN/CHK) remains unchanged.

Chapter 45

I2C Master/Slave Intra-MCU

45.1 Example 22 — Intra-MCU I2C master/slave

45.1.1 Introduction

Up to example 21, the I2C driver has been used exclusively in **master polling** mode: the task transmits a command, waits for the response, and proceeds. This example introduces **slave IRQ-driven** mode: two I2C peripherals on the same microcontroller communicate with each other, I2C1 as master and I2C2 as slave, physically connected with two wires and pull-up resistors.

The practical case demonstrates the entire chain of a combined I2C transaction (*write_read* with *repeated START*): the master sends a command and reads the response in a single sequence without releasing the bus. The slave receives data via interrupt, prepares the response in the ISR callback with `ca_i2c_slave_set_tx()`, and the master reads it in the same bus cycle.

This architecture is directly applicable to systems with a "controller" MCU (master) and a "sensor" or "coprocessor" MCU (slave) connected via I2C.

Demonstrated features

Function / Concept	Description
`ca_i2c_init()`	Master polling initialization on I2C1
`ca_i2c_slave_init(num, addr, cb)`	Slave IRQ-driven initialization on I2C2
`ca_i2c_write_read()`	Combined transaction: write + repeated START + read
`ca_i2c_slave_set_tx()`	Prepare response buffer for the master (from ISR)
`ca_i2c_slave_rx_cb`	Callback invoked by EV-IRQ upon receipt of a complete packet
Slave state machine IRQ	Handling of ADDR/RXNE/TXIS/STOPF/NACKF flags in `ca_i2c_hw_recv_handler`
Repeated START	No STOP between write and read — the bus remains held by the master

Function / Concept	Description
External 4.7 k pull-ups	GPIO configured `CA_GPIO_NOPULL`, I2C lines pulled to VCC externally

CLI Commands

Command	Description
`ping`	Send CMD_PING (0x01) and print the 4 response bytes
`echo`	Send CMD_ECHO (0x02) with `0x12 0x34`, verify inversion
`show`	Master statistics (TX/RX/errors) and slave (packets received)
`stuck`	Block the slave mid-response with SDA low, then release it with `ca_i2c_bus_recovery()`
`help`	List commands and wiring diagram

45.1.2 Required hardware

Reference board: Nucleo-H753ZI (STM32H753ZIT6)

Jumpers (2 wires) + pull-ups (2 x 4.7 k resistors):

```
PB8  (I2C1 SCL)                    PB10 (I2C2 SCL)
PB9  (I2C1 SDA)                    PB11 (I2C2 SDA)
```

Pins change from board to board: the reference manual states which pins *can* carry I2C, the board user manual states which ones are *reachable* from the connectors. On U575, H563, and F446, the driver defaults end up on an LED or on a pin that does not reach the Zio. Run `wire` **first** on a new board: it is a continuity test on pure GPIOs, independent of I2C.

Board	Master (CN7)	Slave (CN9 / CN10)
Nucleo-H753ZI	I2C1 PB8-2 / PB9-4	I2C2 PB10 CN10-32 / PB11 CN10-34
NUCLEO-U575ZI-Q	I2C4 PF14 CN10-8 / PF15 CN10-12	I2C2 PF1 CN9-19 / PF0 CN9-21
NUCLEO-H563ZI	I2C1 PB8-2 / PB9-4	I2C2 PF1 CN9-19 / PF0 CN9-21
NUCLEO-F446ZE	I2C1 PB8-2 / PB9-4	I2C2 PF1 CN9-19 / PF0 CN9-21

On the **F446**, the driver defaults (`i2c_f4xx.c`: I2C1 on PB6/PB7, I2C2 on PB10/PB11) **are not usable**: PB7 is the blue LED LD2, PB6 is QSPI_BK1/D27, and PB11 does not reach any connector. UM1974 Table 18 routes I2C1 to PB8/PB9 (CN7-2 `I2C_A_SCL`, CN7-4 `I2C_A_SDA`) and leaves the PF1/PF0 pair free on CN9 (`I2C_B_SCL` / `I2C_B_SDA`).

The two lines must be pulled up to 3.3 V with external **4.7 k** resistors (one for SCL, one for SDA). The GPIOs are configured `CA_GPIO_NOPULL` (no internal pull-up): the internal resistors of the Cortex-M (typically 40–50 k) are too weak for I2C at 100 kHz and cause slow edges that generate arbitration-loss errors.

Signal	MCU Pin	AF	Nucleo Connector
I2C1 SCL	PB8	4	CN10 pin 3 (D15)
I2C1 SDA	PB9	4	CN10 pin 5 (D14)
I2C2 SCL	PB10	4	CN10 pin 32 (D36)
I2C2 SDA	PB11	4	CN10 pin 34 (D35)

Pull-up schematic:

```
3.3V                    4.7 k              SCL              PB8 /
    PB10
                      4.7 k                SDA            PB9 / PB11
```

UART3 (TX: PD8, RX: PD9, AF7) is already wired to the ST-Link VCP and provides the CLI (or USB CDC depending on the configuration).

45.1.3 The protocol

Each transaction uses a **fixed 4-byte packet**:

```
Master     Slave:

      CMD           D0           D1           D2
     1 byte       1 byte       1 byte       1 byte

Slave     Master (reply):

  CMD  |0x80        ~D0          ~D1         cnt_lo
     1 byte       1 byte       1 byte       1 byte
```

Field	Direction	Description
CMD	M→S	Command identifier (0x01=PING, 0x02=ECHO)
D0, D1	M→S	Command data
D2	M→S	Reserved (zero)
CMD|0x80	S→M	Response: bit 7 set to distinguish it from the command
~D0, ~D1	S→M	Bitwise inversion of received data (round-trip verification)
cnt_lo	S→M	Low byte of the slave packet counter (uptime)

Implemented commands

Command	CMD	CMD Response	Slave behavior
PING	0x01	0x81	Reflects inverted data, confirms connection
ECHO	0x02	0x82	Inverts D0/D1 — verifies data integrity

The master verification is:

```
bool ok = (rx[0] == (cmd | RESP_FLAG)) &&
          (rx[1] == (u8)(~tx[1]))      &&
          (rx[2] == (u8)(~tx[2]));
```

45.1.4 Example Architecture

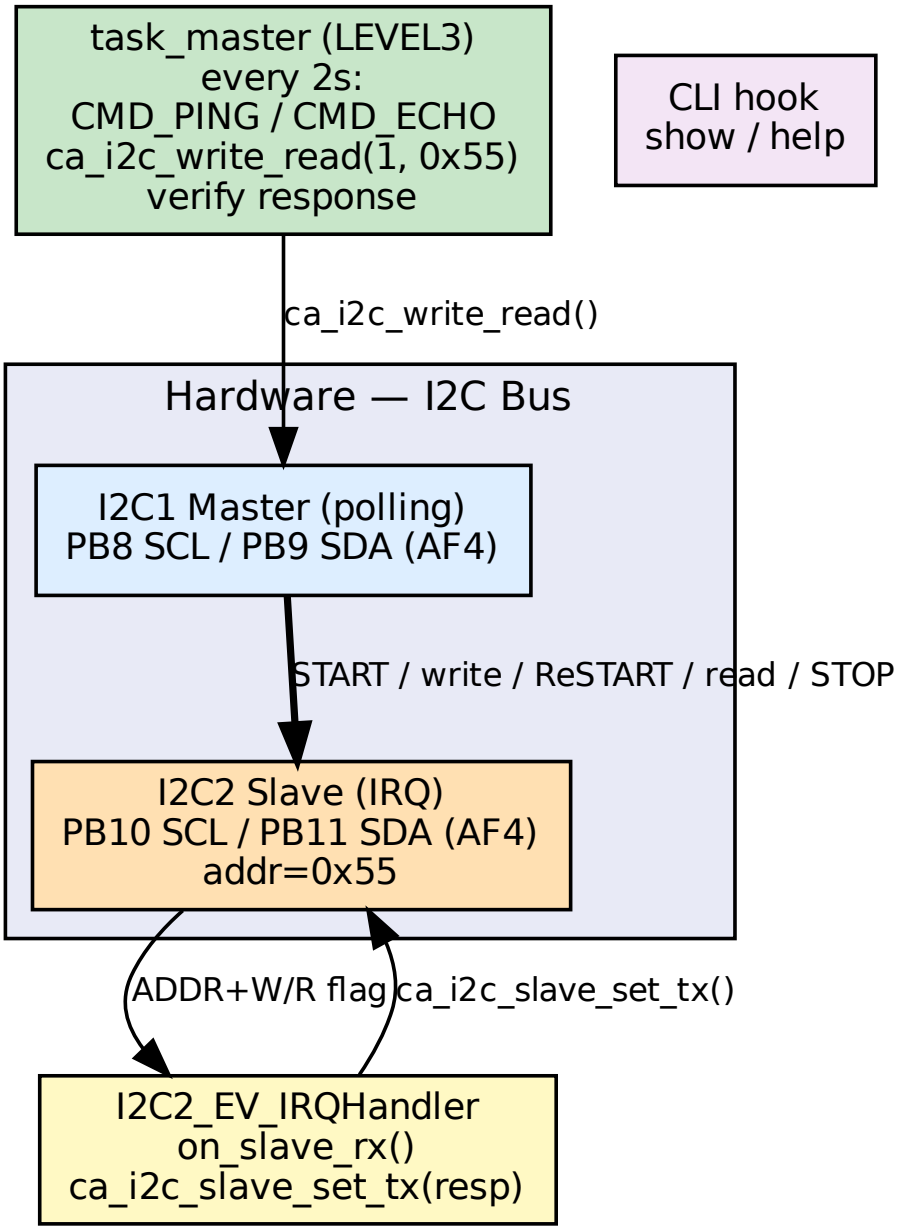

Figure 45.1: Example Architecture 22 — I2C master/slave

Complete data flow (combined transaction):

```
[task_master]                                  [I2C2 EV-IRQ     on_slave_rx]

ca_i2c_write_read(...)

          START
          ADDR+W 0x55
                                                                ADDR flag (DIR=0)
      reset idx
          byte 0: CMD
                                                                RXNE     rx_buf
  [0]
          byte 1: D0
                                                                RXNE     rx_buf
  [1]
          byte 2: D1
                                                                RXNE     rx_buf
  [2]
          byte 3: D2
                                                                RXNE     rx_buf
  [3]

          ReSTART (no STOP)
          ADDR+R 0x55
                                                                ADDR flag (DIR=1)
  :
                                               rx_cb(2, rx_buf, 4)
  on_slave_rx!
                                               ca_i2c_slave_set_tx(resp, 4)
                                               TXDR     resp[0]
          byte 0: resp[0]                                                  TXIS
      TXDR     resp[1]
          byte 1: resp[1]                                                  TXIS
      TXDR     resp[2]
          byte 2: resp[2]                                                  TXIS
      TXDR     resp[3]
          byte 3: resp[3]                                                  NACKF
   (master NACK ultimo byte)
          STOP                                 NACKF     reset tx_idx

verifica rx[]: ok/err
```

45.1.5 The source code

The file is located in `examples/example_22/ca_os_ex22.c`.

Constants and global state

```c
#define SLAVE_ADDR   0x55u
#define PKT_SIZE     4u
#define CMD_PING     0x01u
#define CMD_ECHO     0x02u
#define RESP_FLAG    0x80u

static volatile u32  g_slave_rx_count  = 0;   /* packets received by the slave */
static volatile u32  g_master_tx_count = 0;   /* transactions started by the master */
static volatile u32  g_master_rx_count = 0;   /* valid replies received */
static volatile u32  g_err_count       = 0;   /* risposte errate o timeout */
```

The counters are `volatile` because `g_slave_rx_count` is written by the ISR and read by the CLI task.

Slave callbacks (ISR context)

```
static void on_slave_rx(u8 num, const u8 *buf, u8 len)
{
    if (len < PKT_SIZE) return;

    u8 resp[PKT_SIZE];
    resp[0] = buf[0] | RESP_FLAG;      /* CMD con bit 7 */
    resp[1] = (u8)(~buf[1]);           /* D0 inversion */
    resp[2] = (u8)(~buf[2]);           /* D1 inversion */
    resp[3] = (u8)(g_slave_rx_count & 0xFFu);  /* low counter */

    ca_i2c_slave_set_tx(num, resp, PKT_SIZE);
    g_slave_rx_count++;
}
```

The callback is invoked by the driver when the ISR detects ADDR with DIR=1 (master reads) and `rx_idx > 0` — that is, exactly at the ReSTART of the combined transaction. At that moment, the 4 bytes of the command are already in `buf[]` and the response must be loaded into `tx_buf[]` before the bus controller starts transmitting.

`ca_i2c_slave_set_tx()` copies the buffer into the `g_i2c_slave_ctx[num-1].tx_buf[]` structure and sets `tx_len`. The driver then sends byte by byte on the subsequent TXIS.

Master task

```
static u32 task_master(void *arg)
{
    u8 tx[PKT_SIZE], rx[PKT_SIZE];
    u8 seq = 0;
    ca_os_sleep(500);   /* gives the slave init some time */

    while (1) {
        u8 cmd = ((seq & 1u) == 0u) ? CMD_PING : CMD_ECHO;
        tx[0] = cmd;
        tx[1] = (u8)(seq + 1u);
        tx[2] = (u8)(seq + 2u);
        tx[3] = 0u;

        ca_i2c_write_read(1, SLAVE_ADDR, tx, PKT_SIZE, rx, PKT_SIZE);
        g_master_tx_count++;

        bool ok = (rx[0] == (cmd | RESP_FLAG)) &&
                  (rx[1] == (u8)(~tx[1]))      &&
                  (rx[2] == (u8)(~tx[2]));
        if (ok) g_master_rx_count++;
        else    g_err_count++;

        seq++;
        ca_os_sleep(2000);
    }
    return 0;
}
```

The task alternates between PING and ECHO at each iteration (`seq` even → PING, odd → ECHO). Bytes D0/D1 change at every cycle (`seq+1`, `seq+2`), allowing verification that the slave reflects exactly the received data and not residual values from the previous transaction.

Initialization

```
void ca_os_configure(void)
{
    /* Master: I2C1 polling */
    ca_i2c_init(&(ca_i2c_config_t){ .i2c_num = 1, .speed = CA_I2C_SPEED_STANDARD
    });

    /* Slave: I2C2 IRQ-driven */
    ca_i2c_slave_init(2, SLAVE_ADDR, on_slave_rx);
    ...
}

void ca_os_main(void)
{
    ca_os_job("master", CA_TH_LEVEL3, task_master, NULL, STACK_SMALL, CA_JOB_STD
    , CA_FAULT_RESTART_THREAD);
    EVAL_CLI( ca_cli_register(&s_user_cli_node); )
    ca_os_run(true);
}
```

There is no `task_slave`: the slave is completely managed by I2C2 interrupts. The master task is the only application thread.

45.1.6 Detailed analysis

Combined transaction: write_read with repeated START

The I2C protocol provides two variants for reading data from a slave:

Variant 1 — Separate STOP + START:

```
Master: START     ADDR+W     [write bytes]     STOP     START     ADDR+R     [
    read bytes]     STOP
```

Variant 2 — Repeated START (used in this example):

```
Master: START     ADDR+W     [write bytes]     ReSTART     ADDR+R     [read
    bytes]     STOP
```

With variant 2, the master never releases the bus between write and read: no other master can intervene, and the slave knows for certain that the following read is the response to the previous write. This eliminates the race condition present if `ca_i2c_write` + `ca_os_sleep` + `ca_i2c_read` were used in sequence.

`ca_i2c_write_read()` implements variant 2 for the v2 families (H7xx, H5xx, F7xx):

```
/* write phase: CR2 with NBYTES, START; no AUTOEND */
i2c->CR2 = (addr << 1) | (wn << NBYTES_Pos);
i2c->CR2 |= I2C_CR2_START;
/* waits for TC (Transfer Complete)     the bus stays held */
while (!(i2c->ISR & I2C_ISR_TC)) {}

/* read phase: CR2 con RD_WRN, START (ReSTART), AUTOEND */
i2c->CR2 = (addr << 1) | (rn << NBYTES_Pos) | I2C_CR2_RD_WRN;
i2c->CR2 |= I2C_CR2_START | I2C_CR2_AUTOEND;
```

The `TC` (Transfer Complete) flag is raised by the peripheral when all write bytes have been transmitted **and** the bus is on hold (clock stretching): only then can the master issue the ReSTART.

Slave IRQ state machine (I2C v2)

The H7xx driver handles I2C2 interrupts in `ca_i2c_hw_recv_handler()`. The flags of the ISR register are processed **all in sequence** without premature `return`, with TXIS **before** ADDR:

```
ISR call     leggi ISR register snapshot

           BERR|OVR|ARLO ?      ICR clear, reset idx

           TXIS ?               TXDR     tx_buf[tx_idx++]  (o 0xFF se esaurito)
          FIRST: consume any leftover TXIS BEFORE processing ADDR

           ADDR ?
                 DIR=1 (master legge)      rx_cb(buf, rx_idx)        on_slave_rx
    !
                                          reset idx
                                          TXDR     tx_buf[0]          first reply
    byte
                                          ICR |= ADDRCF
                 DIR=0 (master scrive)     reset idx, ISR|=TXE, ICR|=ADDRCF

           RXNE ?               rx_buf[rx_idx++]     RXDR

           STOPF ?              ICR|=STOPCF, rx_cb se rx_idx>0, reset idx, ISR|=
    TXE

           NACKF ?              ICR|=NACKCF, reset tx_idx, ISR|=TXE
```

Why TXIS before ADDR is critical: when the master issues the ReSTART, the slave peripheral can simultaneously raise TXIS (residue from the previous TX cycle) and ADDR (new address). If ADDR were processed first and loaded `tx_buf[0]` into TXDR, the subsequent handling of TXIS would overwrite TXDR with `tx_buf[1]` — the first byte of the response would be lost. By processing TXIS first, the residual byte is consumed, then ADDR loads the actual `tx_buf[0]`.

This bug was present in the original version of the driver (structure `if/else if` with `return`) and is the cause of the symptom "correct response on the first cycle, then 0xFF as byte 0 on all subsequent cycles".

Pull-up: internal vs external

I2C requires open-drain lines pulled to VCC. The choice of pull-up value influences the edges:

Pull-up	Typical resistance	Rise time at 100 kHz	Notes
Internal Cortex-M GPIO	40–50 k	~2–5 µs	Too slow for 100 kHz (1 bit = 10 µs)
External 4.7 k	4.7 k	~0.3 µs	Correct for SM 100 kHz
External 1 k	1 k	~0.07 µs	Correct for FM 400 kHz, more current

With internal 40 k pull-ups, the RC time constant (R × C_bus 40k × 30pF = 1.2 µs) produces edges so slow that the controller interprets the level as indeterminate and generates `ARLO` (arbitration lost) or `BERR`. The GPIOs are therefore configured `CA_GPIO_NOPULL` in `i2c_h7xx.c`.

ca_i2c_slave_set_tx: slave buffer access from ISR

```
void ca_i2c_slave_set_tx(u8 num, const u8 *buf, u8 len)
{
    ca_i2c_slave_ctx_t *ctx = &g_i2c_slave_ctx[num - 1];
    if (len > sizeof(ctx->tx_buf)) len = sizeof(ctx->tx_buf);
    for (u8 i = 0; i < len; i++) ctx->tx_buf[i] = buf[i];
    ctx->tx_len = len;
    ctx->tx_idx = 0;
}
```

Called from the ISR (inside `on_slave_rx`), it must not use locks: the ISR is the only producer of `tx_buf[]` and the driver (also in ISR) is the only consumer. Writing occurs between ADDR (which has already reset `tx_idx`) and the first TXIS — the bytes are ready in time.

Why only one application task

In this example, the slave has no logic of its own that requires a dedicated thread: all processing (swapping two bytes, incrementing a counter) is O(1) and ISR-safe. A separate slave task would unnecessarily add latency (context switch + `ca_os_sleep`).

The appropriate pattern for a slave with complex processing is: 1. ISR copies data into a volatile buffer and sets a flag 2. Slave task consumes the flag, processes, calls `ca_i2c_slave_set_tx` 3. Upon the next ReSTART from the master, the buffer is already ready

In this example, the master waits 2 seconds between transactions: even a slave task with a 10 ms sleep would have plenty of time.

Bus recovery: slave stuck on SDA

An MCU reset while a slave is transmitting leaves it halfway through a byte with **SDA low**, waiting for clock pulses that will not arrive: the master can no longer generate a START and every transfer fails until the slave loses power. The standard remedy (UM10204 §3.1.16, *bus clear*) is to manually provide up to 9 pulses on SCL until the slave releases SDA, then a STOP.

The driver does this automatically in `ca_i2c_init()` (free on a healthy bus: with SCL and SDA high it does nothing) and exposes `ca_i2c_bus_recovery(num)` to call it after a timeout; from CLI `i2c recover <n>`. Each family uses the pins chosen in init (`ca_i2c_hw_bus_recovery(num, alternate)`), the sequence is unique (`hw/common/i2c_recover.c`).

`stuck` reproduces the real case: it takes the master pins as GPIO, manually performs START, address+R and ACK, then provides clock pulses until the hardware slave holds SDA low on a 0 bit of the response (a `ping` beforehand makes the response known, `0x81`), and releases the pins like an MCU that resets. The driver must return the bus:

```
stuck
  stuck      : ping before=OK, addr ACK=yes, SDA held low by the slave after 1
    data bit(s)=yes
  recovery   : bus idle=yes, ping after=OK
RUN RESULT : OK  (1/1)
```

45.1.7 Expected output

Startup

```
c.a.O.S >
```

The CLI appears after boot. The master task waits 500 ms before the first transaction. There are no dedicated LEDs for this example (no debug GPIO configured).

Command `ping`

```
c.a.O.S > ping
ping: 81 FE AA 00  OK
```

Response: `0x81` = `CMD_PING | 0x80` , `0xFE` = `~0xAA` , `0xAA` = `~0x55` , `0x00` = cnt_lo (first packet).

`echo` command

```
c.a.O.S > echo
echo: 82 ED CB 02  OK
```

Response: `0x82` = `CMD_ECHO | 0x80` , `0xED` = `~0x12` , `0xCB` = `~0x34` . `0x02` = counter (3rd packet if ping + echo have already been executed from the previous CLI).

`show` command after ~20 seconds

```
c.a.O.S > show

--- Example 22 I2C master/slave ---
  master tx   : 10
  master rx   : 10
  errors      : 0
  slave rx    : 10
```

`master tx == master rx == slave rx` and `errors = 0` confirm that every transaction has been completed successfully without data loss.

Wiring error (disconnected wire)

```
c.a.O.S > show

--- Example 22 I2C master/slave ---
  master tx   : 15
  master rx   : 3
  errors      : 12
  slave rx    : 3
```

Errors indicate that the master is not receiving the expected response (`rx[0] != CMD | 0x80`). `i2c_transfer7_v2` includes a counter-based timeout on every busy-wait (50,000 iterations) and checks `NACKF` in each loop: if the bus does not respond within the limit, it sends a STOP, clears the flags, and returns `false`. The master task increments `g_err_count` and continues.

45.1.8 Required configuration in `os_config.h`

```
#define EN_I2C            1    /* I2C driver enabled */
#define STDOUT_ON_UART    1    /* STDOUT and CLI on the debug UART (VCP) */
#define STDIN_ON_UART     1
#define EN_USB            0    /* console on UART, not on USB CDC */
#define ENABLE_CLI        1
#define ENABLE_STDOUT        1
```

In `cpu.cmake`:

```
set(CURR_MCU "H753")
```

45.1.9 Created threads

Thread	Name	Priority	Role
idle	`idle`	0	Scheduler idle task
log	`log`	—	Asynchronous output via USB CDC
CLI	`cli`	—	Command reception via USB CDC
USB CDC	`usb`	—	USB Device CDC stack
`master`	`master`	LEVEL3	I2C transactions every 2 s, response verification

The slave does not have its own thread: it is managed entirely by the I2C2 IRQ.

45.1.10 Summary

1. **IRQ-driven slave**: `ca_i2c_slave_init(num, addr, cb)` configures I2C2 as a slave, enables NVIC EV+ER, and registers the callback. From that moment on, the driver autonomously handles all I2C2 events without task intervention.

2. **Combined write_read transaction**: `ca_i2c_write_read()` uses ReSTART to keep the bus held between write and read. It eliminates the race condition of a separate sequence `write + sleep + read` and ensures that the read retrieves exactly the response to the previous command.

3. **ISR callback**: `on_slave_rx` is called directly by the interrupt handler when ReSTART arrives (ADDR with DIR=1 and rx_idx>0). It must be O(1), without locks, without sleep. `ca_i2c_slave_set_tx()` is safe in this context.

4. **ISR flag order**: the slave handler processes TXIS **before** ADDR in the same ISR call. This ensures that a residual TXIS does not overwrite the first response byte loaded by the ADDR block. Violating this order produced the "byte 0 = 0xFF from the second transaction onwards" bug.

5. **External pull-ups**: GPIO configured `CA_GPIO_NOPULL`. The internal Cortex-M pull-up resistors (40–50 k) are too weak for I2C at 100 kHz and cause ARLO/BERR. 4.7 k pull-ups to 3.3 V are the standard value for SM (100 kHz).

6. **Fixed-size protocol**: 4 bytes in both directions simplify parsing on the slave side (no length state machine) and make timing predictable. For variable payloads, a LEN field is introduced as in example 21.

7. **Scalability**: adding a new command only requires a `case` in `on_slave_rx`. The master/slave framework (write_read + slave_set_tx) remains unchanged regardless of the packet content.

Chapter 46

Internal Flash: Program / Verify / WDT Reset

46.1 Example 23 — Internal Flash: CLI integrated into the driver

46.1.1 Introduction

This example shows the built-in CLI registered by the `flash.c` driver of caOS. There is no additional application logic: after initialization, the firmware is completely driven by the `flash` commands available from the terminal.

The example also enables the IRQ-driven infrastructure (`ca_flash_irq_init`) which prepares the semaphore and the NVIC for the `ca_flash_erase_sector_irq` / `ca_flash_write_irq` APIs, usable by application code.

Demonstrated features

Function / Concept	Description
`ca_flash_init()`	Registers the driver CLI node in the CLI chain
`ca_flash_irq_init()`	Initializes semaphore and enables NVIC FLASH_IRQn
`ca_flash_get_num_sectors()`	Number of physical sectors of the device
`ca_flash_get_sector_addr(s)`	Base address of sector `s`
`ca_flash_get_sector_size(s)`	Size in bytes of sector `s`
`ca_flash_erase_sector_num(s)`	Polling erase of the sector by number
`ca_flash_erase_range(addr, n)`	Polling erase of all sectors in a range
`ca_flash_hw_write()`	Polling write (HW unit per family)
`ca_hexdump()`	Hexadecimal dump to stdout
`EN_FLASH` / `EN_CLI_FLASH`	Compilation guards for the driver and its CLI

Driver CLI commands

Command	Description
`flash help`	List all available flash commands
`flash info`	Number of sectors, total/used/free KB, grouped sector map
`flash info <s>`	Base address, size, and end address of sector `<s>`

Command	Description
`flash dump <addr>`	Hexdump 256 bytes from `<addr>`; saves position for the next call
`flash dump`	Hexdump 256 bytes from the point following the last `dump` (↑ Enter to advance)
`flash erase <addr> <n>`	Erase range `[addr, addr+n)`: fully covered sectors → direct erase; partial sectors → read-modify-erase-write (allocates heap)
`flash erase_s <s>`	Erase of sector number `<s>`
`flash test <s>`	Erase + write pattern `0xCAA55ACA` on the entire sector `<s>` + verify (polling)
`flash test_irq <s>`	Erase IRQ + write pattern `0xCAA55ACA` IRQ (32 B chunk) + verify + dump first lines on sector `<s>`

46.1.2 Required hardware

Board: Nucleo-H753ZI (STM32H753ZIT6) — no external components required.
CLI and stdout via **USB CDC**.

46.1.3 Sector map by family

MCU	Sectors	Size	Total
F103C8	~64 pages	2 KB	128 KB
F407VE	12 (s0-3=16KB, s4=64KB, s5-11=128KB)	mixed	512 KB
F429ZI	12 per bank	mixed	1 MB
F446ZE	8	mixed	512 KB
F746ZG	8 (s0-3=32KB, s4=128KB, s5-7=256KB)	mixed	1 MB
H747/H753	8+8 × 128 KB	128 KB	2 MB
H563	128+128 × 8 KB	8 KB	2 MB

46.1.4 Flash alignment constraints

Family	Write unit	Notes
F1xx	2 bytes (halfword)	PSIZE=0
F4xx	4 bytes (word)	PSIZE=2
F7xx	4 bytes (word)	PSIZE=2, invalidate cache after write
H7xx	32 bytes (256 bit)	dual bank, write in 8-word blocks
H5xx	16 bytes (128 bit)	BKSEL for bank2, FW force-flush

`flash test` writes in 32-byte chunks, compatible with all families.

46.1.5 Example architecture

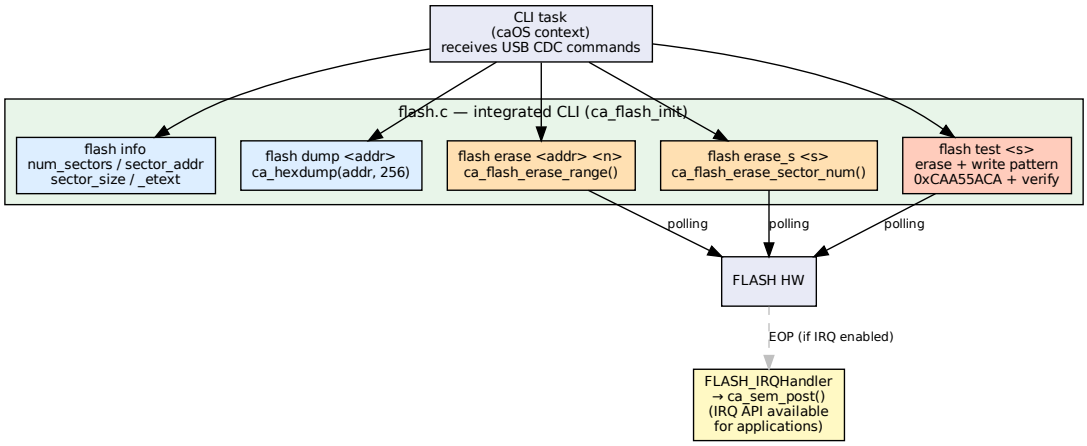

Figure 46.1: Example 23 Architecture — Flash CLI

No dedicated application task: all flash operations are executed in the context of the **CLI task** (regular caOS task, can block on `ca_sem_wait`).

46.1.6 Flash IRQ driver architecture

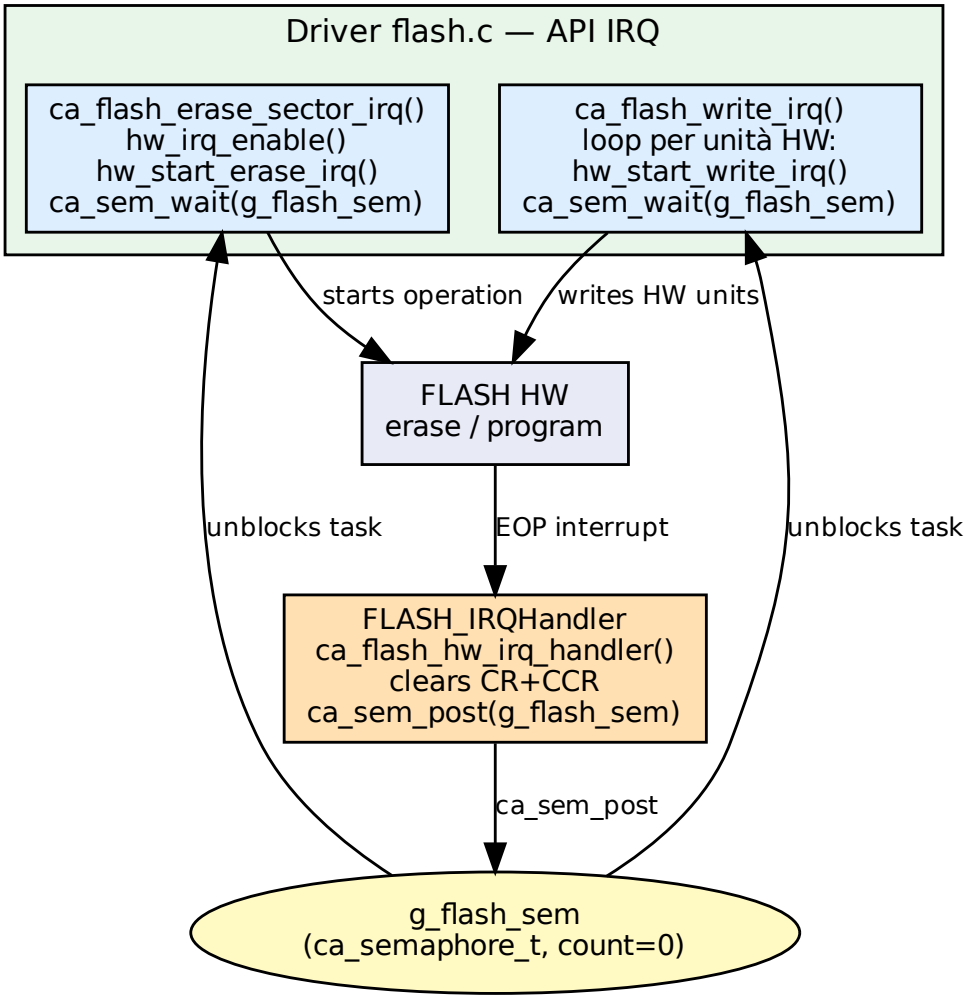

Figure 46.2: Flash IRQ driver architecture

46.1.7 Source code

The file is located in `examples/example_23/ca_os_ex23.c`.

Initialization

```
void ca_os_configure(void)
{
    ca_flash_irq_init();   /* semaphore + NVIC     enables the IRQ-driven API */
    /* stdout / CLI / USB CDC ... */
}

void ca_os_main(void)
```

```
{
    ca_flash_init();   /* registers the driver's CLI node */
    ca_os_run(true);
}
```

`ca_flash_init()` registers a `ca_cli_node_t` node in the CLI chain; from that moment on, all `flash` commands are available without additional hooks.

`ca_flash_irq_init()` is idempotent and must be called before using the `_irq` APIs. The driver CLI internally uses polling APIs; IRQ APIs are available for application code that requires them.

46.1.8 Command analysis

`flash info` / `flash info <s>`

Without an argument, it queries `ca_flash_hw_num_sectors()`, `ca_flash_hw_sector_addr()`, and `ca_flash_hw_sector_size()` to build the map. It uses the `_etext` linker symbol to calculate the flash used by the firmware. Sectors with the same size are grouped:

```
flash: 16 sectors  total=2048KB  used=58KB  free=1989KB
  s0-15: 128KB each @ 0x08000000
```

With the sector number, it resolves the base address, size, and end:

```
flash info 15
s15: 128KB @ 0x081E0000  end=0x081FFFFF
```

`flash dump [<addr>]`

Accepts the address in hexadecimal with or without the `0x` prefix. Calls `ca_hexdump((u8*)addr, 256U)` — the flash is memory-mapped, readable directly via pointer. After each dump, it saves `addr + 256` internally:

```
flash dump 0x081E0000            prima pagina, salva next=0x081E0100
flash dump                       dump 0x081E0100, salva next=0x081E0200
```

Out-of-range address is rejected before touching memory:

```
flash dump 0x80000000
dump: 0x80000000 out of flash range [0x08000000-0x08200000)
```

Typical usage: `flash dump <addr>` the first time, then ↑ **Enter** to scroll.

`flash erase_s <s>`

Call `ca_flash_erase_sector_num(s)`: unlock → `ca_flash_hw_erase_sector` → lock.

```
flash erase_s 15
s15 erased OK
```

`flash erase <addr> <n>`

Calls `ca_flash_erase_range(addr, n)`. For each sector overlapping the range:

- **Completely covered** (`addr` `sa` and `sa+ss` `addr+n`): direct erase, no allocation.
- **Partially covered**: allocates `ss` bytes with `ca_memory_allocate`, copies the entire sector, zeroes out the bytes in the range at `0xFF`, erases, and rewrites. If the heap does not have sufficient memory → `erase: error` without touching the flash.

Prints `wait...` before operating (on H753, a 128 KB sector takes a few seconds).

```
flash erase 0x08100000 0x20000
wait...
erase 0x08100000 +131072 OK
```

`flash test <s>`

Complete sequence on sector `<s>` in **polling** mode: 1. Erase via `ca_flash_erase_sector_num` 2. Write pattern `0xCAA55ACA` repeated across the entire sector (32-byte chunks) 3. Byte-by-byte verification via direct flash pointer 4. Print PASS or number of errors

```
flash test 15
flash test s15 @ 0x081E0000  128KB
wait...
PASS: s15 pattern OK
```

The command is useful for verifying the integrity of the erase/write cycle on a non-critical sector before using it for persistent data.

`flash test_irq <s>`

Complete sequence on sector `<s>` in **IRQ-driven** mode — exercises the `ca_flash_erase_sector_irq` / `ca_flash_write_irq` path with task→ISR semaphore:

1. Erase via `ca_flash_erase_sector_irq(addr)` — the task blocks on `ca_sem_wait` until the ISR signals EOP
2. Write pattern `0xCAA55ACA` in 32-byte chunks via `ca_flash_write_irq(addr+off, wbuf, 32)` — loop for the entire sector, one chunk per iteration
3. Byte-by-byte verification via direct flash pointer
4. Hexdump of the first lines of the sector
5. Print PASS or number of errors

Requires that `ca_flash_irq_init()` has already been called (`g_flash_irq_ready` flag).

```
flash test_irq 13
flash test_irq s13 @ 0x081A0000  128KB
erase (IRQ)...
write (IRQ)...
PASS: s13 pattern OK (IRQ)
dump 0x081A0000:
0x081A0000  ca a5 5a ca ca a5 5a ca |..Z...Z...Z...Z.|
```

46.1.9 Expected output

Startup

```
c.a.O.S >
```

No automatic operation. The flash is not touched at boot.

Full session on H753

```
c.a.O.S > flash info

0x081A0000  ca a5 5a ca ca a5 5a ca |..Z...Z...Z...Z.|

c.a.O.S > flash dump 0x080000000
dump: 0x80000000 out of flash range [0x08000000-0x08200000)
```

46.1.10 Required configuration in `os_config.h`

```
#define EN_FLASH          1
#define EN_CLI_FLASH      1
#define ENABLE_STDOUT     1
#define STDOUT_ON_UART    1    /* STDOUT and CLI on the debug UART (VCP) */
#define STDIN_ON_UART     1
#define EN_USB            0    /* console on UART, not on USB CDC */
#define ENABLE_CLI        1
```

46.1.11 Created threads

Thread	Role
idle	Scheduler idle task
log	Asynchronous output via USB CDC
CLI	Command reception — also executes flash operations
USB CDC	USB Device CDC stack

46.1.12 Summary

1. **Zero-config CLI**: `ca_flash_init()` is enough to make all `flash` commands available. No application hooks required.

2. **Polling operations in CLI**: driver commands use polling APIs (unlock → hw_erase/write → lock). Simple, predictable, no NVIC requirements.

3. **IRQ-driven available**: `ca_flash_irq_init()` enables the semaphore and the NVIC for `ca_flash_erase_sector_irq` / `ca_flash_write_irq` APIs, usable by application tasks that do not want to occupy the CPU while waiting. CLI commands use **polling** APIs — IRQ APIs are for application code that calls them directly (not from the CLI).

   Bug fix note (2026-05-22): `ca_flash_hw_start_erase_irq` on H7/F4/F7/H5 used direct assignment `FLASH->CR = ...` which cleared EOPIE as soon as it was set

by `ca_flash_hw_irq_enable`. Fix: `(CR & IE_MASK) | operazione`. Corrected families: H7xx, F4xx, F7xx, H5xx. F1xx was already correct (`|=`).

4. **Portability**: the same source code works on all families. The write unit and sector geometry are encapsulated in `flash_<family>.c` files.

5. **Quick polling test**: `flash test <s>` validates the erase/write polling cycle on a sector. The fixed pattern `0xCAA55ACA` covers all bits and makes failures easily detectable.

6. **IRQ-driven test**: `flash test_irq <s>` exercises the entire IRQ path — erase + write + verify — blocking the CLI task on the semaphore and unblocking it from the ISR on EOP. Requires `ca_flash_irq_init()` in `ca_os_configure()`. HW verified on NUCLEO-H753ZI (s13 → PASS).

Chapter 47

Timer: Periodic + Counter

47.1 Example 24 — Timer IRQ: 10 kHz generator + external countdown counter

47.1.1 Introduction

This example shows how to use two STM32 timers in a master-slave configuration to generate a precise periodic signal and count it via an external input (ETR - External Trigger).

The system demonstrates: - **TIM3** as a 10 kHz signal generator (100 µs period) - **TIM2** in counter-irq mode with external clock on ETR (PA0) - Physical connection between the two timers via a single wire - Pulse counting and interrupt generation every N edges

Demonstrated features

Function / Concept	Description
`ca_timer_init_periodic()`	Initializes TIM3 in 100 µs periodic mode
`ca_timer_init_counter_irq()`	Initializes TIM2 in counter mode with IRQ on preset
`ca_gpio_configure()`	Configures GPIO for push-pull output and AF (Alternate Function)
`CA_GPIO_MODE_AF`	Alternate Function mode for TIM2_ETR
`CA_GPIO_PULLUP`	Pull-up on ETR input for signal stability
`EN_TIMER` guard	The entire example is conditioned on the timer driver being enabled

CLI Commands

Application commands:

Command	Description
`info`	Expected wiring (PD0 TIM3 out → PA0 TIM2_ETR), generator and counter

Command	Description
`wire`	Continuity of jumpers on pure GPIO, verdict `WIRE RESULT : OK|FAIL (n/1)`; must be launched first

The example also registers the timer driver CLI via `ca_timer_init()`.

Command	Description
`timer info`	Shows all acquired timers (TIM2, TIM3), mode and current CNT
`timer info <n>`	Single timer detail: mode and CNT
`timer stop <n>`	Stops TIMn
`timer start <n>`	Restarts TIMn
`timer free <n>`	Deinitializes and releases TIMn
`timer cnt <n>`	For encoder/counter: reads the accumulated value; for periodic: raw CNT

STDOUT log output every 5 seconds with statistics.

47.1.2 Required Hardware

Board: Nucleo-H753ZI (STM32H753ZIT6)

Wiring

A single jumper connects the generator to the counter:

Pin	Signal	Description
PD0 (CN9 pin 25)	TIM3 output	10 kHz signal generated
PA0 (CN10 pin 29)	TIM2_ETR	External counter input

```
PD0 (generatore)                    PA0 (ETR counter)
```

Status LEDs

LED	Pin	Color	Function
LD2	PE1	Yellow	Blink 20 Hz — confirms TIM3 active
LD1	PB0	Green	Blink 1 Hz — confirms ETR counting

47.1.3 Timer configuration

TIM3 — 10 kHz generator

Parameter	Value	Notes
Frequency	10 kHz	Period 100 µs
Output	PD0	Toggle in ISR
ISR	`cb_10khz()`	Toggle PD0 + LD2 + increment counter

TIM2 — External counter

Parameter	Value	Notes
Clock	ETR (PA0)	Rising edges
Preset	5000	IRQ every 5000 pulses
ETR Frequency	5 kHz	TIM3_Hz / 2 (toggle = 2 edges/cycle)
IRQ Period	1 s	5000 pulses / 5000 Hz = 1 s
ISR	`cb_1sec()`	Toggle LD1 + increment counter

47.1.4 System architecture

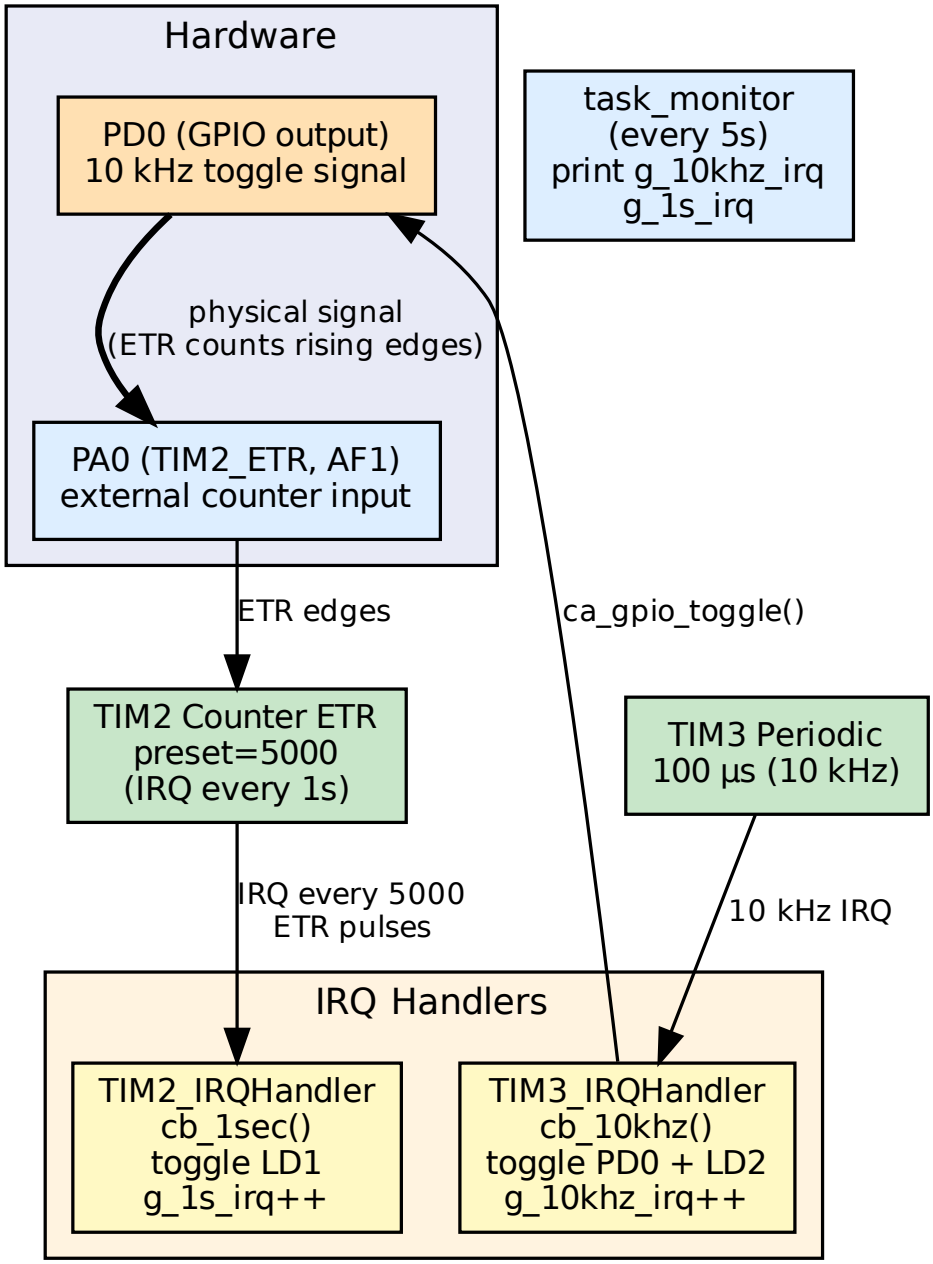

Figure 47.1: Architecture Example 24 — Timer counter ETR

47.1.5 Source code

The file is located in `examples/example_24/ca_os_ex24.c`.

Hardware configuration

```
#define TIM_GEN       3U          /* TIM3     generator */
#define TIM_CNT       2U          /* TIM2     external countdown counter */

#define PERIOD_GEN    100U        /* 100  s  = 10 kHz */
#define PRESET_CNT    5000U       /* 5000 pulses = 1 s @ 5 kHz */

/* signal GPIO output */
#define GPIO_OUT_PORT  CA_GPIO_PORT_D
#define GPIO_OUT_PIN   CA_GPIO_PIN_0

/* GPIO ETR input TIM2: PA0, AF1 = TIM2_ETR (H7xx) */
#define GPIO_ETR_PORT  CA_GPIO_PORT_A
#define GPIO_ETR_PIN   CA_GPIO_PIN_0
#define GPIO_ETR_AF    1U
```

Frequency relationship

```
/* ETR counts only RISING edges of PD0: pulses_ETR = TIM3_Hz / 2
 * DEBUG:      20 Hz TIM3     10 edges/s, preset=10      IRQ every 1 s
 * PRODUCTION: 10 kHz TIM3     5000 edges/s, preset=5000     IRQ every 1 s  */
```

Explanation: TIM3 toggles PD0 every interrupt. A full cycle (HIGH→LOW→HIGH) requires 2 interrupts, so the signal frequency on PD0 is `TIM3_Hz / 2`. ETR counts rising edges, therefore: - TIM3 at 10 kHz → 5000 edges/s on ETR - Preset 5000 → IRQ every 1 second

ISR Callback

```
static volatile u32 g_10khz_irq = 0;
static volatile u32 g_1s_irq    = 0;

static void cb_10khz(void)
{
    ca_gpio_toggle(GPIO_OUT_PORT, GPIO_OUT_PIN);
    ca_gpio_toggle(GPIO_LED2_PORT, GPIO_LED2_PIN);
    g_10khz_irq++;
}

static void cb_1sec(void)
{
    g_1s_irq++;
    ca_gpio_toggle(GPIO_LED_PORT, GPIO_LED_PIN);
}
```

Note: - `g_10khz_irq` counts TIM3 interrupts (actual 10 kHz) - `g_1s_irq` counts TIM2 interrupts (every 5000 ETR pulses) - Both variables are `volatile` because they are accessible from ISRs

Task monitor

```
static u32 task_monitor(void *arg)
{
    (void)arg;

```

```
    while (1) {
        ca_os_sleep(5000);
        u32 hz  = g_10khz_irq;
        u32 sec = g_1s_irq;
        EVAL_STDOUT( ca_stdout_printf_n("EX24: os_ms=%u  10khz_irq=%u  1s_irq=%u
    ",
                                        (unsigned)ca_os_tick_ms(), (unsigned)hz, (
    unsigned)sec); )
    }
    return 0;
}
```

The task reads the global counters and prints the statistics every 5 seconds.

Initialization in `ca_os_configure`

```
void ca_os_configure(void)
{
    /* PD0: fast push-pull output     10 kHz signal */
    ca_gpio_init_port(GPIO_OUT_PORT);
    ca_gpio_configure(GPIO_OUT_PORT, GPIO_OUT_PIN,
                      CA_GPIO_MODE_OUTPUT, CA_GPIO_OTYPE_PP,
                      CA_GPIO_SPEED_VERY_HIGH, CA_GPIO_NOPULL, 0U);

    /* PA0: AF1 (TIM2_ETR)     external clock input TIM2 */
    ca_gpio_init_port(GPIO_ETR_PORT);
    ca_gpio_configure(GPIO_ETR_PORT, GPIO_ETR_PIN,
                      CA_GPIO_MODE_AF, CA_GPIO_OTYPE_PP,
                      CA_GPIO_SPEED_HIGH, CA_GPIO_PULLUP, GPIO_ETR_AF);

    /* LED 1 blinks at 1 Hz from TIM2, LED 2 at 20 Hz from TIM3 (visual
     * confirmation that the generator runs). Pins come from objmap.h. */
    ca_led_init();

    /* TIM3: 20 Hz generator (debug) */
    ca_timer_init_periodic(TIM_GEN, PERIOD_GEN, cb_10khz);
    ca_timer_start(TIM_GEN);

    /* TIM2: countdown 10 ETR rising edges @ 20Hz/2=10Hz = 1 s (debug) */
    ca_timer_init_counter_irq(TIM_CNT, PRESET_CNT, cb_1sec);
    ca_timer_start(TIM_CNT);

    EVAL_STDOUT(
        ca_stdout_init();
        ca_stdout_set_sender(STDOUT);
        ca_stdout_create_thread();
    )
    EVAL_CLI(
        ca_cli_init(2048);
        ca_cli_set_sender(STDOUT);
        ca_cli_create_thread();
    )
    EVAL_USB_CDC_STD(ca_usb_dev_mng_cdc_cli();)
}
```

47.1.6 Detailed analysis

Timer modes used

TIM3 — Periodic mode TIM3 is configured in periodic mode with an interrupt every 100 µs. The ISR executes: 1. Toggle of PD0 (generates effective 5 kHz square wave) 2. Toggle

of LD2 (visual confirmation 20 Hz — every 2 interrupts = 1 visible toggle) 3. Global counter increment

TIM2 — External clock mode 1 TIM2 uses the ETR (External Trigger) input as a clock source. The counter: 1. Counts rising edges on PA0 2. When CTR (counter register) reaches the preset, it generates an interrupt 3. The ISR toggles LD1 and increments the 1s counter

Why PA0 requires pull-up

The ETR input must be stable when there are no transitions. The pull-up: - Keeps the signal HIGH at rest - Prevents false triggers due to noise - Ensures sharp edges when PD0 switches LOW

Debug vs Production

The code includes comments for two configurations:

Mode	TIM3 Hz	ETR edges/s	Preset	IRQ/s
DEBUG	20 Hz	10	10	1 Hz
PRODUCTION	10 kHz	5000	5000	1 Hz

The production configuration (10 kHz) is more accurate and demonstrates the maximum timer resolution.

Exact timing

```
TIM3 ISR (every 100  s ):
         t=0  s :   PD0 = HIGH
         t=100  s : PD0 = LOW
         t=200  s : PD0 = HIGH      1 fronte salita ETR
         t=300  s : PD0 = LOW
         t=400  s : PD0 = HIGH      1 fronte salita ETR

Periodo segnale PD0: 200  s  (5 kHz)
Fronti salita/s: 5000
Preset TIM2: 5000
IRQ TIM2: every exact 1 s
```

47.1.7 Expected output

Startup

```
c.a.O.S >
```

No automatic output at startup. Timers start immediately.

Periodic log (every 5 s)

```
EX24: os_ms=5000  10khz_irq=50000  1s_irq=5
EX24: os_ms=10000  10khz_irq=100000  1s_irq=10
EX24: os_ms=15000  10khz_irq=150000  1s_irq=15
```

Verification: - `10khz_irq` should increment by ~50000 every 5 s (10 kHz × 5 s) - `1s_irq` should increment by 5 every 5 s (1 Hz × 5 s)

Oscilloscope/logic analyzer signals

Channel	Pin	Frequency	Waveform
CH1	PD0	5 kHz	50% duty square wave
CH2	PA0	5 kHz	Identical to PD0
CH3	LD2	20 Hz	Square wave (ISR toggle)
CH4	LD1	1 Hz	Square wave (ETR IRQ)

47.1.8 Required configuration in `os_config.h`

```
#define EN_TIMER          1
#define EN_CLI_TIMER      1
#define ENABLE_STDOUT     1
#define STDOUT_ON_UART    1    /* STDOUT and CLI on the debug UART (VCP) */
#define STDIN_ON_UART     1
#define EN_USB            0    /* console on UART, not on USB CDC */
#define ENABLE_CLI        1
```

47.1.9 Created threads

Thread	Priority	Role
idle	0	Scheduler idle task
monitor	3	Log statistics every 5 s
log	—	Asynchronous output via USB CDC
CLI	—	Command reception
USB CDC	—	USB Device CDC stack

47.1.10 Possible extensions

1. ETR precision measurement

Add a CLI command to measure the ETR count drift compared to the internal timer:

```
static void cmd_measure(void)
{
    u32 start_10k = g_10khz_irq;
    u32 start_1s  = g_1s_irq;
    ca_os_sleep(10000);  /* 10 secondi */
    u32 delta_10k = g_10khz_irq - start_10k;
    u32 delta_1s  = g_1s_irq - start_1s;

    ca_stdout_printf_n("10s measure: 10k_irq=%u (expected 100000), 1s_irq=%u (
    expected 10)",
                       delta_10k, delta_1s);
}
```

2. Variable frequency generator

Add a CLI command to change the TIM3 frequency dynamically:

```
static void cmd_freq(u32 freq_hz)
{
    u32 period_us = 1000000 / freq_hz;
    ca_timer_stop(TIM_GEN);
    ca_timer_init_periodic(TIM_GEN, period_us, cb_10khz);
```

```
    ca_timer_start(TIM_GEN);
    ca_stdout_printf_n("TIM3 set to %u Hz (period %u us)", freq_hz, period_us);
}
```

3. Variable preset

Allow changing the TIM2 preset to obtain IRQs at different intervals:

```
static void cmd_preset(u32 preset)
{
    ca_timer_stop(TIM_CNT);
    ca_timer_init_counter_irq(TIM_CNT, preset, cb_1sec);
    ca_timer_start(TIM_CNT);
    ca_stdout_printf_n("TIM2 preset: %u (IRQ every %u ms)",
                       preset, preset / 5);  /* @ 5 kHz ETR */
}
```

47.1.11 Summary

1. **Dual-timer configuration**: TIM3 generates a signal, TIM2 counts it via ETR — demonstrates the combined use of independent timers.
2. **External trigger mode**: TIM2 uses PA0 as an external clock, showing how to count external events without CPU intervention.
3. **Hardware connection**: A single wire (PD0→PA0) connects the two timers — minimal configuration for precision testing.
4. **Visual feedback**: Two LEDs show the activity of both timers (LD2 at 20 Hz, LD1 at 1 Hz).
5. **Statistics logging**: STDOUT output every 5 seconds allows verifying the correctness of the count and the stability of the system.
6. **Scalability**: The same architecture can be used to:
   - Count pulses from rotary encoders
   - Measure the frequency of external signals
   - Generate precise baud rates for UART
   - Create multiple timebases derived from a single timer

Chapter 48

Timer: Periodic + Encoder Counter

48.1 Example 25 — Quadrature Signal Generator + Timer Encoder

48.1.1 Introduction

This example demonstrates how to generate quadrature signals (CW/CCW) using a timer and how to count them using a second timer in encoder mode.

Hardware (Nucleo-H753ZI, MB1364)

- **TIM3**: 100 µs (10 kHz) generator
  - ISR: every 4 pulses generates a quadrature cycle on PB8/PB9 (2.5 kHz)
- **PB8** (GPIO output): Signal A (quadrature) - CN7 pin 2
- **PB9** (GPIO output): Signal B (quadrature, 90° phase shifted) - CN7 pin 4
- **TIM4**: encoder mode
  - **PB6** (TIM4_CH1, AF2): Channel A input - CN10 pin 13
  - **PB7** (TIM4_CH2, AF2): Channel B input - CN10 pin 15

Direction

- **CW (ClockWise)**: A leads B → counter increments
- **CCW (CounterClockWise)**: B leads A → counter decrements

Wiring (2 jumpers)

```
PB8 (CN7 pin 2)                  PB6 (CN10 pin 13)  [Segnale A]
PB9 (CN7 pin 4)                  PB7 (CN10 pin 15)  [Segnale B]
```

Application CLI Commands

Command	Description
`setcw`	Sets CW (clockwise) direction
`setccw`	Sets CCW (counterclockwise) direction
`show`	Shows encoder position and statistics
`wire`	Bridge continuity on pure GPIO, verdict `WIRE RESULT : OK|FAIL (n/2)`; must be run first

CLI driver timer commands (`ca_timer_init`)

Command	Description
`timer info`	Shows TIM3 (periodic) and TIM4 (encoder) with current CNT
`timer info <n>`	Single timer details
`timer stop <n>`	Stops the timer
`timer start <n>`	Restarts the timer
`timer cnt 4`	Reads accumulated encoder position TIM4

48.1.2 System Architecture

5   * Example 25     Timer IRQ: quadrature generator + Timer Encoder
6   *
7   * Hardware (Nucleo-H753ZI, MB1364):
```

```
 *
 *   TIM3  periodic 100  s  (10 kHz)
 *         ISR: every 4 pulses generates one quadrature cycle on PB8/PB9
 *
 *   PB8   (GPIO output)     Signal A (quadrature) - CN7 pin 2
 *   PB9   (GPIO output)     Signal B (quadrature, 90   shifted) - CN7 pin 4
 *
 *   TIM4  Encoder mode     Counts pulses on PB6/PB7
 *   PB6   (TIM4_CH1, AF2)     Channel A input (jumper from PB8) - CN10 pin 13
 *   PB7   (TIM4_CH2, AF2)     Channel B input (jumper from PB9) - CN10 pin 15
 *
 *   Direction:
 *     - CW  (ClockWise)          A leads B     counter increments
 *     - CCW (CounterClockWise)     B leads A     counter decrements
 *
 * Wiring (2 jumpers):
 *   PB8 (CN7 pin 2)                  PB6 (CN10 pin 13)  [Signal A]
 *   PB9 (CN7 pin 4)                  PB7 (CN10 pin 15)  [Signal B]
 */

48.1.4 Detailed Analysis

Quadrature Signal Generation

The TIM3 generates an interrupt every 100 µs (10 kHz). In the ISR, every 4 interrupts a complete quadrature cycle is generated:

```
1 #define TIM3_PERIOD_US      100U      /* 10 kHz */
2 #define QUAD_DIVISOR        4U        /* 4 interrupts = 1 quadrature cycle */
3                                     /* Result: 2.5 kHz */
```

PB8 and PB9 are configured as pure **GPIO output**: the ISR drives them directly with `ca_gpio_write()`. No timer alternate function is used.

Quadrature sequences

CW (ClockWise):

```
1 State  A  B
2   0    0  0
3   1    1  0      A leads
4   2    1  1
5   3    0  1
```

CCW (CounterClockWise):

```
1 State  A  B
2   0    0  0
3   1    0  1      B leads
4   2    1  1
5   3    1  0
```

TIM4 Encoder mode

TIM4 is configured in encoder mode, which automatically counts the edges on channels CH1 (PB6) and CH2 (PB7):

```
1 ca_timer_init_encoder(TIM_ENC, &encoder_pos_accum);
2 ca_timer_start(TIM_ENC);
```

The timer increments/decrements the counter based on the relative phase between the two signals.

Note: The STM32 encoder mode requires the main channels CH1 and CH2 — the complementary channels (CH1N, CH2N) cannot be used as encoder inputs.

Variable `g_req_cw`

```
1 static volatile u8 g_req_cw = 1;  /* Default CW */
```

- `g_req_cw = 1`: generate CW sequence
- `g_req_cw = 0`: generate CCW sequence

Modifiable via CLI commands `setcw` and `setccw`.

48.1.5 Expected output

At startup

```
=== Example 25: Quadrature Encoder ===
TIM3: 10 kHz generator (100  s )
Quadrature: 2.5 kHz on PB8/PB9
Encoder: TIM4 on PB6/PB7
Connect: PB8(CN7-2)->PB6(CN10-13), PB9(CN7-4)->PB7(CN10-15)
Type 'help' for commands
Default direction: CW
```

Command `show`

```
c.a.O.S > show
=== QUADRATURE ENCODER STATUS ===
  pos       : 5000
  dir       : CW
  tim3_irq  : 50000
  quad_cyc  : 12500
  cw_cyc    : 12500
  ccw_cyc   : 0
  expected  : 12500
```

Command `timer info`

```
c.a.O.S > timer info
timer: in_use=0x0000000A
  TIM3  periodic   cnt=0x00001F4A
  TIM4  encoder    cnt=0x00001388
```

Periodic log (every 5 seconds)

```
EX25: pos=125  dir=CW  tim3_irq=50000  quad_cycles=12500  cw=12500  ccw=0
```

48.1.6 Required Configuration in `os_config.h`

```
#define EN_TIMER          1
#define EN_CLI_TIMER      1
#define ENABLE_STDOUT     1
#define STDOUT_ON_UART    1    /* STDOUT and CLI on the debug UART (VCP) */
#define STDIN_ON_UART     1
#define EN_USB            0    /* console on UART, not on USB CDC */
#define ENABLE_CLI        1
```

48.1.7 Important Notes

1. Frequencies

Signal	Frequency	Period
TIM3 ISR	10 kHz	100 µs
Quadrature	2.5 kHz	400 µs
LED toggle	5 kHz	200 µs

2. Encoder Resolution

TIM4 in encoder mode x4 counts: - 4 edges per quadrature cycle - Effective resolution: 4× the quadrature frequency

3. Required Jumpers

2 jumpers are required: 1. PB8 (CN7 pin 2) → PB6 (CN10 pin 13) [Signal A] 2. PB9 (CN7 pin 4) → PB7 (CN10 pin 15) [Signal B]

4. Pins and Alternate Functions

Pin	Function	AF	Connector
PB8	GPIO output (signal A)	—	CN7 pin 2
PB9	GPIO output (signal B)	—	CN7 pin 4
PB6	TIM4_CH1 (encoder A)	AF2	CN10 pin 13
PB7	TIM4_CH2 (encoder B)	AF2	CN10 pin 15

5. GPIO Speed

- **Quadrature output**: `CA_GPIO_MODE_OUTPUT` + `CA_GPIO_SPEED_VERY_HIGH` for sharp edges
- **Encoder input**: `CA_GPIO_MODE_AF` + `CA_GPIO_SPEED_HIGH` with pull-up

48.1.8 Summary

1. **TIM3** generates interrupt at 10 kHz for precise quadrature timing.
2. **Quadrature signal** generated on PB8/PB9 (GPIO output) with CW or CCW sequence.
3. **TIM4** in encoder mode automatically counts edges on CH1/CH2 (PB6/PB7).
4. **Application CLI** (`setcw`, `setccw`, `show`, `wire`) in chain of responsibility. **CLI driver** (`timer info/stop/start/cnt`) registered by `ca_timer_init()`.
5. **2 jumpers** connect quadrature output to encoder input.
6. **Default direction**: CW (changeable via CLI).
7. **Statistics**: CW/CCW cycle count, TIM3 interrupts, encoder position.

Chapter 49

Cryptography: CRC32, HASH, AES, RNG and Key Derivation

49.1 Example 26 — Cryptography: CRC32, HASH, AES, RNG and Key Derivation

49.1.1 Introduction

This example demonstrates the use of STM32 cryptographic modules:

1. **CRC32** — Checksum calculation for data integrity verification
2. **HASH** — SHA-256 calculation (one-shot and concurrent contextual)
3. **AES** — AES-256 encryption/decryption (ECB, CTR, GCM)
4. **RNG** — Hardware random number generation
5. **Multithreading** — HASH and AES support context swap with mutex
6. **Key Derivation** — Key derivation: IV+KEY_SECRET → SHA256 → 32-byte key
7. **Key-Store** — Secure storage with MPU protection, validity period for data and auto-lock

> **Hardware or software AES (2026-07-21):** the AES driver automatically selects the path based on the device (see chap. 13.4). On Nucleo-H753 it uses the hardware CRYP; on Nucleo-U575 — which lacks HW AES — it uses the software AES-256 implementation (FIPS-197 + SP 800-38D). The example runs **identically** on both: the commands `aes`, `aes_gcm`, `aes_mt` do not change. The command `aes_nist test` verifies the NIST vectors (absolute correctness of the software path).
>
> **AES-128 (23/10/2026):** the software path now also supports 128-bit keys, required by the mandatory TLS 1.3 suite. This example continues to test only AES-256; AES-128 is verified on the PC (184/184 against the `cryptography` library) and on the boards via HTTPS (examples 45 and 80), including on the H753 CRYP.

Hardware (Nucleo-H753ZI or Nucleo-U575ZI-Q)

- **Console UART** for STDOUT/CLI: the ST-LINK VCP (`UART_DBG_NUM` in `objmap.h`: USART3 on H753, USART1 on U575)
- **USB CDC** for alternative output

CLI Commands

Command	Source	Description
`crc32`	application	Calculate CRC32 on test buffer
`hash`	application	Calculate SHA-256 one-shot
`hash_mt`	application	Concurrent HASH test (2 synchronized threads)
`aes`	application	AES-256 ECB encrypt/decrypt test
`aes_gcm`	application	AES-256 GCM (authenticated encryption) test
`aes_mt`	application	Concurrent AES test (2 synchronized threads)
`aes_nist`	application	Known-answer test: GCM 4/4 (McGrew/Viega) + ECB 2/2 (FIPS-197)
`rng get`	driver `rng.c`	Generate and print a single 32-bit random value
`derive`	application	Derive key: IV+KEY → SHA256 → 32-byte key
`kstore`	application	Key-store test: 3 keys with different validity
`test`	application	Run all tests (crc32, hash, hash_mt, aes_ecb, aes_gcm, aes_mt, aes_nist, derive, kstore) and print PASS/FAIL for each, with final verdict
`full`	application	Run entire sequence: derive + kstore + use
`kstore info`	driver `keys_store.c`	Global status: slots used, occupied area
`kstore list`	driver `keys_store.c`	Key list: id, size, access, validity, status
`crc32 calc <addr> <len>`	driver `crc32.c`	Calculate CRC32 on memory range
`help`	chain	Command list (driver + application)

The CLI uses the **chain of responsibility** pattern. Commands `rng get`, `kstore info/list` and `crc32 calc` are handled by driver nodes registered automatically during driver init.

STDOUT Log (every 5 s)

```
EX26: rng=0xXXXXXXXX  tick=NNNNN
```

/* ... (continua nel file completo) ... */
```

49.1.4 Detailed analysis

1. CRC32 Example

The hardware CRC32 module calculates a 32-bit checksum to verify data integrity:

```
static void example_crc32(void) {
    init_test_buffer();

    u32 crc = ca_crc32_get(g_test_data, TEST_BUFFER_SIZE);
    ca_stdout_put_n("=== CRC32 Example ===");
```

```
    ca_stdout_printf_n("Buffer size: %u bytes", TEST_BUFFER_SIZE);
    ca_stdout_printf_n("CRC32: 0x%08X", crc);

    /* Modifica un byte e ricalcola */
    g_test_data[100] ^= 0xFF;
    u32 crc_modified = ca_crc32_get(g_test_data, TEST_BUFFER_SIZE);
    ca_stdout_printf_n("CRC32 (modified): 0x%08X (different!)", crc_modified);
}
```

Note on output functions: - `ca_stdout_put_n()` and `ca_stdout_printf_n()` automatically add a trailing `\n` - `ca_stdout_put()` and `ca_stdout_printf()` do NOT add a trailing `\n` - Use `_n` for messages that automatically wrap to a new line

Expected output:

```
=== CRC32 Example ===
Buffer size: 256 bytes
CRC32: 0x12345678
CRC32 (modified): 0xABCDEF01 (different!)
```

2. HASH Example (SHA-256)

```
static void example_hash_oneshot(void) {
    u8 digest[HASH_SHA256_DIGEST_SIZE];
    u32 digest_len;

    init_test_buffer();

    if (ca_hash_compute(CA_HASH_ALGO_SHA256, g_test_data, TEST_BUFFER_SIZE,
                        digest, &digest_len)) {
        ca_stdout_put_n("=== HASH SHA-256 One-Shot ===");
        print_hex_label("SHA-256 digest", digest, digest_len);
    }
}
```

Multithread Hash (Context Swap) HASH supports context swap via mutex, allowing multiple threads to calculate hashes concurrently:

```
static u32 task_hash_thread1(void *arg) {
    (void)arg;
    ca_hash_ctx_t ctx;
    u8 digest[HASH_SHA256_DIGEST_SIZE];
    u32 digest_len;

    g_hash_threads_started++;
    ca_sem_wait(&g_start_sem);  /* Attendi start sincronizzato */

    while (1) {
        ca_hash_ctx_init(&ctx, CA_HASH_ALGO_SHA256);

        /* Calcolo incrementale in 3 step */
        ca_hash_ctx_update(&ctx, (const u8*)"Hello ", 6);
        ca_os_sleep(10);
        ca_hash_ctx_update(&ctx, (const u8*)"concurrent ", 11);
        ca_os_sleep(10);
        ca_hash_ctx_update(&ctx, (const u8*)"world!", 6);

        ca_hash_ctx_final(&ctx, digest, &digest_len);
        g_hash_thread1_count++;

        ca_os_sleep(100);
```

```
    }
    return 0;
}
```

Synchronization:

```
static void example_hash_multithread(void) {
    ca_sem_init(&g_start_sem, 0, 10);  /* Semaphore a 0 */

    /* Crea 2 thread */
    ca_os_job("hash_t1", CA_TH_LEVEL2, task_hash_thread1, NULL, STACK_MEDIUM,
    CA_JOB_STD, 0);
    ca_os_job("hash_t2", CA_TH_LEVEL2, task_hash_thread2, NULL, STACK_MEDIUM,
    CA_JOB_STD, 0);

    /* Attendi che entrambi i thread siano in ca_sem_wait */
    while (g_hash_threads_started < 2) {
        ca_os_sleep(10);
    }

    /* Start sincronizzato: 2 post per 2 thread */
    ca_sem_post(&g_start_sem);
    ca_sem_post(&g_start_sem);
}
```

3. AES Example

```
static void example_aes_ecb(void) {
    u8 plaintext[16] = "Hello AES World!";
    u8 ciphertext[16];
    u8 decrypted[16];
    ca_aes_ctx_t ctx;

    generate_random_key_iv();
    ca_aes_ctx_setup(&ctx, CA_AES_MODE_ECB, CA_AES_KEY_256, g_aes_key, NULL);

    ca_aes_encrypt(&ctx, plaintext, ciphertext, 16);
    ca_aes_decrypt(&ctx, ciphertext, decrypted, 16);

    if (ca_memcmp(plaintext, decrypted, 16) == 0) {
        ca_stdout_put_n("AES-256 ECB: SUCCESS (plaintext recovered)");
    }
}
```

```
static void example_aes_gcm(void) {
    u8 plaintext[48] = "AES-GCM authenticated encrypt!";
    u8 ciphertext[48];
    u8 decrypted[48];
    u8 tag[GCM_TAG_SIZE];
    u8 aad[16] = "authenticated!";
    ca_aes_ctx_t ctx;

    generate_random_key_iv();
    ca_aes_ctx_setup(&ctx, CA_AES_MODE_GCM, CA_AES_KEY_256, g_aes_key, g_aes_iv)
    ;

    /* Encrypt con GCM */
    ca_aes_gcm_encrypt(&ctx, aad, 16, plaintext, ciphertext, 32, tag);

    /* Decrypt con verifica tag */
```

```
    if (ca_aes_gcm_decrypt(&ctx, aad, 16, ciphertext, decrypted, 32, tag)) {
        ca_stdout_put_n("AES-256 GCM Decrypt: SUCCESS");
    }

    /* Test tamper detection */
    tag[0] ^= 0xFF;
    if (!ca_aes_gcm_decrypt(&ctx, aad, 16, ciphertext, decrypted, 32, tag)) {
        ca_stdout_put_n("AES-256 GCM Tamper Detection: SUCCESS");
    }
}
```

Verification against known vectors (aes_nist) `aes`/`aes_gcm` test the **round-trip** (encrypt→decrypt with the same key), but a round-trip *hides* symmetric bugs: if the hardware path incorrectly orders the bytes during encryption **and** decryption in the same way, the plaintext still returns correctly. A **known-answer test** (KAT) does not: it compares the output against a known external value. The `aes_nist` command — from the example — executes two KAT batteries through the **public dispatch** (`ca_aes_encrypt`/`ca_aes_gcm_*`), thereby validating the **active** backend, HW on H753 or SW on U575:

- `ca_aes_gcm_selftest()` — AES-256-GCM vectors (McGrew/Viega, the same as the NIST suites): 4 cases;
- `ca_aes_ecb_selftest()` — AES-256-ECB single-block vector FIPS-197 App. C.3.

```
c.a.O.S > aes_nist
aes-gcm: NIST AES-256-GCM known-answer tests (dispatch: HW/SW)
  case13 empty                PASS
  case14 one block            PASS
  case15 payload              PASS
  case16 aad+payload          PASS
aes-gcm: ALL PASS (4/4)
aes-ecb: FIPS-197 AES-256-ECB known-answer (dispatch: HW/SW)
  ecb256 encrypt              PASS
  ecb256 decrypt              PASS
aes-ecb: ALL PASS (2/2)
```

The four GCM cases cover: no data, a single block, long payload (60 B), and AAD+payload; each case also verifies the decryption round-trip and the rejection of a tampered tag (constant-time). ECB verifies encryption and decryption of a block against the FIPS-197 vector. The KATs run **in-place** (same input and output buffer), as in the actual SSH record path.

> **Why KAT and not round-trip:** this distinction unmasked three real bugs in the H753 hardware CRYP during SSH bring-up (IV counter, data endianness, missing `ca_aes_init()`) that a simple encrypt→decrypt would have let pass. General rule: **HW crypto always validated with known-answer, never with round-trip.**

4. RNG

Random number generation is used internally by `generate_random_key_iv()` and `example_key_derivation()` via `ca_rng_fill()`.

The CLI command `rng get` is provided directly by the `rng.c` driver (automatically registered by `ca_rng_init()`):

```
c.a.O.S > rng get
rng: 0xA3F12C7B  (2751987835)
```

The periodic log every 5 seconds also shows an RNG sample:

```
EX26: rng=0x1A2B3C4D  tick=5000
```

The application command `rng` (which generated 8 values) has been removed. Use `rng get` from the driver for interactive RNG testing.

5. Key Derivation: IV+KEY_SECRET → SHA256 → 32-BYTE KEY

```
static void example_key_derivation(void) {
    u8 iv_secret[IV_SECRET_SIZE];
    u8 key_secret[KEY_SECRET_SIZE];
    u8 hash_input[IV_SECRET_SIZE + KEY_SECRET_SIZE];
    u8 sha256_digest[HASH_SHA256_DIGEST_SIZE];
    u32 digest_len;

    /* Genera IV e KEY_SECRET casuali */
    ca_rng_fill(iv_secret, IV_SECRET_SIZE);
    ca_rng_fill(key_secret, KEY_SECRET_SIZE);

    print_hex_label("IV_SECRET", iv_secret, IV_SECRET_SIZE);
    print_hex_label("KEY_SECRET", key_secret, KEY_SECRET_SIZE);

    /* Step 1: Concatena IV + KEY_SECRET */
    ca_memcpy(hash_input, iv_secret, IV_SECRET_SIZE);
    ca_memcpy(hash_input + IV_SECRET_SIZE, key_secret, KEY_SECRET_SIZE);
    ca_stdout_printf_n("Step 1: IV + KEY_SECRET concatenated (%u bytes)",
            IV_SECRET_SIZE + KEY_SECRET_SIZE);

    /* Step 2: SHA-256 hash */
    ca_hash_compute(CA_HASH_ALGO_SHA256, hash_input,
                    IV_SECRET_SIZE + KEY_SECRET_SIZE,
                    sha256_digest, &digest_len);

    /* Step 3: Usa SHA-256 digest come chiave AES-256 (32 byte) */
    ca_memcpy(g_derived_key, sha256_digest, 32);
    g_derived_key_ready = 1;

    print_hex_label("Derived 32-BYTE SECRET KEY", g_derived_key, 32);
}
```

Derivation flow:

```

     IV_SECRET            KEY_SECRET
     (16 byte)             (32 byte)

                   Concatenazione

            IV || KEY          (48 byte)

             SHA-256
              (HASH)

            32-byte KEY
```

```
            (chiave AES-256)

```

Note: The derivation uses only SHA-256. The SHA-256 digest (32 bytes) is the derived key itself, without further AES steps.

6. Key-Store Example (Secure Storage with MPU + Validity)

The key-store protects cryptographic keys via the **MPU (Memory Protection Unit)**: all keys reside in a single memory area covered by a single MPU region. Each key can have a **validity period by date** (start/stop); if the key has expired, it is automatically locked (`NO_ACCESS`) upon the first verification.

```c
void ca_os_configure(void) {
    EVAL_CRC(ca_crc32_init();)
    EVAL_HASH(ca_hash_init();)
    EVAL_AES(ca_aes_init();)
    EVAL_RNG(ca_rng_init();)
#if EN_KEYS_STORE
    ca_keys_store_init(10);   /* max 10 chiavi     CLI kstore disponibile subito
    */
#endif
    /* ... stdout, CLI ... */
}
```

Early init ensures that `kstore info` and `kstore list` respond immediately without waiting for the execution of the `kstore` command.

6.2 Packed date — validity format The date is encoded in a `u32` with the `KSTORE_DATE_PACK` macro:

```c
/* Macro definite in keys_store.h */
#define KSTORE_DATE_PACK(y, m, d)  (((u32)(y) << 16) | ((u32)(m) << 8) | (u32)(d
    ))
#define KSTORE_DATE_YEAR(v)        (((v) >> 16) & 0xFFU)
#define KSTORE_DATE_MONTH(v)       (((v) >>  8) & 0xFFU)
#define KSTORE_DATE_DAY(v)         ((v) & 0xFFU)

/* Esempio: 2026-03-15 */
u32 d = KSTORE_DATE_PACK(26, 3, 15);   /* year    relativo al 2000 */
```

The packed u32 is **directly comparable** as an integer: larger values = more recent dates.

```c
/* Imposta periodo di validit  per chiave all'indice key_idx */
int  ca_keys_store_set_expiry(u8 key_idx, u32 start, u32 stop);

/* Verifica se chiave    scaduta; se s  , la blocca automaticamente */
bool ca_keys_store_is_key_expired(void *ptr);
```

Rules:

`validity_start`	`validity_stop`	Behavior
0	0	no validity → always valid
date	0	valid from `start` onwards, no expiration
0	date	valid until `stop` (immediately operational)

validity_start	validity_stop	Behavior
date	date	valid within the window [start, stop]

RTC Dependency:

- RTC disabled (EN_RTC=0) and validity set → key **not usable** (auto-lock)
- RTC enabled but date invalid (year < 2024 or > 2300, month > 12, day > 31) → key **not usable**
- RTC enabled and date valid → comparison against current date

```
static u8 get_key_id(void *ptr) {
    ca_secure_key_entry_t info[MAX_SECURE_KEYS];
    u8 cnt = MAX_SECURE_KEYS;
    if (!ptr || ca_keys_store_get_keys_info(info, &cnt) != 0) return 0xFF;
    for (u8 i = 0; i < cnt; i++) {
        if (info[i].base_address == (u32)ptr) return (u8)info[i].key_id;
    }
    return 0xFF;
}
```

ca_keys_store_set_expiry requires the slot index (key_id). get_key_id derives it from the pointer via get_keys_info, without touching the area protected by the MPU.

```
static void example_key_store(void) {
    u8 key_data[32];

    /* --- KEY 0: permanente (AES-256, derived o random) --- */
    g_secure_key_area = ca_keys_store_allocate(32);

    if (g_derived_key_ready)
        ca_memcpy(key_data, g_derived_key, 32);
    else
        ca_rng_fill(key_data, 32);

    ca_keys_store_temp_enable_access(g_secure_key_area, CA_KEYS_STORE_READ_WRITE
    );
    ca_keys_store_copy(g_secure_key_area, key_data, 32);
    ca_keys_store_lock_completely(g_secure_key_area);
    /* nessuna set_expiry     validity_start=0, validity_stop=0     permanente
    */

    /* --- KEY 1: valida 2026-01-01     2027-12-31 --- */
    void *kv = ca_keys_store_allocate(16);
    ca_keys_store_temp_enable_access(kv, CA_KEYS_STORE_READ_WRITE);
    /* ... copia e lock ... */
    ca_keys_store_set_expiry(get_key_id(kv),
        KSTORE_DATE_PACK(26, 1,  1),
        KSTORE_DATE_PACK(27, 12, 31));
    bool exp = ca_keys_store_is_key_expired(kv);
    /* exp = false se RTC indica data 2026-xx-xx .. 2027-xx-xx */

    /* --- KEY 2: scaduta 2024-01-01     2025-12-31 --- */
    void *ke = ca_keys_store_allocate(16);
    ca_keys_store_temp_enable_access(ke, CA_KEYS_STORE_READ_WRITE);
    /* ... copia e lock ... */
```

```
    ca_keys_store_set_expiry(get_key_id(ke),
        KSTORE_DATE_PACK(24, 1,  1),
        KSTORE_DATE_PACK(25, 12, 31));
    bool exp2 = ca_keys_store_is_key_expired(ke);
    /* exp2 = true     ca_keys_store_is_key_expired chiama lock_completely
    automaticamente */

    /* --- Uso della chiave permanente --- */
    if (!ca_keys_store_is_key_expired(g_secure_key_area)) {
        ca_keys_store_temp_enable_access(g_secure_key_area,
    CA_KEYS_STORE_READ_ONLY);
        u8 retrieved[32];
        ca_memcpy(retrieved, g_secure_key_area, 32);
        ca_keys_store_temp_disable_access(g_secure_key_area);
    }
}
```

```
CA_KEYS_STORE_NO_ACCESS   = 0   (default     nessun accesso)
CA_KEYS_STORE_READ_ONLY   = 1   (sola lettura)
CA_KEYS_STORE_READ_WRITE  = 2   (lettura + scrittura)
CA_KEYS_STORE_EXEC_ONLY   = 3   (solo esecuzione     uso raro)
```

6.7 CLI driver kstore The CLI driver is automatically registered by `ca_keys_store_init()` (guard `EN_CLI_KSTORE=1`):

```
c.a.O.S > kstore info
kstore: slots=3/10  area=64/2048 bytes  mpu_rgn=2

c.a.O.S > kstore list
id  size  access  start       stop        status
 0    32  LOCKED  *           *           permanent
 1    16  LOCKED  2026-1-1    2027-12-31  valid
 2    16  LOCKED  2024-1-1    2025-12-31  EXPIRED
```

- `*` = no limit (validity_start=0 or validity_stop=0)
- `EXPIRED` = key already locked by `is_key_expired()`
- `permanent` = no validity set

7. Full Demo: Derive → Store → Use

```
static void example_full_demo(void) {
    ca_stdout_put_n("=========================================================");
    ca_stdout_put_n("         FULL CRYPTO DEMO: Derive -> Store -> Use        ");
    ca_stdout_put_n("=========================================================");

    /* Step 1: Key derivation */
    example_key_derivation();
    ca_os_sleep(500);

    /* Step 2: Store in key-store */
    example_key_store();
    ca_os_sleep(500);

    /* Step 3: Usa la chiave dal key-store per AES-GCM */
    if (g_secure_key_area && g_derived_key_ready) {
        ca_keys_store_temp_enable_access(g_secure_key_area,
    CA_KEYS_STORE_READ_ONLY);
```

```

        u8 stored_key[32];
        ca_memcpy(stored_key, g_secure_key_area, 32);
        ca_keys_store_temp_disable_access(g_secure_key_area);

        ca_aes_ctx_t ctx;
        u8 iv[16];
        ca_rng_fill(iv, 16);

        u8 plaintext[64] = "Msg encrypted with derived stored key!";
        u8 ciphertext[64];
        u8 tag[16];

        ca_aes_ctx_setup(&ctx, CA_AES_MODE_GCM, CA_AES_KEY_256, stored_key, iv);
        ca_aes_gcm_encrypt(&ctx, NULL, 0, plaintext, ciphertext, 48, tag);
    }
}
```

49.1.5 Expected output

At startup

```
=== Example 26: Crypto + Key-Store ===
Hardware: CRC32 | SHA-256 | AES-256 | RNG
Multithread: HASH & AES with context swap
Key derivation: IV+KEY -> SHA256 -> 32-byte key
Key-store: MPU protected, validity per date, auto-lock
CLI driver: crc32 calc | rng get | kstore info | kstore list
Type 'help' for app commands
```

kstore command

```

```

Periodic log (every 5 seconds)

```
EX26: rng=0x1A2B3C4D  tick=5000
EX26: rng=0x5E6F7A8B  tick=10000
```

49.1.6 Required configuration in `os_config.h`

```
#define EN_CRC         1    /* Driver CRC32 */
#define EN_HASH        1    /* Driver HASH (SHA-256) */
#define EN_AES         1    /* Driver AES */
#define EN_RNG         1    /* Driver RNG */
#define EN_KEYS_STORE  1    /* Secure key-store con MPU */
#define EN_RTC         1    /* RTC     obbligatorio per validit  chiavi */
#define ENABLE_CLI     1    /* CLI per comandi utente */
#define ENABLE_STDOUT  1    /* STDOUT per output */
/* CLI driver */
#define EN_CLI_CRC     1    /* crc32 calc <addr> <len> */
#define EN_CLI_RNG     1    /* rng get */
#define EN_CLI_KSTORE  1    /* kstore info | kstore list */
```

Note: if `EN_RTC=0`, keys with set validity are always **unusable** (auto-locked). If `EN_RTC=1` but the RTC is not yet initialized with a valid date (year < 2024 or > 2300), keys with validity are likewise locked.

49.1.7 Important notes

1. Context Swap for Concurrency

Both HASH and AES support **context swap**, allowing multiple threads to use the hardware modules concurrently:

- **HASH**: `ca_hash_ctx_t` saves/restores the CSR[] registers
- **AES**: `ca_aes_ctx_t` preserves key and IV; the driver reloads them into the peripheral (HW) or uses them directly (SW) at each operation

Both use internal mutexes to protect access.

2. Thread Synchronization

Multithreaded threads use a **semaphore** to start in sync:

```
ca_sem_init(&g_start_sem, 0, 10);  /* Inizializza a 0 */

/* Ogni thread incrementa il contatore e si blocca */
g_hash_threads_started++;          /* thread 1 */
g_hash_threads_started++;          /* thread 2 */
ca_sem_wait(&g_start_sem);         /* entrambi si bloccano */

/* Chiamante attende che ENTRAMBI siano pronti, poi d  il via */
while (g_hash_threads_started < 2) { ca_os_sleep(10); }
ca_sem_post(&g_start_sem);         /* Sblocca primo thread */
ca_sem_post(&g_start_sem);         /* Sblocca secondo thread */
```

3. Key-Store, MPU and Validity

The key-store uses the **MPU** to protect keys in a single shared area:

- A single MPU region covers all keys (1 region = max 10 keys)
- Default: `NO_ACCESS` — no access, any read/write generates a Hard Fault
- Temporary access: `temp_enable_access` → use the key → `temp_disable_access`

Validity by date:

```
/* Imposta finestra di validit  */
ca_keys_store_set_expiry(key_idx,
    KSTORE_DATE_PACK(26, 1, 1),   /* start: 2026-01-01 */
    KSTORE_DATE_PACK(27, 12, 31)); /* stop:  2027-12-31 */

/* Verifica (auto-lock se scaduta) */
if (ca_keys_store_is_key_expired(ptr)) {
    /* chiave bloccata     non usabile */
}
```

`is_key_expired()` **Behavior:**

Condition	Result
`validity_start=0` and `validity_stop=0`	`false` (permanent)
RTC disabled, validity set	`true` + auto-lock
RTC enabled, invalid date	`true` + auto-lock
Current date outside window	`true` + auto-lock
Current date inside window	`false`

4. AES-GCM Tag Verification

AES-GCM provides **authenticated encryption**:

- The tag (16 bytes) authenticates the ciphertext
- Decryption automatically verifies the tag
- If the tag is tampered with, decryption fails

5. CLI — Chain of Responsibility

The CLI uses the **chain of responsibility** pattern. The application node handles cryptographic commands; the driver node `rng.c` handles `rng get` (automatically registered by `ca_rng_init()`).

```
static bool user_cli_handler(c_str *pcmd)
{
    c_str cmd = *pcmd;
    const char *p = ca_skip_sp(cmd->data);

    if (ca_strncmp(p, "help", 4) == 0) {
        CLI_PUT_N("ex26      : test (all, with verdict) | full (derive+kstore+
    gcm)");
        CLI_PUT_N("            crc32 | hash | hash_mt | aes | aes_gcm | aes_mt")
    ;
        CLI_PUT_N("            aes_nist (GCM+ECB KAT) | derive | kstore");
        CLI_PUT_N("            rng get  (driver command)");
        return false;
    }
    if (ca_strncmp(p, "crc32", 5) == 0)   { example_crc32();              return
     true; }
    if (ca_strncmp(p, "hash_mt", 7) == 0) { example_hash_multithread();   return
     true; }
```

```
    if (ca_strncmp(p, "hash", 4) == 0)    { example_hash_oneshot();        return true; }
    if (ca_strncmp(p, "aes_nist", 8) == 0) { EVAL_AES_GCM_SW_TEST((void)ca_aes_gcm_selftest(); (void)ca_aes_ecb_selftest();) return true; }
    if (ca_strncmp(p, "aes_gcm", 7) == 0) { example_aes_gcm();             return true; }
    if (ca_strncmp(p, "aes_mt", 6) == 0)  { example_aes_multithread();     return true; }
    if (ca_strncmp(p, "aes", 3) == 0 && (p[3] == 0 || p[3] == ' ')) { example_aes_ecb(); return true; }
    if (ca_strncmp(p, "derive", 6) == 0)  { example_key_derivation();      return true; }
    if (ca_strncmp(p, "kstore", 6) == 0)  { example_key_store();          return true; }
    if (ca_strncmp(p, "test", 4) == 0)    { run_all_tests();              return true; }
    if (ca_strncmp(p, "full", 4) == 0)    { example_full_demo();          return true; }
    return false;
}
```

Registration:

```
EVAL_CLI( ca_cli_register(&s_user_cli_node); )
```

6. Hardware RNG

The hardware RNG module generates true random numbers:

- `ca_rng_get()`: single 32-bit value
- `ca_rng_fill()`: fills buffer with random bytes
- Protected by mutex for concurrent access
- CLI: `rng get` automatically registered by `ca_rng_init()`

6. STDOUT Output Functions

STDOUT output functions have different behaviors:

Function	Adds trailing `\n`	Typical use
`ca_stdout_put_n()`	Yes	Complete messages
`ca_stdout_printf_n()`	Yes	Formatted string with newline
`ca_stdout_put()`	No	Messages without newline
`ca_stdout_printf()`	No	Formatted string without newline

Example:

```
/* Corretto: _n aggiunge newline automaticamente */
ca_stdout_put_n("=== CRC32 Example ===");
ca_stdout_printf_n("Buffer size: %u bytes", TEST_BUFFER_SIZE);

/* Corretto: senza _n, newline va specificato se serve */
ca_stdout_printf("\n%s (%u bytes):", label, len);  /* Solo \n iniziale */
ca_hexdump((u8*)data, lines);  /* hexdump gestisce il resto */
```

49.1.8 Summary

1. **CRC32**: checksum for data integrity; `crc32 calc <addr> <len>` via CLI driver
2. **HASH SHA-256**: one-shot and incremental with context swap

3. **AES-256**: ECB, CTR, GCM with context swap; automatic dispatch HW (CRYP/AES) or software; `aes_nist` = known-answer test of the active backend (GCM 4/4 + ECB 2/2), not round-trip
4. **RNG**: hardware random number generation; `rng get` via CLI driver
5. **Multithreading**: 2 threads synchronized with semaphore
6. **Key Derivation**: IV+KEY → SHA256 → 32-byte key
7. **Key-Store**: MPU + date-based validity; `ca_keys_store_set_expiry()` sets the window; `is_key_expired()` verifies and auto-locks; `kstore info/list` via CLI driver
8. **RTC-dependent validity**: if RTC is disabled or date is invalid, keys with validity are automatically locked (fail-secure)
9. **STDOUT**: use `_n` for automatic newline, without `_n` for manual control
10. **CLI chain of responsibility**: driver nodes (`crc32.c`, `rng.c`, `keys_store.c`) automatically registered at init; application node handles cryptographic commands; `help` propagates the entire chain

Chapter 50

DAC Output and ADC Readback (Polling and ISR)

50.1 Example 27 — DAC output and ADC readback (polling and ISR)

50.1.1 Introduction

This example demonstrates the combined use of the **DAC** and **ADC** on the Nucleo-H753ZI, connecting the DAC analog output directly to an ADC input via a simple hardware jumper.

The CLI commands are provided directly by the `dac.c` and `adc.c` drivers via the **chain of responsibility** — the example does not register any CLI handler of its own.

The coexistence of DAC, ADC, and USB CDC in the same system requires correct configuration of the ADC kernel clock, a topic covered in detail in the technical notes at the end of the chapter.

Hardware (Nucleo-H753ZI, MB1364)

Signal	MCU Pin	Nucleo Connector	Function
DAC CH1	PA4	CN7 pin 17 (D24)	Analog output
ADC1 CH10	PC0	CN9 pin 3 (A1)	Analog input

Required jumper:

```
CN7 pin 17 (PA4, DAC CH1)                    CN9 pin 3 (PC0, ADC1 CH10)
```

Without the jumper, the DAC works correctly (verifiable with a multimeter), but the ADC reads an indeterminate value.

Application CLI Commands

Command	Description
`test`	DAC→ADC sweep with readback, 5% full-scale tolerance (205 counts), final verdict
`info`	Expected jumper, DAC channel and ADC channel on this board
`wire`	Jumper continuity on pure GPIO, verdict `WIRE RESULT : OK|FAIL (n/1)`; must be run first

Command	Description
`adcmap`	**U575 only**, no wire: checks on silicon the ADC1 channel→pin map CH15=PB0, CH16=PB1, CH17=PB2. The pin is driven high/low as an output, then made analog: the charge left on the floating pad moves the reading only on the right channel (CH1-19 scan). Verdict `ADCMAP RESULT: PASS|FAIL`. CH13/14 (PC4/PC5) left out: they reach no Nucleo connector

Commands are registered **without prefix** (`test`, not `ex27 test`).

CLI Commands (`dac.c` driver)

Command	Description
`dac info`	Show active channels and current values
`dac set <1|2> <0-4095>`	Set DAC value (0 = 0 V, 4095 = 3.3 V)
`dac run <1|2>`	Start automatic sawtooth; needs `EN_SW_TIMER`, off in ex27: here it answers `dac run: requires EN_SW_TIMER=1`
`dac stop <1|2>`	Stop sawtooth and set to 0 V

CLI Commands (`adc.c` driver)

Command	Description
`adc info`	Show active ADCs, ISR mode, counters
`adc read <1..3> <ch>`	Single polling read
`adc volt <1..3> <ch>`	Polling read with output in Volts
`adc isr <1..3> <ch>`	Start continuous conversion via ISR
`adc stop <1..3>`	Stop ISR mode

STDOUT Log (every 5 s)

```
EX27: adc=NNNN  N.NNNv  tick=NNNNN
```

50.1.4 Detailed analysis

1. Configuration constants

```
#define ADC_NUM           1U        /* ADC1 */

#if MCU_ID == 575
#define DAC_CHANNEL       1U        /* DAC1_OUT1     PA4, CN7-17 */
#define ADC_CHANNEL       1U        /* CH1       PC0 = ADC12_INP1  (U575) */
#elif MCU_ID == 563
#define DAC_CHANNEL       2U        /* DAC1_OUT2     PA5, CN7-10 */
#define ADC_CHANNEL       10U       /* CH10      PC0 = ADC12_INP10 */
#else
#define DAC_CHANNEL       1U        /* DAC1_OUT1     PA4, CN7-17 */
#define ADC_CHANNEL       10U       /* CH10      PC0 = ADC12_INP10 (H7xx) */
#endif
/* each branch also defines DAC_TXT, ADC_TXT, WIRE_TXT and WIRE_OUT_PIN */

#define ADC_SAMPLE_TIME   4U        /* 64.5 cycles     good accuracy compromise
    */
#define VREF_MV           3300U     /* 3.3 V reference */
```

Channels and pins depend on the board, not on the family: on the U575 PC0 is channel 1 (CN9-11); on the H563 PA4 reaches only the morpho header, so DAC channel 2 on PA5 is used (CN7-10, D13). On the H753 (`#else` branch), ADC channel 10 corresponds to pin PC0 both in the GPIO driver mapping (`set_channel_gpio: ch >= 10` → `CA_GPIO_PORT_C`, pin `ch-10`) and in the hardware connection of ADC1/2 (ADC12_INP10 = PC0). This correspondence is the only one guaranteed for ADC1/2 on H753; other channels present misalignments between the driver mapping and the physical pinout.

2. Shared state

The example no longer has its own shared state — ISR and counter management is internal to the `adc.c` driver (`s_cli_isr_*` variables). The monitor task reads directly via `ca_adc_read()` every 5 seconds.

3. Raw → millivolt conversion

The conversion is inline in the monitor task:

```
u32 mv = ((u32)adc * VREF_MV) / 4095U;
```

The multiplicand is promoted to `u32` to avoid overflow ($4095 \times 3300 = 13\,513\,500$, which exceeds the range of `u16`).

4. Task monitor

```
static u32 task_monitor(void *arg)
{
    (void)arg;

    ca_os_sleep(2000);
    ca_stdout_put_n("EX27: " DAC_TXT);
    ca_stdout_put_n("      " ADC_TXT);
    ca_stdout_put_n("Jumper: " WIRE_TXT);
    ca_stdout_put_n("Commands: test | info | wire   (+ the driver's dac/adc)");

    while (1) {
        ca_os_sleep(5000);
        u16 adc = ca_adc_read(ADC_NUM, ADC_CHANNEL);
        u32 mv  = ((u32)adc * VREF_MV) / 4095U;
        ca_stdout_printf_n("EX27: adc=%u  %u.%03uV  tick=%u",
            (unsigned)adc, mv/1000U, mv%1000U, (unsigned)ca_os_tick_ms());
    }
    return 0;
}
```

The example's unique task. It reads ADC1 ch10 in polling mode every 5 seconds and prints the raw value and voltage. DAC and ADC ISR control is performed via the driver's CLI commands.

5. ca_os_configure

```
void ca_os_configure(void)
{
    /* DAC CH1: PA4 analog output */
    ca_dac_config_t dac_cfg = { DAC_CHANNEL };
    ca_dac_init(&dac_cfg);
    ca_dac_write(DAC_CHANNEL, 0U);

    /* ADC CH10: PC0 analog input */
    ca_adc_config_t adc_cfg = { ADC_NUM, ADC_SAMPLE_TIME };
    ca_adc_init(&adc_cfg);
    ca_adc_pin_init(ADC_NUM, ADC_CHANNEL);

    EVAL_STDOUT(
        ca_stdout_init();
        ca_stdout_set_sender(STDOUT);
        ca_stdout_create_thread();
    )
    EVAL_CLI(
        ca_cli_init(2048);
        ca_cli_set_sender(STDOUT);
        ca_cli_create_thread();
    )
    EVAL_USB_CDC_STD(ca_usb_dev_mng_cdc_cli();)
}
```

The order is significant: DAC and ADC must be initialized **before** USB CDC (technical note on ADC clock). `ca_dac_init()` and `ca_adc_init()` automatically register their CLI nodes in the chain of responsibility.

6. ca_os_main

```
void ca_os_main(void)
```

```
{
    ca_os_job("monitor", CA_TH_LEVEL3, task_monitor, NULL, STACK_SMALL, ...);
    ca_os_run(true);
}
```

A single task. No local CLI hook — commands arrive from the drivers.

Task	Priority	Function
`monitor`	CA_TH_LEVEL3	Periodic log every 5 s

50.1.5 Expected output

At startup

```
EX27: DAC  CH1  -> PA4  CN7-17 (D24)
      ADC1 CH10 <- PC0  CN9-3  (A1)
Jumper: PA4 CN7-17 (DAC out) ---- PC0 CN9-3  (ADC in)
Commands: test | info | wire   (+ the driver's dac/adc)
```

Typical test sequence

```
> dac set 1 2048
DAC1 = 2048  1.650 V

> adc read 1 10
ADC1 ch10 = 2041  1.644 V

> adc volt 1 10
ADC1 ch10 = 1.644 V (raw=2041)

> adc isr 1 10
ADC1 ch10 ISR started

EX27: adc=2041  1.644V  tick=5000
EX27: adc=2039  1.643V  tick=10000

> adc stop 1
ADC1 stopped  4092116 samples
```

Periodic log (every 5 s)

```
EX27: adc=2041  1.644V  tick=5000
```

50.1.6 ADC driver architecture — ISR mode

ISR API added to the `adc.c` driver

```
/* Type of the callback called by the IRQ handler */
typedef void (*ca_adc_isr_cb_t)(u8 adc_num, u16 value);

/* Initialize the ADC with ISR support and register the callback */
bool ca_adc_init_isr(const ca_adc_config_t *cfg, ca_adc_isr_cb_t cb);

/* Starts a single conversion in ISR mode */
void ca_adc_start_isr(u8 adc_num, u8 channel);

/* Called by the IRQ handler of the hardware family */
void ca_adc_irq_handler(u8 adc_num);
```

Full ISR mode flow

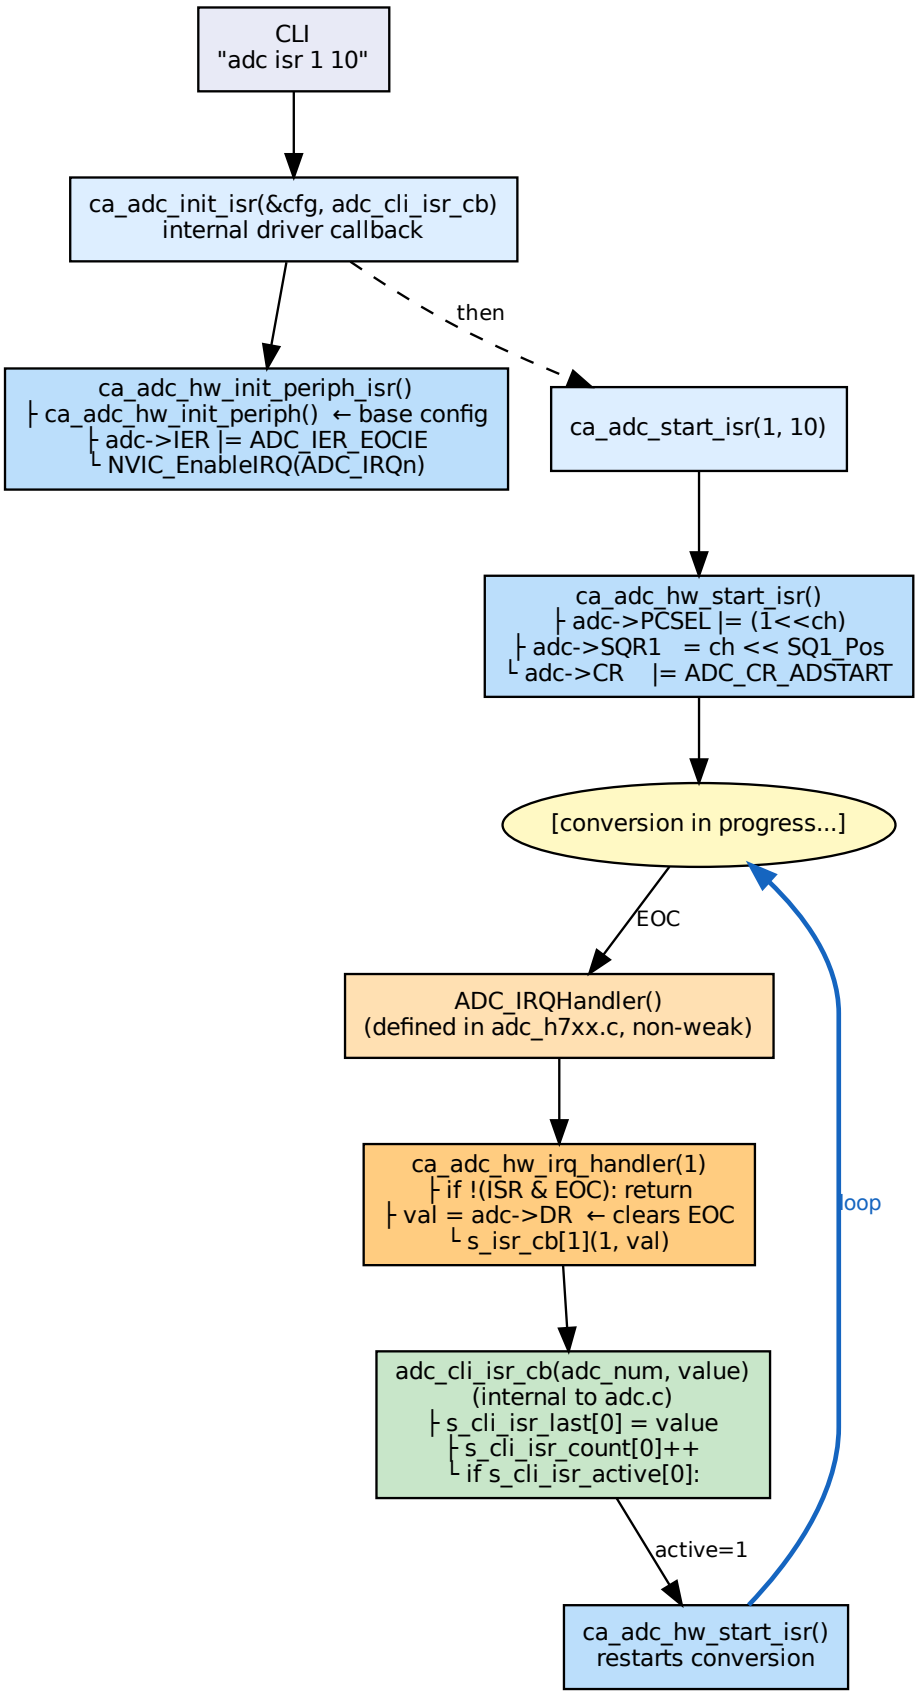

Figure 50.2: ADC ISR flow — init and loop

IRQ handlers by family

ADC IRQ handlers are protected by `#if EN_ADC`. On **F4xx/F7xx/H5xx** they are located in `hw/<famiglia>/common/handlers.c`; on **H7xx** they are defined directly in `hw/h7xx/drivers/adc_h7xx.c` (non-weak functions) to prevent the linker from using the `weak` handler of `handlers.c` (which would execute `CA_SAFE_FAIL`):

Family	IRQ handler	Source	Call
F1xx	`ADC1_2_IRQHandler`	`handlers.c`	`ca_adc_irq_handler(1)`
F4xx	`ADC_IRQHandler`	`handlers.c`	`ca_adc_irq_handler(1)`
F7xx	`ADC_IRQHandler`	`handlers.c`	`ca_adc_irq_handler(1)`
H5xx	`ADC1_IRQHandler`	`handlers.c`	`ca_adc_irq_handler(1)`
H5xx	`ADC2_IRQHandler`	`handlers.c`	`ca_adc_irq_handler(2)`
H7xx	`ADC_IRQHandler`	`adc_h7xx.c` (non-weak)	`ca_adc_hw_irq_handler(1)`
H7xx	`ADC3_IRQHandler`	`adc_h7xx.c` (non-weak)	`ca_adc_hw_irq_handler(3)`

50.1.7 Required configuration in `os_config.h`

```
#define EN_DAC         1     /* Driver DAC */
#define EN_ADC         1     /* Driver ADC */
#define ENABLE_CLI     1     /* CLI for user commands */
#define ENABLE_STDOUT  1     /* STDOUT for output */
```

To also enable USB CDC (alternative output to UART):

```
#define EN_USB_CDC     1
```

50.1.8 Technical notes

1. ADC kernel clock on H7xx — issue and solution

On STM32H7xx, the ADC kernel clock is selected by `RCC->D3CCIPR.ADCSEL` (it applies to ADC1, ADC2, and ADC3). The reset value `00` selects `pll2_p_ck`, which is not configured in the caOS `clock.c` (only PLL1 is started).

If the clock is not available, the calibration loop in the ADC init:

```
adc->CR |= ADC_CR_ADCAL;
while (adc->CR & ADC_CR_ADCAL) {}   /*     never ends */
```

never terminates, blocking the entire `ca_os_configure()`. Consequently, any peripheral initialized after the ADC (such as USB CDC) is never enabled.

Implemented solution in `hw/h7xx/drivers/adc_h7xx.c`, function `ca_clock_hw_adc_init()`:

```
/* D3CCIPR.ADCSEL = 10     per_ck (HSI 64 MHz, always available) */
RCC->D3CCIPR = (RCC->D3CCIPR & ~RCC_D3CCIPR_ADCSEL_Msk)
             | RCC_D3CCIPR_ADCSEL_1;

/* CKMODE=00 (async) + PRESC=0001 ( 2 )      ADC_CLK = 32 MHz      50 MHz      */
ADC_Common_TypeDef *cmn = (adc_num <= 2U) ? ADC12_COMMON : ADC3_COMMON;
cmn->CCR = (cmn->CCR & ~(ADC_CCR_CKMODE_Msk | ADC_CCR_PRESC_Msk))
         | ADC_CCR_PRESC_0;
```

With `per_ck = HSI = 64 MHz` (default at reset, always active) and divider `/2`, the resulting ADC clock is **32 MHz**, within the 50 MHz limit for the H753 @ VOS0.

```
HSI (64 MHz)              ADCSEL=per_ck              CCR PRESC= 2
    ADC_CLK = 32 MHz
```

2. Difference between DAC and ADC value

It is normal to observe a small difference between the value set on the DAC and the one read by the ADC:

- The DAC has 12-bit resolution over 3.3 V → 1 LSB 0.8 mV
- The ADC has 12-bit resolution over 3.3 V → 1 LSB 0.8 mV
- Both introduce an offset and non-linearity of a few LSBs

A difference of ±10 LSB (±8 mV) is typical and acceptable. The monitor task shows the raw ADC value; the comparison with the set DAC value is done via `dac info`.

3. Polling / ISR coexistence

The monitor task calls `ca_adc_read()` every 5 seconds (blocking polling). If ISR mode is active via CLI in the meantime (`adc isr 1 10`), the two modes use the same ADC: the monitor's single polling interferes with the ISR sequence. In practice, during an ISR test, one can stop the periodic log by increasing the period or simply read `adc volt 1 10` (which the driver handles by drawing from the last accumulated ISR value).

4. Pin PC0 as ADC12_INP10 channel

On STM32H7xx, the ADC channel mapping is not sequential with respect to the port pins. Channel 10 of ADC1/ADC2 physically corresponds to PC0 (ADC12_INP10), which is also pin A1 of the Nucleo-144 CN9 connector (the Arduino A1 equivalent).

The driver `adc_h7xx.c` automatically configures the pin in ANALOG mode with:

```
/* ch >= 10 && ch <= 15      CA_GPIO_PORT_C, pin (ch-10) */
ca_gpio_configure(CA_GPIO_PORT_C, (u8)(CA_GPIO_PIN_0 + (ch - 10)),
                  CA_GPIO_MODE_ANALOG, CA_GPIO_OTYPE_PP,
                  CA_GPIO_SPEED_LOW, CA_GPIO_NOPULL, 0);
```

For CH10: port C, pin 0 → PC0 .

5. ISR mode: cascaded one-shot

The ISR mode does not use the hardware automatic trigger (continuous mode) but implements a chain of single-shots. The internal callback in the `adc.c` driver immediately restarts the next conversion:

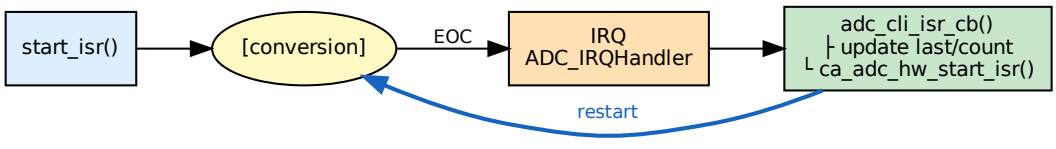

Figure 50.3: ISR mode — cascaded one-shot

This approach maximizes the sampling rate (270k samples/s on H753 at 32 MHz ADC_CLK) without requiring dedicated tasks or semaphores.

50.1.9 Summary

1. **DAC** — generates 0–3.3 V on PA4; configurable with `dac set 1 <0-4095>` (CLI driver)
2. **ADC polling** — blocking `ca_adc_read()`, `adc read 1 10` from CLI; monitor task every 5 s
3. **ADC ISR** — interrupt-driven cascaded one-shot, 270k sps; `adc isr 1 10` / `adc stop 1`
4. **ISR state in driver** — no dedicated task; `s_cli_isr_last/count` updated in IRQ
5. **H7xx IRQ fix** — non-weak `ADC_IRQHandler` in `adc_h7xx.c` (avoids SAFEGUARD FATAL)
6. **H7xx ADC clock** — `D3CCIPR.ADCSEL = per_ck`, `CCR PRESC=2` $\rightarrow$ 32 MHz essential
7. **Hardware jumper** — CN7 pin 17 (PA4) CN9 pin 3 (PC0) mandatory for loopback

Chapter 51

Real-Time Clock (Polling and ISR)

51.1 Example 28 — RTC: setting, reading, and alarms with callbacks

51.1.1 Introduction

This example demonstrates the use of the **Real Time Clock (RTC)**, showing the four main features of the caOS driver:

1. **Initialization** — clock source selection (LSI/LSE), date/time setting
2. **Reading** — acquisition of current date/time from a periodic task
3. **Alarms** — periodic Alarm A (every minute) and configurable one-shot Alarm B via CLI
4. **Calibration** — drift correction in ppm via the CALR register

The clock source depends on the board, and it is the only difference between the two:

board	32.768 kHz crystal	RTC clock	precision
NUCLEO-U575ZI-Q	mounted	`CA_RTC_CLK_LSE`	< 5 ppm
NUCLEO-H753ZI	absent (X2 not populated)	`CA_RTC_CLK_LSI`	$\pm 5\%$, temperature dependent

On the H753, the drift is therefore visible even over short periods; the `cal` command allows for partial compensation. The rest of the example is identical on both boards.

The output is transmitted via **UART** (`STDOUT_ON_UART`) and commands are sent using any serial terminal (e.g., minicom, PuTTY, screen).

Hardware

No additional connections: the RTC uses only internal resources.

Signal	Description
console UART	Board debug UART (ST-Link VCP)
RTC clock	LSE on U575, LSI on H753 — no external pin

No additional hardware connections are necessary: the RTC uses only internal resources.

CLI Commands (`rtc.c` driver)

Commands are handled directly by the driver via the CLI chain of responsibility.

Command	Description
`rtc info`	Read current date/time
`rtc set YYYY-MM-DD HH:MM:SS`	Set date/time
`rtc alarm <a|b> HH:MM:SS`	Set Alarm A or B to the specified time (one-shot)
`rtc cal <ppm>`	Calibrate RTC (e.g., `rtc cal -10`); range ±487 ppm
`rtc unix [<sec>]`	With value: set RTC from a Unix UTC time (`ca_rtc_from_net`); without: read it back (`ca_rtc_to_net`)
`help`	List commands (propagates to the chain)

STDOUT Log (every 5 s)

```
EX28: Ven 21 Mar 2026  12:00:05
```

The day of the week and the month are printed in Italian (Lun. . . Dom, Gen. . . Dic). Alarms produce additional messages when they trigger.

51.1.2 System architecture

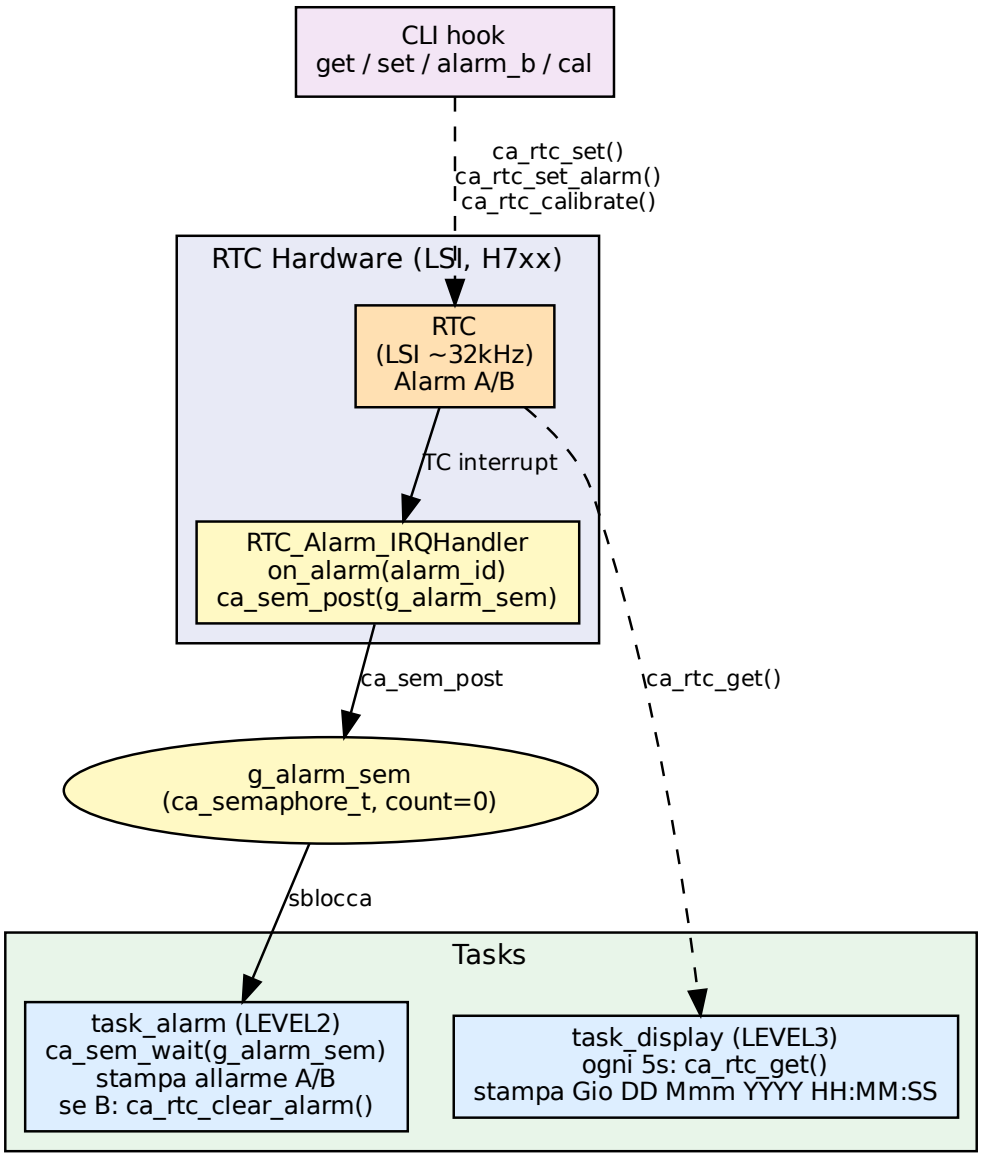

Figure 51.1: Architecture Example 28 — RTC

ISR → semaphore → task pattern: the `on_alarm()` callback is invoked directly by the `RTC_Alarm_IRQHandler` (H7xx) and only performs `ca_sem_post()`. The `task_alarm` task, awakened by the semaphore, performs all the processing (reading date/time, printing, optional disable Alarm B) outside the IRQ context.

51.1.3 Source code

The file is located in `examples/example_28/ca_os_ex28.c`:

```
// Proprietary     All rights reserved
// Copyright (c) 2026 Angelo Coppi

/*
 * Example 28     RTC: setting, reading, alarms with callbacks
 *
 * Hardware: NUCLEO-H753ZI and NUCLEO-U575ZI-Q
 * RTC Clock: CA_RTC_CLK_AUTO - the 32.768 kHz LSE crystal (every Nucleo-144
 *            carries one, H753ZI included) when it is found running at boot,
 *            else the LSI calibrated against the SysTick (less accurate,
 *            temperature-dependent: expect drift over long runs).
 *
 * Tasks:
 *   task_display      prints date/time every 5 seconds via STDOUT
 *   task_alarm        responds to alarm callbacks (via semaphore)
 *
 * Alarms:
 *   Alarm A     periodic: triggers every minute when seconds return to 0
 *   Alarm B     one-shot:  triggers at the time set via CLI, then disables
   itself
 *
 * CLI Commands (rtc.c driver):
 *   rtc info                          read current date/time
 *   rtc set YYYY-MM-DD HH:MM:SS       set date/time
 *   rtc alarm <a|b> HH:MM:SS          set alarm A or B
 *   rtc cal <ppm>                     calibrate RTC (e.g. rtc cal -10)
 *
 * STDOUT Log (every 5 s):
 *   EX28: Mon 21 Mar 2026  12:00:05
 *
 * REQUIREMENTS os_config.h:
 *   EN_RTC 1
 */

#include "caos.h"

#if EN_RTC
```

51.1.4 Detailed analysis

1. Configuration constants

```
#define INIT_YEAR   26u   /* 2026 */
#define INIT_MONTH   3u
#define INIT_DAY    21u
#define INIT_WDAY    5u   /* 1=Lun     7=Dom */
#define INIT_HOUR   12u
#define INIT_MIN     0u
#define INIT_SEC     0u
```

The initial date/time is set directly in the source code. In a real application, it should be saved in backup registers or retrieved from an external source. The year is stored as 2 digits (26 = 2026) as in the RTC BCD register.

2. Shared state

```
static ca_semaphore_t   g_alarm_sem;
static volatile u8   g_alarm_last = 0;
```

Only two variables shared between tasks and IRQs: - `g_alarm_sem` — semaphore initialized to 0; the ISR performs `post`, the task performs `wait` - `g_alarm_last` — ID of the last triggered alarm (`CA_RTC_ALARM_A` or `CA_RTC_ALARM_B`)

`g_alarm_last` is `volatile` because it is written by the IRQ and read by the task.

3. Helper: day and month names

```
static const char * const wday_str[]  = { "", "Lun", "Mar", "Mer",
                                          "Gio", "Ven", "Sab", "Dom" };
static const char * const month_str[] = { "", "Gen", "Feb", "Mar", "Apr",
                                          "Mag", "Giu", "Lug", "Ago",
                                          "Set", "Ott", "Nov", "Dic" };
```

Arrays are 1-indexed, with an empty string at position 0 as a guard against out-of-range values. `wday_str` uses the `dt.wday & 7u` index to limit access to [0..7]; `month_str` uses `dt.month <= 12u ? dt.month : 0u`.

4. Helper: `parse_u8`

```
static u32 parse_u8(const char **pp)
{
    const char *p = *pp;
    u32 v = 0;
    while (*p >= '0' && *p <= '9')
        v = v * 10u + (u32)(*p++ - '0');
    *pp = p;
    return v;
}
```

Parses a decimal number from the string pointed to by `*pp`, advancing the pointer beyond the consumed digits. Used by the `set` and `alarm_b` commands to extract HH, MM, SS, DD, MM, YY from a string with mixed separators (`:` and `/`).

5. Alarm callback

```
static void on_alarm(u8 alarm_id)
{
    g_alarm_last = alarm_id;
    ca_sem_post(&g_alarm_sem);
}
```

Invoked directly by the `RTC_Alarm_IRQHandler`. It must be very brief: it saves the alarm ID and performs a `post` on the semaphore. `ca_sem_post()` is ISR-safe in caOS (uses `BASEPRI` for the critical section, not `__disable_irq`).

6. Task display

```
static u32 task_display(void *arg)
{
    ca_rtc_dt_t dt;

    while (1) {
        if (ca_rtc_get(&dt)) {
            ca_stdout_printf_n("EX28: %s %02u %s 20%02u  %02u:%02u:%02u",
                wday_str[dt.wday & 7u],
                (unsigned)dt.day,
                month_str[dt.month <= 12u ? dt.month : 0u],
                (unsigned)dt.year,
                (unsigned)dt.hour, (unsigned)dt.min, (unsigned)dt.sec);
        } else {
            ca_stdout_put_n("EX28: RTC read error");
        }
        ca_os_sleep(5000);
```

```
    }
    return 0;
}
```

Simple loop: every 5 seconds it reads the date/time and prints it with readable names. `ca_rtc_get()` returns `false` only if the RTC is not synchronized (RSF/INITS flags not set), a condition that should not occur after `ca_rtc_set()`.

7. Task alarm

```
static u32 task_alarm(void *arg)
{
    ca_rtc_dt_t dt;

    while (1) {
        ca_sem_wait(&g_alarm_sem);

        u8 id = g_alarm_last;
        ca_rtc_get(&dt);

        if (id == CA_RTC_ALARM_A) {
            ca_stdout_printf_n("*** ALARM A ***  %02u:%02u:%02u  (every minute)"
    ,
                (unsigned)dt.hour, (unsigned)dt.min, (unsigned)dt.sec);
        } else {
            ca_stdout_printf_n("*** ALARM B ***  %02u:%02u:%02u  (one-shot,
    disabled)",
                (unsigned)dt.hour, (unsigned)dt.min, (unsigned)dt.sec);
            ca_rtc_clear_alarm(CA_RTC_ALARM_B);
        }
    }
    return 0;
}
```

The task remains blocked on `ca_sem_wait()` until an alarm triggers. Upon receiving the signal:
- **Alarm A**: prints the event; the alarm remains active (it will trigger again at the next minute)
- **Alarm B**: prints the event and calls `ca_rtc_clear_alarm()` to disable it

Reading `id` before `ca_rtc_get()` ensures that the timestamp is consistent with the alarm even if two alarms trigger in rapid succession.

8. `rtc.c` driver CLI

The RTC commands are implemented directly in the driver via the CLI **chain of responsibility**. The example does not register any custom CLI handler: `ca_rtc_init()` automatically registers the driver's CLI node.

```
ca_rtc_dt_t dt = { .year=26, .month=4, .day=21, .hour=12, .min=0, .sec=0, .wday
    =1 };
ca_rtc_set(&dt);
```

The parsing in the driver uses `ca_strtol()` on year-month-day and hour-minute-second. `dt.wday` is set to 1 as a placeholder — the RTC does not automatically calculate the day of the week.

```
ca_rtc_alarm_t al = {
    .sec = s, .min = m, .hour = h, .day = 0,
    .match_sec = true, .match_min = true, .match_hour = true, .match_day = false
};
```

```
ca_rtc_set_alarm(alarm_id, &al, rtc_cli_alarm_cb);
```

With all hour/min/sec masks at `true` and `match_day = false`, the alarm triggers when the time matches HH:MM:SS regardless of the day. The driver's default callback prints `RTC Alarm ON!`.

```
ca_rtc_calibrate(ppm);
```

Use `ca_strtol()` to parse a signed integer. Range ±487 ppm (~0.954 ppm/step resolution).

9. ca_os_configure

```
void ca_os_configure(void)
{

    EVAL_STDOUT(
        ca_stdout_init();
        ca_stdout_set_sender(STDOUT);
        ca_stdout_create_thread();
    )
    EVAL_CLI(
        ca_cli_init(2048);
        ca_cli_set_sender(STDOUT);
        ca_cli_create_thread();
    )
    EVAL_USB_CDC_STD(ca_usb_dev_mng_cdc_cli();)

    /* LSE if the 32.768 kHz crystal is found running, else LSI */
    ca_rtc_init(CA_RTC_CLK_AUTO);

    /* Set initial date/time */
    ca_rtc_dt_t dt = {
        .sec   = INIT_SEC,   .min   = INIT_MIN,   .hour  = INIT_HOUR,
        .wday  = INIT_WDAY,  .day   = INIT_DAY,
        .month = INIT_MONTH, .year  = INIT_YEAR
    };
    ca_rtc_set(&dt);

    /* Alarm A     periodic: every minute (match only seconds == 0) */
    ca_rtc_alarm_t alarm_a = {
        .sec        = 0,
        .match_sec  = true,
        .match_min  = false,
        .match_hour = false,
        .match_day  = false,
    };
    ca_rtc_set_alarm(CA_RTC_ALARM_A, &alarm_a, on_alarm);

    /* Semaphore for alarm callbacks */
    ca_sem_init(&g_alarm_sem,"EX28_S1", 0, 8);
}

void ca_os_main(void)
{
    ca_os_job("display", CA_TH_LEVEL3, task_display, NULL, STACK_SMALL,
    CA_JOB_STD, CA_FAULT_RESTART_THREAD);
    ca_os_job("alarm",   CA_TH_LEVEL2, task_alarm,   NULL, STACK_SMALL,
    CA_JOB_STD, CA_FAULT_RESTART_THREAD);

    ca_os_run(true);
```

```
}
```

The order is significant: 1. `ca_rtc_init(CA_RTC_CLK_AUTO)` probes the LSE crystal: if it oscillates, it uses it, otherwise it falls back to the (calibrated) LSI and resets the backup domain 2. `ca_rtc_set()` loads the initial date/time 3. `ca_rtc_set_alarm()` configures Alarm A **before** creating the tasks 4. `ca_sem_init()` with name `"EX28_S1"`, count=0 (blocking) and max=8 (buffer for alarm bursts) 5. tasks `display` and `alarm` are created in `ca_os_main()`, after the configuration

The tasks are created with `CA_FAULT_RESTART_THREAD` for automatic recovery in case of an exception.

51.1.5 Tasks and priorities

Task	Priority	Function
`display`	CA_TH_LEVEL3	Print date/time every 5 s
`alarm`	CA_TH_LEVEL2	Alarm semaphore consumer (high relative priority)

`task_alarm` has a higher priority than `task_display` to ensure that the alarm message is printed immediately when the semaphore is signaled, without waiting for the display task sleep.

51.1.6 Expected output

At startup

```
EX28: Ven 21 Mar 2026  12:00:05
EX28: Ven 21 Mar 2026  12:00:10
EX28: Ven 21 Mar 2026  12:00:15
...
```

`rtc info`

```
RTC  2026-03-21  12:00:42
```

`rtc set 2026-03-22 14:30:00`

```
RTC set 2026-03-22 14:30:00
```

`rtc alarm b 14:31:00`

```
rtc alarm B set 14:31:00
```

When the alarm triggers:

```
RTC Alarm ON!
*** ALARM B ***  14:31:00  (one-shot, disabled)
```

Alarm A (every minute)

```
*** ALARM A ***  14:32:00  (every minute)
*** ALARM A ***  14:33:00  (every minute)
```

cal -20

```
Calibrazione: -20 ppm applicata.
```

Typical test sequence

```
> rtc info

51.1.7 RTC driver architecture

Public API (caos/drivers/inc/rtc.h)

```c
/* Clock source */
typedef enum { CA_RTC_CLK_LSE = 1, CA_RTC_CLK_LSI, CA_RTC_CLK_HSE }
    ca_rtc_clk_src_t;

/* Date/time */
typedef struct {
    u8 sec, min, hour;    /* 0-59, 0-59, 0-23 */
    u8 wday;              /* 1= L u n 7 =Dom       */
    u8 day, month;        /* 1-31, 1-12        */
    u8 year;              /* 0-99 (offset 2000)*/
} ca_rtc_dt_t;

/* Alarm structure */
typedef struct {
    u8   sec, min, hour, day;
    bool match_sec, match_min, match_hour, match_day;
} ca_rtc_alarm_t;

typedef void (*ca_rtc_alarm_cb_t)(u8 alarm_id);

```

```
/* Alarm constants */
#define CA_RTC_ALARM_A   1u
#define CA_RTC_ALARM_B   2u

/* API */
bool ca_rtc_init(ca_rtc_clk_src_t src);
bool ca_rtc_set(const ca_rtc_dt_t *dt);
bool ca_rtc_get(ca_rtc_dt_t *dt);
bool ca_rtc_calibrate(i32 ppm);
bool ca_rtc_set_alarm(u8 alarm_id, const ca_rtc_alarm_t *al, ca_rtc_alarm_cb_t
    cb);
bool ca_rtc_clear_alarm(u8 alarm_id);
```

IRQ → semaphore → task flow

```
RTC_Alarm_IRQHandler()        [hw/h7xx/common/rtc_h7xx.c]
         ISR & ALRAF?      chiama g_alarm_cb[0](CA_RTC_ALARM_A)
                               on_alarm(CA_RTC_ALARM_A)
                                     g_alarm_last = CA_RTC_ALARM_A
                                     ca_sem_post(&g_alarm_sem)

         ISR & ALRBF?      chiama g_alarm_cb[1](CA_RTC_ALARM_B)
                             on_alarm(CA_RTC_ALARM_B)
                                   g_alarm_last = CA_RTC_ALARM_B
                                   ca_sem_post(&g_alarm_sem)

task_alarm (risvegliato da sem_wait)
         legge g_alarm_last e ca_rtc_get()
         prints the alarm message
         se Alarm B: ca_rtc_clear_alarm(CA_RTC_ALARM_B)
```

ALRMAR register configuration (Alarm A — every minute)

```
ALRMAR bits:
  MSK4 [31]   = 1      ignora giorno
  MSK3 [23]   = 1      ignore hours
  MSK2 [15]   = 1      ignora minuti
  MSK1 [ 7]   = 0      confronta secondi
  ST   [6:4] = 0       secondi decine BCD = 0
  SU   [3:0] = 0       secondi unit  BCD = 0
```

With all masks set to 1 except MSK1, the alarm triggers every time the seconds are 0 — that is, at the beginning of every minute, regardless of the hour and day.

Calibration — CALR register

The RTC CALR register (common to F4/F7/H5/H7) allows for correcting the RTC clock frequency within a range of ±487 ppm:

```
CALP [15]    = 1      adds 512 pulses every 32 s  (+15.9 ppm)
CALM [8:0]   = N      subtracts N pulses every 32 s     (step ~0.954 ppm)
```

The `ca_rtc_calibrate(ppm)` driver automatically calculates CALP and CALM from the value in ppm:

requested ppm	CALP	CALM	actual ppm
0	0	0	0.000
-10	0	10	-9.537
+5	1	11	+5.126
-487	0	511	-487.137
+15	1	0	+15.954

51.1.8 Technical notes

1. LSI vs LSE — depends on the board

It is not true that "there is no crystal on Nucleo boards": it depends on the board, and that is the only reason why this example has a `#if MCU_ID` block. The NUCLEO-H753ZI (MB1364) does not mount the X2 footprint (32.768 kHz), the **NUCLEO-U575ZI-Q does**. The driver supports both sources:

Source	Frequency	Precision	PRER (async/sync)	Notes
LSE	32.768 kHz	<5 ppm	127/255	External crystal — **present on U575ZI-Q**
LSI	~32 kHz	±5%	127/249	Internal, always available — used on H753ZI
HSE/128	configurable	same as HSE	variable	Rare, for special applications

With LSI and `PRER = (127, 249)`, the resulting frequency is:

```
f_RTC = 32000 / (128    250) = 1.000 Hz (ideale)
```

In practice, the LSI varies between ~28 and ~34 kHz depending on the temperature and the chip batch, causing an accumulated drift of several seconds per day. The `cal` command allows for partial compensation of this drift.

2. Differences between families — RTC registers

The caOS driver abstracts the differences between families through the implementations in `hw/<family>/common/rtc_<family>.c`:

Family	Init/status reg	Alarm status	Alarm clear	IRQ handler	EXTI line 17
F4xx	`RTC->ISR`	`ISR.ALRAF`	`ISR &= ~flag`	`RTC_Alarm_IRQHandler`	`EXTI->IMR/RTSR`
F7xx	`RTC->ISR`	`ISR.ALRAF`	`ISR &= ~flag`	`RTC_Alarm_IRQHandler`	`EXTI->IMR/RTSR`
H7xx	`RTC->ISR`	`ISR.ALRAF`	`ISR &= ~flag`	`RTC_Alarm_IRQHandler`	`EXTI_D1->IMR1 / EXTI->RTSR1`
H5xx	`RTC->ICSR`	`RTC->SR`	`RTC->SCR`	`RTC_IRQHandler`	Not necessary (direct IRQ)

The most relevant differences: - **H5xx**: uses `RTC->ICSR` (Init Control/Status Register) instead of `RTC->ISR`; alarm clearing is performed by writing to the write-only register `RTC->SCR` - **H7xx**:

requires `EXTI_D1->IMR1` (CPU1 domain) instead of the simple `EXTI->IMR` - **F4/F7**: use `PWR->CR |= PWR_CR_DBP` to unlock the backup domain; H7 uses `PWR->CR1 |= PWR_CR1_DBP`; H5 uses `PWR->DBPCR |= PWR_DBPCR_DBP`

3. RTC Write Protection (Write Protection Register)

Before any write to the RTC registers (PRER, TR, DR, ALRMAR, ALRMBR, CALR), it is necessary to disable the hardware protection with the sequence:

```
RTC->WPR = 0xCA;   /* key 1 */
RTC->WPR = 0x53;   /* key 2 */
/* ... register writes ... */
RTC->WPR = 0xFF;   /* re-enable protection */
```

An error in the sequence leaves the register protected and the write is silently ignored. The driver handles this protection internally.

4. INIT mode

Modifying TR, DR, and PRER requires entering INIT mode:

```
RTC->ISR |= RTC_ISR_INIT;              /* request INIT */
while (!(RTC->ISR & RTC_ISR_INITF)) {} /* wait for INITF */
/* ... write PRER, TR, DR ... */
RTC->ISR &= ~RTC_ISR_INIT;            /* leave INIT */
```

In INIT mode, the RTC counter stops; upon completion, it resumes from the set value. Synchronization with the calendar is immediate.

5. Alarm B one-shot — behavior upon restart

Alarm B is configured via CLI and is not saved in backup registers. If the board is restarted after setting Alarm B but before it triggers, the alarm is lost. In a real-world application, the configuration should be saved in one of the 4 RTC backup registers (RTC->BKPxR) and restored at startup.

51.1.9 Required configuration in `os_config.h`

```
#define EN_RTC          1    /* Driver RTC */
#define EN_CLI_RTC      1    /* Driver 'rtc *' commands */
#define ENABLE_CLI      1    /* CLI for user commands */
#define ENABLE_STDOUT   1    /* STDOUT for output */
#define STDOUT_ON_UART  1    /* Console on UART, not on USB CDC */
#define STDIN_ON_UART   1
```

The example is conditioned by the `EN_RTC` flag:

```
#if EN_RTC
/* ... all the example code ... */
#else /* EN_RTC == 0 */

/* Pre-scheduler diagnostic: ca_stdout_* needs a task context (TLB=NULL before
 * ca_os_run), so print straight to the console backend with PUT_N. */
PRIVATE_STRING(m28a, "=== Example 28 ===");
PRIVATE_STRING(m28b, "EN_RTC == 0, skipping RTC example");
void ca_os_configure(void)
```

```
{
    /* The line the bench matches to know this example cannot run on
       this part. The reason follows it. */
    CA_EXAMPLE_UNSUPPORTED();
    PUT_N(&priv_m28a);
    PUT_N(&priv_m28b);
}
void ca_os_main(void) { ca_os_run(true); }

#endif /* EN_RTC */
```

51.1.10 Summary

1. **Initialization** — `ca_rtc_init()` with the board source (LSE on U575, LSI on H753) resets the backup domain and sets the prescalers for 1 Hz
2. **Set date/time** — `ca_rtc_set(&dt)` enters INIT mode, writes TR/DR in BCD, exits
3. **Get date/time** — `ca_rtc_get(&dt)` reads TR/DR and converts from BCD; waits for RSF if necessary
4. **Periodic Alarm A** — match only on seconds (=0): triggers at the beginning of every minute
5. **One-shot Alarm B** — match on HH:MM:SS; the task disables it via `ca_rtc_clear_alarm()` after the first trigger
6. **ISR→sem→task pattern** — the callback is minimal (post semaphore); all processing occurs in the task
7. **Calibration** — `ca_rtc_calibrate(ppm)` writes CALR; range ±487 ppm; useful for compensating LSI drift
8. **H5/H7/F4/F7 differences** — completely hidden in the hardware-specific implementation

Chapter 52

SPI Master and Slave (Polling and ISR)

52.1 Example 29 — SPI master-slave on the same MCU

52.1.1 Introduction

This example demonstrates the caOS **SPI** driver on a NUCLEO-H753ZI with two SPI peripherals on the same MCU connected via wires: **SPI1 as master** and **SPI3 as slave**. The example covers three operating modes:

1. **Loopback** (`EN_SPI_LOOPBACK`) — verifies the master in isolation with a single MOSI→MISO wire
2. **Polling** (`EN_SPI_EX_POLL`) — master and slave on separate tasks, handshake via volatile flags
3. **IRQ** — the slave accumulates bytes in interrupt and calls a callback upon frame completion

Hardware (NUCLEO-H753ZI, MB1364)

SPI	SCK Pin	MISO Pin	MOSI Pin	Bus	Role
SPI1	PA5 (CN7-10)	PA6 (CN7-12)	PB5 (CN7-14)	APB2	Master
SPI3	PC10 (CN7-1)	PC11 (CN7-5)	PC12 (CN7-3)	APB1L	Slave

PB5 Note: PA7 is shared with RMII_CRS_DV (Ethernet, SB31 ON on H753ZI) and is not available. PB5 is used as an alternative MOSI for SPI1 (AF5, CN7-14).

Wiring for polling/IRQ mode (3 wires):

```
PA5 (CN7-10) SCK              PC10 (CN7-1)  SCK  SPI3
PB5 (CN7-14) MOSI             PC12 (CN7-3)  MOSI SPI3
PA6 (CN7-12) MISO             PC11 (CN7-5)  MISO SPI3
```

Wiring for loopback test (1 wire):

```
PB5 (CN7-14) MOSI             PA6 (CN7-12) MISO   (adiacenti su CN7)
```

NSS software on both peripherals (SSM=1): no CS pin required.

52.1.2 Source configuration

The three modes are selected with `#define` at the top of the file `examples/example_29/ca_os_ex29.c`:

```
/* Uncomment to switch to polling mode */
/* #define EN_SPI_EX_POLL */

/* Define for the master loopback test: PB5(MOSI)     PA6(MISO). */
/* #define EN_SPI_LOOPBACK */
```

These are **example-local** macros, not `os_config.h` flags: they are enabled by uncommenting them in the source code. In the file, both are commented out, so the default mode is **IRQ**.

Active define	Mode	Tasks started
`EN_SPI_LOOPBACK`	Loopback master	only `task_master`
`EN_SPI_EX_POLL`	Polling master+slave	`task_master` + `task_slave_poll`
none (default)	IRQ slave callback	only `task_master` + SPI3 ISR

In `os_config.h` it is necessary to:

```
#define EN_SPI    1
```

52.1.3 System architecture

Polling mode

```
task_master                          task_slave_poll

      g_slave_ready = false
                                  g_slave_ready = true
                                  ca_spi_read_buf(SPI3, ...)      blocca
      while (!g_slave_ready) yield()
      ca_spi_write_buf(SPI1, g_tx_buf, 8)
                8    ca_spi_xfer(SPI1, byte)
                      SCK genera clock     SPI3 riceve
                                              ritorna con 8 byte
                                  g_slave_ready = false
                                  verifica pattern
      ca_os_sleep(500)            ca_os_sleep(200)
```

IRQ Mode

```
task_master                          SPI3_IRQHandler

      ca_spi_write_buf(SPI1, g_tx_buf, N)
                N    ca_spi_xfer                  RXPIE     byte     s_rx_buf
                                               s_rx_count == frame_size?
                                                 slave_irq_cb(num, buf, len)
      ca_os_sleep(1000)                              verifica + stampa
```

52.1.4 Source code

The file is located in `examples/example_29/ca_os_ex29.c`.

1. Configuration constants

```
#define POLL_FRAME_SIZE    8U          /* 8 bytes: fits the H7 FIFO (16 bytes) */
#define IRQ_FRAME_SIZE     SPI_DEF_PKT_SIZE   /* 128 byte */
#define MASTER_SPI         1U          /* SPI1 */
#define SLAVE_SPI          3U          /* SPI3 */
```

`POLL_FRAME_SIZE` is intentionally small: the H753 has a 16-byte TX FIFO, so 8 bytes fit entirely into the FIFO before the master stalls waiting for TXP. In this way, byte-level synchronization between master and slave is not required.

2. Shared state

```
/* Polling mode only */
static volatile bool g_slave_ready = false;
static u8 g_rx_poll[POLL_FRAME_SIZE];

/* Loopback mode only */
static u8 g_rx_loopback[POLL_FRAME_SIZE];

static u8 g_tx_buf[SPI_DEF_PKT_SIZE];  /* buffer TX master */
```

The `g_slave_ready` flag is `volatile` because it is written by the slave task and read by the master task without explicit synchronization mechanisms. The correct sequence is: the slave sets the flag **before** entering `ca_spi_read_buf`; the master waits for the flag with `ca_os_yield()` before calling `ca_spi_write_buf`.

3. Slave IRQ callback

```
static void slave_irq_cb(u8 spi_num, const u8 *data, u16 len)
{
    u16 errors = 0U;
    for (u16 i = 0; i < len; i++)
        if (data[i] != (u8)(i & 0xFFU)) errors++;
    g_frame_count++;
    if (errors == 0U)
        ca_stdout_printf_n("EX29 IRQ: frame %u OK (%u byte)", ...);
    else
        ca_stdout_printf_n("EX29 IRQ: frame %u ERRORS=%u", ...);
}
```

The callback is invoked by the SPI3 IRQ handler after accumulating `frame_size` bytes in the driver's internal buffer. Execution occurs in an IRQ context: it must be brief and non-blocking.

4. Master task — loopback mode

```
#ifdef EN_SPI_LOOPBACK
    while (1) {
        u8 errors = 0U;
        for (u8 i = 0; i < POLL_FRAME_SIZE; i++) {
            u8 rx = ca_spi_xfer(MASTER_SPI, i);
            g_rx_loopback[i] = rx;
            if (rx != i) errors++;
        }
        frame++;
        if (errors == 0U)
            ca_stdout_printf_n("EX29 LOOPBACK: frame %u OK", (unsigned)frame);
        else
            ca_stdout_printf_n("EX29 LOOPBACK: frame %u ERR=%u", ...);
        ca_os_sleep(500);
    }
```

In loopback, `ca_spi_xfer` sends the byte `i` on MOSI (PB5) and reads the byte received on MISO (PA6). With the wire PB5→PA6, the received byte is identical to the transmitted one: `rx == i` for all bytes.

5. Master task — polling mode

```
#elif defined(EN_SPI_EX_POLL)
    while (1) {
        while (!g_slave_ready)
            ca_os_yield();          /* yields the CPU until the slave is ready
    */

        for (u8 i = 0; i < POLL_FRAME_SIZE; i++)
            g_tx_buf[i] = i;

        ca_spi_write_buf(MASTER_SPI, g_tx_buf, POLL_FRAME_SIZE);
        frame++;
        ca_stdout_printf_n("EX29 POLL M: frame %u TX OK", (unsigned)frame);
        ca_os_sleep(500);
    }
```

6. Task slave polling

```
    while (1) {
        g_slave_ready = true;                                   /* signal ready */
        ca_spi_read_buf(SLAVE_SPI, g_rx_poll, POLL_FRAME_SIZE); /* blocca */
        g_slave_ready = false;

        u8 errors = 0U;
        for (u8 i = 0; i < POLL_FRAME_SIZE; i++)
            if (g_rx_poll[i] != i) errors++;
        frame++;
        if (errors == 0U)
            ca_stdout_printf_n("EX29 POLL S: frame %u OK", ...);
        else
            ca_stdout_printf_n("EX29 POLL S: frame %u ERR=%u", ...);
        ca_os_sleep(200);
    }
```

7. ca_os_configure

```
void ca_os_configure(void)
{
    /* ... stdout, log, cli, usb ... */

    /* Init SPI1     MASTER (no external CS: software NSS) */
    ca_spi_config_t m_cfg = {
        .spi_num    = MASTER_SPI,
        .br         = CA_SPI_BR_DIV64,   /* APB2/64     1.87 MHz su H753 @480MHz
     */
        .cpol       = 0, .cpha = 0,
        .master     = true,
        .frame_size = 0, .on_rx = NULL,
        .manage_cs  = false,          /* CS not managed: slave always selected (
    SSM=1) */
    };
    ca_spi_init(&m_cfg);

#ifndef EN_SPI_LOOPBACK
    /* Init SPI3     SLAVE */
    ca_spi_config_t s_cfg = {
        .spi_num    = SLAVE_SPI,
        .br         = 0,              /* slave: baud ignored */
        .cpol       = 0, .cpha = 0,
        .master     = false,
```

```
        .manage_cs  = false,
#ifdef EN_SPI_EX_POLL
        .frame_size = POLL_FRAME_SIZE,
        .on_rx      = NULL,           /* polling */
#else
        .frame_size = IRQ_FRAME_SIZE,
        .on_rx      = slave_irq_cb,   /* IRQ */
#endif
    };
    ca_spi_init(&s_cfg);
#endif
}
```

In loopback mode, SPI3 is not initialized. In IRQ mode, passing `on_rx != NULL` automatically enables `RXPIE` and the NVIC in the driver.

52.1.5 Technical notes — MODF on STM32H7 SPI v3

The STM32H7 uses version 3 of the SPI controller (CFG1/CFG2 registers, separate TXDR/RXDR, endless mode TSIZE=0). This peripheral exhibits critical behavior regarding the **MODF (Mode Fault)**:

Cause

In master mode with SSM=1, MODF is triggered when SSI=0. It can be generated by a previous run that left the flag dirty in the SR register, or by a race condition during peripheral reinitialization.

Effect

MODF clears **both** `CR1.SPE` **and** `CFG2.MASTER`. If not handled before the master/slave dispatch in the driver, the `ca_spi_hw_xfer` function reads `CFG2.MASTER == 0` and enters the slave branch, where it hangs waiting for `SPI_SR_RXP` which will never arrive (deadlock).

Solution implemented in caOS

```
/* ca_spi_hw_xfer     spi_h7xx.c / spi_h5xx.c */

/* 1. MODF recovery BEFORE the master/slave dispatch */
if ((spi->SR & SPI_SR_MODF) || !(spi->CR1 & SPI_CR1_SPE)) {
    (void)spi->SR;               /* step 1: read SR (unlock) */
    spi->IFCR  = (1U << 9U);   /* step 2: clear MODFC      */
    spi->CFG2 |= SPI_CFG2_MASTER; /* step 3: restore MASTER */
    spi->CR1   = SPI_CR1_SSI | SPI_CR1_SPE;
}

/* 2. Master/slave dispatch after the recovery */
if (spi->CFG2 & SPI_CFG2_MASTER) {
    spi->CR1 |= SPI_CR1_CSTART;  /* avvia burst (non settato in init) */
    /* ... TXP wait     write TXDR     RXP wait con SPE check ... */
}
```

CSTART is not set during init: it is set in every call to `ca_spi_hw_xfer`. This prevents the peripheral in endless mode from generating MODF during the idle period between frames (master task sleep).

MODF-clear procedure in init (H7/H5)

```
spi->CR1 = 0;
(void)spi->SR;              /* step 1 */
spi->IFCR = (1U << 9U);  /* step 2: MODFC */
spi->CFG1 = ...;
spi->CFG2 = SPI_CFG2_MASTER | SPI_CFG2_SSM | ...;  /* step 3 */
spi->CR2  = 0;
spi->CR1  = SPI_CR1_SSI | SPI_CR1_SPE;   /* no CSTART */
```

Differences by family

Family	SPI ver	MODF effect	Recovery
F1/F4xx	v1 (DR/SR)	clears only SPE	simple: SPE=1
F7xx	v2 (CR2 DS+FRXTH)	clears only SPE	simple: SPE=1
H5/H7xx	v3 (CFG1/CFG2)	clears SPE **and** MASTER	read SR + IFCR.MODFC + write CFG2

52.1.6 Expected output

Loopback (`EN_SPI_LOOPBACK` + wire PB5→PA6)

```
EX29 LOOPBACK: frame 1 OK
EX29 LOOPBACK: frame 2 OK
EX29 LOOPBACK: frame 3 OK
```

Polling (`EN_SPI_EX_POLL` + 3 wires)

```
EX29 POLL M: frame 1 TX OK
EX29 POLL S: frame 1 OK
EX29 POLL M: frame 2 TX OK
EX29 POLL S: frame 2 OK
```

IRQ (no define + 3 wires)

```
EX29 IRQ: frame 1 OK (128 byte)
EX29 IRQ M: frame 1 TX OK
EX29 IRQ: frame 2 OK (128 byte)
EX29 IRQ M: frame 2 TX OK
```

52.1.7 CLI Commands

```
ex29 wire       continuity of the 3 jumpers (SCK, MOSI, MISO), verdict WIRE
    RESULT : OK|FAIL (n/3)
ex29 info       the three links expected on this board and the LED pin
```

`wire` first **parks** the SPI tasks (waits ~1.2 s for them to finish their cycle) and stops the two peripherals, then tests each line on pure GPIO, driving it from the side that drives it during normal operation: master → slave for SCK and MOSI, slave → master for MISO. Driving the same side always resulted in a MISO FAIL with the wires connected correctly (two drivers on the same line). If the peripheral does not stop, `wire` reports it (`WARNING: spi_stop ...`) instead of making it look like a missing wire. At the end, the pins remain GPIO, so the board **restarts itself** after 2.5 s.

A heartbeat task blinks **LED 1** (pin from `objmap.h`), on a port already used by the example: if it blinks, the port clock, GPIO, and scheduler are working, and a `wire` FAIL concerns the pins, not the GPIO.

52.1.8 Tasks and priorities

Task	Priority	Mode	Function
`master`	CA_TH_LEVEL3	all	Sends SPI frame
`slave`	CA_TH_LEVEL3	polling	Receives and verifies frame
—	ISR SPI3	IRQ	Accumulates bytes + callback

In polling mode, master and slave have the same priority: the `g_slave_ready` + `ca_os_yield()` mechanism ensures that the slave enters reception before the master starts transmitting.

52.1.9 SPI APIs used

```
/* Inizializzazione */
bool ca_spi_init(const ca_spi_config_t *cfg);

/* CS manuale (no-op se manage_cs == false) */
void ca_spi_cs_assert(u8 spi_num);
void ca_spi_cs_deassert(u8 spi_num);

/* Trasferimento singolo byte full-duplex */
u8 ca_spi_xfer(u8 spi_num, u8 data);

/* Invio buffer (scarta RX) */
u16 ca_spi_write_buf(u8 spi_num, const u8 *buf, u16 len);  /* bytes sent; < len
    on timeout */

/* Ricezione buffer polling (invia 0x00) */
u16 ca_spi_read_buf(u8 spi_num, u8 *buf, u16 len);   /* bytes received; < len on
     timeout */

/* Called by the IRQ handler (slave IRQ mode) */
void ca_spi_recv_handler(u8 spi_num);
```

52.1.10 Required configuration in `os_config.h`

```
#define EN_SPI    1    /* Driver SPI */
```

The example is conditioned by `EN_SPI`:

```
#if EN_SPI
/* ... all the code ... */
#else
void ca_os_configure(void) {}
void ca_os_main(void) { ca_os_run(true); }
#endif
```

52.1.11 Summary

1. **Loopback** — a PB5→PA6 wire verifies the master in isolation; `ca_spi_xfer` returns the sent byte
2. **Polling** — `g_slave_ready` handshake ensures the slave is waiting before the master transmits

3. **IRQ** — `on_rx != NULL` in `ca_spi_config_t` automatically enables RXPIE and NVIC; the callback receives complete frames
4. **MODF H7/H5** — recovery before master/slave dispatch; per-xfer CSTART avoids idle MODF
5. **Non-DMA Pattern** — suitable for frames up to ~32 bytes at reduced baud rate; for large frames or high clock speeds, consider DMA

Chapter 53

EXTI: Interrupt from the User Button

53.1 Example 30 — EXTI: interrupt from user button

53.1.1 Introduction

This example demonstrates the caOS **EXTI** driver on NUCLEO-H753ZI. The goal is to handle the **B1** user button press via interrupt on the RISING edge, showing the interaction between ISR, tasks, and CLI.

The example adopts a **progressive debugging** strategy:

1. At startup, EXTI is disabled: first, it is verified that GPIO polling reads the button correctly
2. The `exti_on` command from CLI enables the interrupt
3. The ISR callback filters bounces and counts presses; `task_monitor` reports them

Hardware (NUCLEO-H753ZI, MB1364)

Signal	MCU Pin	Connector	Description
B1 USER	PC13	—	Blue button, external pull-down, press = HIGH
LED1 (green)	PB0	—	Toggle on every press via EXTI
LED2 (yellow)	PE1	—	Toggle every 5 presses
LED3 (red)	PB14	—	Heartbeat 500 ms

The LEDs are driven with `ca_led_toggle(1..3)`: the pins come from `objmap.h` of the board, not from the example. The button changes with the board (`BTN_TXT`): PC13 on H753 and U575, PA0 (WK_UP) on the F407.

> **Polarity note**: the B1 button on the Nucleo-H753ZI has an external pull-down resistor. At rest PC13=0; when pressed PC13=1. The interrupt is configured on **RISING edge**.

53.1.2 Required configuration in `os_config.h`

```
#define EN_EXTI       1    /* Driver EXTI */
#define ENABLE_CLI    1    /* Comando exti_on / exti_off / btn */
#define EN_TAMP       1    /* Tamper sullo stesso pulsante (solo versione a
    pagamento) */
#define EN_RTC        1    /* Clock dell'RTC: serve al tamper su F446, F767, H753
    */
```

With `EN_TAMP = 0` (FREE package) the example is the usual one: the `tamper` commands are not compiled.

53.1.3 System architecture

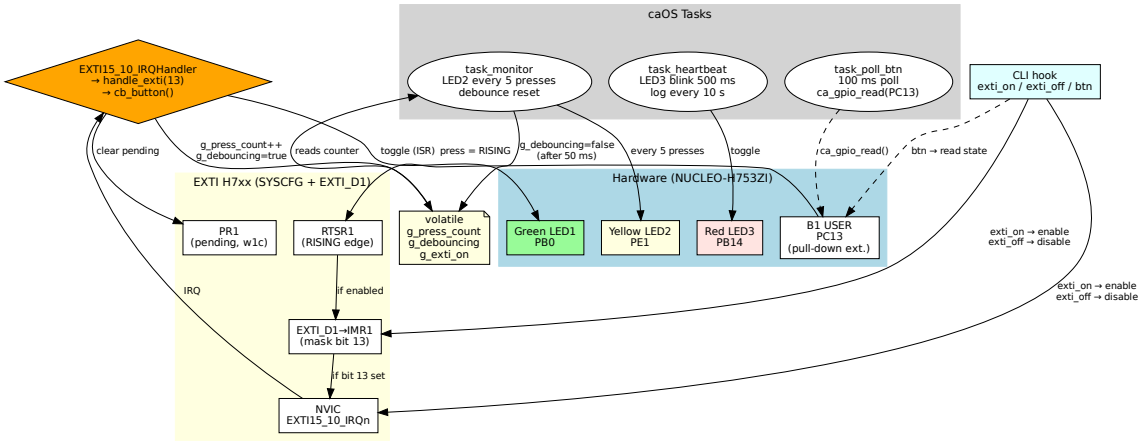

Figure 53.1: Example architecture 30

The flow consists of three levels:

```
B1 (PC13)        RISING       > EXTI15_10_IRQHandler     cb_button()
                                   scarta l'impulso se < DEBOUNCE_MS dall'
    ultimo (ISR)
                                   ca_led_toggle(1)
       (ISR)
                                   g_press_count++
       (ISR)

task_poll_btn         100ms       > init LED/B1/EXTI, poi ca_gpio_read(B1)     log
     cambi stato
task_monitor            10ms        > legge g_press_count, ogni 5 press
    ca_led_toggle(2)
task_heartbeat        500ms       > ca_led_toggle(3) + log ogni 10 s

nodo CLI             exti_on       ca_exti_enable(BTN_PIN)  (IMR + NVIC)
                     exti_off      ca_exti_disable(BTN_PIN)
                     btn           ca_gpio_read(B1) + stampa
```

53.1.4 Software debounce

Debouncing is performed in the callback, **by timestamp**: an edge arriving less than `DEBOUNCE_MS` (50 ms) after the last accepted one is discarded. The window starts from the pulse itself, without a flag that a task must then reset.

```
press                                                              rimbalzi <
    50 ms dal primo fronte: scartati

B1

                       g_last_edge_ms = now   (ISR, fronte accettato)
```

The previous version raised a flag and left the task of resetting it after 50 ms to `task_monitor`; however, the task checks every 10 ms, so the window started late and ended early. Longer bounces were counted as actual presses: on the H563, a single press registered two or three.

Why not use `ca_exti_disable()` for debouncing? `ca_exti_disable()` also disables the NVIC, and the subsequent `ca_exti_enable()` must re-enable both the IMR and the NVIC. The time comparison in the callback is simpler and does not touch the hardware.

53.1.5 Source code

The file is located in `examples/example_30/ca_os_ex30.c`.

1. Constants and shared state

```
#define DEBOUNCE_MS     50U
#define LED2_THRESHOLD  5U

static volatile u32  g_press_count = 0U;
static volatile u32  g_last_edge_ms = (u32)0 - DEBOUNCE_MS;
static volatile bool g_exti_on     = false;   /* EXTI enabled? */
static volatile bool g_hw_ready    = false;
```

Variables shared between ISRs and tasks are `volatile`. A mutex is not needed: the counter is only incremented by the ISR and only read by tasks. `g_last_edge_ms` starts a window in the past, so the first press is accepted immediately. `g_hw_ready` raises it `task_poll_btn` when the button, LED, and EXTI line are ready: other tasks touch the LEDs and wait for it, because the task creation order does not guarantee the execution order.

2. EXTI Callback (ISR context)

```
static void cb_button(void)
{
    /* Debounce by timestamp, not by a flag another task has to clear: the
     * bounce window is measured from THIS edge. The previous version raised a
     * flag and let task_monitor clear it DEBOUNCE_MS after it noticed - and it
     * only looks every 10 ms, so the window started late and closed early.
     * Contact bounces outliving it were counted as real presses: on the H563
     * a single press could log two or three. */
    u32 now = ca_os_tick_ms();

    if ((u32)(now - g_last_edge_ms) < DEBOUNCE_MS)
        return;                 /* still inside the bounce window */

    g_last_edge_ms = now;
    ca_led_toggle(1U);
    g_press_count++;
}
```

The callback is invoked by `EXTI15_10_IRQHandler` via the driver dispatch. It must be brief: no blocking or sleep calls.

3. CLI Node — user commands

```
static bool user_cli_handler(c_str *pcmd)
{
    const char *p = ca_skip_sp((*pcmd)->data);
    if (ca_strncmp(p, "help", 4) == 0) {
        CLI_PUT_N("exti_on | exti_off | btn");
        return false;
    }
```

```
    if (ca_strncmp(p, "exti_on", 7) == 0) {
        /* task_poll_btn owns the EXTI setup: enabling the line before it ran
         * would arm a callback the driver has not configured yet. */
        if (!g_hw_ready) {
            CLI_PUT_N("EX30: hardware not ready yet, retry in a moment");
            return true;
        }
        g_last_edge_ms = ca_os_tick_ms() - DEBOUNCE_MS;  /* accept the next edge */
        ca_exti_enable(BTN_PIN);
        g_exti_on = true;
        CLI_PUT_N("EX30: EXTI enabled (RISING edge on the B1 pin)");
        return true;
    }
    if (ca_strncmp(p, "exti_off", 8) == 0) {
        ca_exti_disable(BTN_PIN);
        g_exti_on = false;
        CLI_PUT_N("EX30: EXTI disabled");
        return true;
    }
    if (ca_strncmp(p, "btn", 3) == 0) {
        u32 v = ca_gpio_read(BTN_PORT, BTN_PIN);
        CLI_PRINTF_N("EX30: " BTN_TXT "=%u (%s)", v, v ? "HIGH(pressed)" : "LOW(released)");
        return true;
    }
    return false;
}
static ca_cli_node_t s_user_cli_node = { user_cli_handler, NULL };
```

The handler returns `true` if it has handled the command, `false` to pass it to the next node. On `help` it adds its own line and returns `false`, so the chain continues. `exti_on` refuses to start until `task_poll_btn` has configured the line: enabling it beforehand would arm a callback that the driver has not yet set.

4. GPIO polling task (and hardware init)

```
static u32 task_poll_btn(void *arg)
{
    (void)arg;

    u32 prev = 2U;   // impossible value     force log on first cycle

    /* Hardware init lives here rather than in ca_os_configure: with a task
     * context ca_stdout_* works, so the setup and the messages that describe it
     * stay together. LEDs come from objmap.h through the driver. */
    ca_led_init();

    /* B1: input, no internal pull - the board provides the network.
     * On the U575 the button pin must NEVER be driven as OUTPUT/LOW: UM2861
     * warns it shorts the button network. Input is what we want anyway. */
    ca_gpio_configure(BTN_PORT, BTN_PIN,
                      CA_GPIO_MODE_INPUT, CA_GPIO_OTYPE_PP,
                      CA_GPIO_SPEED_LOW, CA_GPIO_NOPULL, 0U);

    /* RISING edge, but the line starts DISABLED: phase 1 is polling only. */
    ca_exti_init(BTN_PORT, BTN_PIN, CA_EXTI_EDGE_RISING, cb_button);
    ca_exti_disable(BTN_PIN);
    g_exti_on = false;

    g_hw_ready = true;

```

```
    /* Let ca_os_banner() finish first: it is a task too, at CA_TH_LEVEL6, and it
     * paces itself with sleeps to let the UART drain. This task runs at LEVEL3
     * and would otherwise print straight through the middle of it. The hardware
     * above is already up, so the other tasks are not held back by this wait.
     */
    ca_os_sleep(1000);

    ca_stdout_printf_n("EX30: started - EXTI OFF");

    /* Phase 1 is only half the example: polling proves the pin is read, it says
     * nothing about the EXTI path. Say so out loud, because a run that stops
     * here looks like a pass - it is how the EXTICR field-width bug survived a
     * "passed" record on the U575 (see the driver comment in exti_u5xx.c). */
    ca_stdout_printf_n("EX30: polling active on " BTN_TXT
                       " - type 'exti_on' to enable the EXTI interrupt");

    while (1) {
        u32 cur = ca_gpio_read(BTN_PORT, BTN_PIN);
        if (cur != prev) {
            prev = cur;
            if (cur == 1U)
                ca_stdout_printf_n("EX30 POLL: B1 PRESSED  (" BTN_TXT "=1)");
            else
                ca_stdout_printf_n("EX30 POLL: B1 RELEASED (" BTN_TXT "=0)");
        }
        ca_os_sleep(100);
    }
    return 0;
}
```

Hardware initialization is here and not in `ca_os_configure()`: in a task `ca_stdout_*` it works, so the configuration and the messages describing it remain together. Then the task reads the pin every 100 ms, independently of the EXTI: it is used to verify the pin before enabling the interrupt. Polling alone, however, does not test the EXTI path, and the startup message explicitly states this.

5. Task monitor — LED2 threshold

```
static u32 task_monitor(void *arg)
{
    (void)arg;

    u32 last_count = 0U;
    u32 led2_group = 0U;

    while (!g_hw_ready) ca_os_sleep(10);

    while (1) {
        u32 cur = g_press_count;
        if (cur != last_count) {
            u32 delta = cur - last_count;
            last_count = cur;
            ca_stdout_printf_n("EX30 EXTI: total presses=%u (delta=%u)",
                               (unsigned)cur, (unsigned)delta);

            u32 grp = cur / LED2_THRESHOLD;
            if (grp != led2_group) {
                led2_group = grp;
                ca_led_toggle(2U);
                ca_stdout_printf_n("EX30: LED2 toggle (group %u)", (unsigned)grp
    );
```

```
            }
        }
        ca_os_sleep(10);
    }
    return 0;
}
```

The task sleeps for 10 ms per cycle; the debounce no longer concerns it, as it is entirely handled in the callback.

6. ca_os_configure and ca_os_main

```
void ca_os_configure(void)
{
    EVAL_STDOUT(
        ca_stdout_init();
        ca_stdout_set_sender(STDOUT);
        ca_stdout_create_thread();
    )
    EVAL_CLI(
        ca_cli_init(4096);
        ca_cli_set_sender(STDOUT);
        ca_cli_create_thread();
        ca_cli_register(&s_user_cli_node);
    )

    EVAL_USB_CDC_STD(ca_usb_dev_mng_cdc_cli();)

    /* The button, the LEDs and the EXTI line are set up by task_poll_btn, not
     * here: this hook runs before ca_os_run, where ca_stdout_* has no task
     * context and refuses to print. Doing the init inside the task keeps the
     * hardware setup next to the messages that describe it. */
}

void ca_os_main(void)
{

    ca_os_job("poll_btn",   CA_TH_LEVEL3, task_poll_btn,   NULL,
              STACK_MEDIUM, CA_JOB_STD, CA_FAULT_RESTART_THREAD);

    ca_os_job("monitor",    CA_TH_LEVEL3, task_monitor,    NULL,
              STACK_MEDIUM, CA_JOB_STD, CA_FAULT_RESTART_THREAD);

    ca_os_job("heartbeat",  CA_TH_LEVEL3, task_heartbeat,  NULL,
              STACK_MEDIUM, CA_JOB_STD, CA_FAULT_RESTART_THREAD);

    ca_os_run(true);
}
```

`ca_exti_init` (called in `task_poll_btn`) configures SYSCFG, RTSR1, IMR and NVIC; the subsequent `ca_exti_disable` disables IMR and NVIC, leaving the configuration ready.

53.1.6 Technical notes

EXTI on STM32H7xx

On STM32H7 (dual-core), the interrupt mask for the M7 core is located in `EXTI_D1->IMR1` (not in `EXTI->IMR1`). The source selection uses `SYSCFG->EXTICR[3]` (pin 13 → register 3, bits [7:4]):

```
/* pin=13     reg=3, shift=4 */
SYSCFG->EXTICR[3] = (SYSCFG->EXTICR[3] & ~0xF0U) | ((u32)CA_GPIO_PORT_C << 4U);
```

The pending register `EXTI->PR1` is cleared by writing 1 to the corresponding bit (write-1-to-clear). The pending status is read **before** calling the callback to avoid double dispatching on fast bounces.

`ca_exti_enable` — IMR and NVIC

The function `ca_exti_enable` re-enables both IMR and NVIC, because `ca_exti_disable` disables them both:

```
void ca_exti_enable(u8 pin)
{
    if (pin < 16U) {
        ca_exti_hw_imr_enable(pin);    /* EXTI_D1->IMR1 |= bit */
        ca_exti_hw_nvic_enable(pin);   /* NVIC_EnableIRQ */
    }
}
```

> **Warning**: in previous versions of the driver `ca_exti_enable` only re-enabled IMR, leaving the NVIC disabled. The fix was introduced in `caos/drivers/src/exti.c` along with this example.

EXTI15_10 pin sharing

Pins 10–15 share `EXTI15_10_IRQn`. The handler loops through all pins in the group and calls `ca_exti_dispatch(p)` only if the pending bit is active:

```
void EXTI15_10_IRQHandler(void)
{
    for (u8 p = 10U; p <= 15U; p++) handle_exti(p);
}
```

The central dispatcher in `exti.c` calls the registered callback for the pin:

```
void ca_exti_dispatch(u8 pin)
{
    if (pin < 16U && callbacks[pin])
        callbacks[pin]();
}
```

53.1.7 Expected output

Phase 1 — polling (EXTI disabled)

```
EX30: started - EXTI OFF
EX30: polling active on PC13 - type 'exti_on' to enable the EXTI interrupt
EX30 POLL: B1 PRESSED  (PC13=1)
EX30 POLL: B1 RELEASED (PC13=0)
EX30: uptime=10s  press=0  exti=OFF
```

Phase 2 — EXTI enabled via CLI

```
exti_on
EX30: EXTI enabled (RISING edge on the B1 pin)
EX30 EXTI: total presses=1 (delta=1)
EX30 POLL: B1 PRESSED  (PC13=1)
EX30 POLL: B1 RELEASED (PC13=0)
EX30 EXTI: total presses=2 (delta=1)
...
EX30 EXTI: total presses=5 (delta=1)
EX30: LED2 toggle (group 1)
```

53.1.8 Tamper on the same button (`EN_TAMP`)

The B1 pin, PC13, is also **tamper 1** on all five Nucleo boards. With `EN_TAMP` the example adds the `tamper` command, which arms the tamper on the same button and verifies what the hardware erases (Backup SRAM and tamper).

Command	What it does
`tamper arm`	writes a pattern in the backup registers, in the first 256 bytes of the backup SRAM and in the secret area (first 64 words and last word), then arms the tamper
`tamper check`	number of events, status of each area (`erased`, `kept`, `MIXED`) against the family expectation, verdict
`tamper off`	disarms

The expectation by family: registers always erased; backup SRAM erased on U575, H563 and H753, **preserved** on F446 and F767; secret area (SRAM2) erased on U575 and H563, absent on the others.

```
c.a.O.S > tamper arm
EX30 TAMPER ARMED: 32 regs, 2048 B backup SRAM, 64 KB secret - press B1
   (pressione di B1)
c.a.O.S > tamper check
EX30 TAMPER events=1
EX30 TAMPER backup registers: erased (want erased)
EX30 TAMPER backup SRAM: erased (want erased)
EX30 TAMPER secret area 64 KB at 0x20030000: erased (want erased)
EX30 TAMPER CHECK PASS
```

(U575 output). The fact that the CLI responds after the tamper is already a verification: on the U575 and H563, the erased SRAM2 is outside the heap, and caOS continues to run.

Bench: the `test_homo_ex30` class has a sixth phase, `tamper_erases_backup_domain`, which arms the tamper, asks the operator to press B1, and expects `TAMPER CHECK PASS`. Passed on all five boards on 10/24/2026.

53.1.9 Tasks and priorities

Task	Priority	Period	Function
`poll_btn`	CA_TH_LEVEL3	100 ms	Hardware init, then button GPIO polling
`monitor`	CA_TH_LEVEL3	10 ms	Press count + LED2 threshold
`heartbeat`	CA_TH_LEVEL3	500 ms	Blink LED3 + log
—	ISR EXTI15_10	on-demand	Debounce, toggle LED1 + counter

53.1.10 EXTI API used

```c
/* Inizializzazione: configura SYSCFG, edge, IMR, NVIC e registra callback */
bool ca_exti_init(u8 port, u8 pin, ca_exti_edge_t edge, ca_exti_cb_t cb);

/* Abilita interrupt (IMR + NVIC) */
void ca_exti_enable(u8 pin);

/* Disabilita interrupt (IMR + NVIC) */
void ca_exti_disable(u8 pin);
```

```
#if EN_TAMP
/* Tamper 1 sul pin di B1 (PC13), fronte di salita, modo confermato:
 * l'hardware cancella, poi cb gira nell'interrupt */
bool ca_exti_tamper_enable(ca_exti_cb_t cb);
void ca_exti_tamper_disable(void);
#endif
```

```
/* Edge selezionabile */
typedef enum {
    CA_EXTI_EDGE_RISING  = 0,
    CA_EXTI_EDGE_FALLING = 1,
    CA_EXTI_EDGE_BOTH    = 2,
} ca_exti_edge_t;
```

53.1.11 Summary

1. **Polling first, EXTI later** — the GPIO polling phase allows verifying the correct pin configuration before enabling the interrupt
2. **Debounce for timestamp in ISR** — the window starts from the edge itself; a flag cleared by a task caused it to start late and allowed bounces to pass through
3. `ca_exti_enable` **re-enables NVIC** — fix introduced in this example: `ca_exti_enable` must re-enable both IMR and NVIC to function after a `ca_exti_disable`
4. **CLI node** — `ca_cli_register()` adds a node to the CLI chain; the handler returns `true` if it handled the command, `false` to pass it on
5. **EXTI_D1 on H7xx** — use `EXTI_D1->IMR1` (CPU1/M7), not `EXTI->IMR1`

Chapter 54

DMA: Memory-to-Memory and Memory-to-Peripheral (DAC1)

54.1 Example 31 — DMA: memory-to-memory and memory-to-peripheral (DAC1)

54.1.1 Introduction

This example demonstrates the caOS **DMA** driver on NUCLEO-H753ZI and NUCLEO-U575ZI-Q, with two distinct operating modes:

1. **M2M (Memory-to-Memory)**: copying a buffer from SRAM to SRAM, with content verification.
2. **M2P (Memory-to-Peripheral)**: writing a 12-bit sine table to `DAC1->DHR12R1` via DMA, producing an analog wave on **PA4**.

The two transfers use **independent DMA channels** dynamically allocated via `ca_dma_free_channel()`. The NVIC for each channel is automatically enabled upon allocation and disabled upon release.

Hardware — two boards

The two pins do not coincide: the LED is the only difference between the boards.

Signal	H753 (MB1364)	U575 (MB1549)	Description
LED3 (red)	PB14	**PG2**	Heartbeat 1 Hz
DAC1_OUT1	PA4	PA4	Sine analog output ~1.56 Hz (0–3.3 V)

The code selects the pin with a `#if MCU_ID == 575` block. **PB14 is not an LED on the U575** (LD1 PC7, LD2 PB7, LD3 PG2): as long as the block was missing, the board ran correctly but with the heartbeat invisible — and the tests looked at the console, not the board.

> **Verification**: connect an oscilloscope or voltmeter to **PA4** (CN10 pin 17 on Nucleo-H753ZI) to observe the sine wave.

54.1.2 Configuration required in `os_config.h`

```
#define EN_DMA        1    /* Driver DMA */
#define EN_DAC        1    /* Driver DAC */
#define EN_CLI_DMA    1    /* dma info */
#define ENABLE_CLI    1
```

54.1.3 CLI Commands

Command	Description
`dma info`	Total channels, in-use bitmask, list of allocated channels

Typical output with the two channels allocated from the example:

```
dma: total=24  in_use=0x00000003
  flat=0  DMA1_s0  in-use
  flat=1  DMA1_s1  in-use
```

Channel `flat=0` is allocated by `task_dma_m2m`, channel `flat=1` by `task_dma_dac`.

54.1.4 System architecture

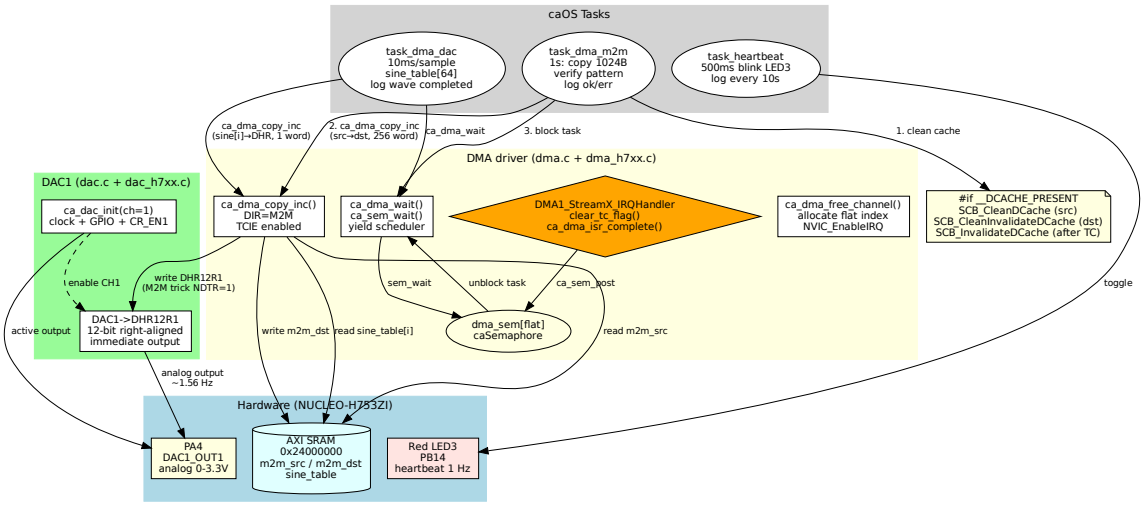

Figure 54.1: Example architecture 31

DMA M2M flow

```
ca_os_configure()
              ca_dma_init()           inizializza semafori e bitmask
              ca_dac_init(ch=1)       clock APB1L + PA4 analog + DAC_CR_EN1

task_dma_m2m:
    1. ca_dma_free_channel()    alloca flat index, NVIC_EnableIRQ automatico
    2. [every 1 s]
       __DSB()                  retires the writes before the DMA reads
       ca_dma_copy_inc(ch, src, dst, 256, CA_DMA_WIDTH_32)
       ca_dma_wait(ch, ms)      blocca task     yield scheduler
       checks the pattern     logs ok/errors
```

DMA M2P Flow (DAC)

```
task_dma_dac:
    1. ca_dma_free_channel()    canale separato da M2M
    2. SCB_CleanDCache(sine_table)  once at startup
```

```
    3. [every 10 ms, for 64 samples]
       ca_dma_copy_inc(ch, &sine_table[i], &DAC1->DHR12R1, 1, CA_DMA_WIDTH_32)
       ca_dma_wait(ch, ms)
       i = (i+1) % 64
       se i==0: logga "onda #N completata"

DAC1->DHR12R1           PA4 (output analogico immediato, no trigger)
```

ISR → semaphore mechanism

```
DMA trasferimento completo

              DMA1_StreamX_IRQHandler()   [definito in dma_h7xx.c, non-weak]
            clear_tc_flag(flat)
            ca_dma_isr_complete(controller, stream)
                         ca_sem_post(&dma_sem[flat])
                                 sblocca task in ca_dma_wait()
```

The task remains suspended (zero CPU) for the entire duration of the transfer. The scheduler executes other tasks in the meantime.

54.1.5 Source code

The file is located in `examples/example_31/ca_os_ex31.c`.

1. DMA buffer — cache alignment

```
#define BUF_WORDS    256U
#define CACHE_LINE   32U    /* Cortex-M7: cache line = 32 byte */

__attribute__((aligned(CACHE_LINE))) static u32 m2m_src[BUF_WORDS];
__attribute__((aligned(CACHE_LINE))) static u32 m2m_dst[BUF_WORDS];

__attribute__((aligned(CACHE_LINE))) static u32 sine_table[64] = { ... };
```

The buffers are declared `static` (they go into BSS → AXI SRAM at `0x24000000` on the H753, SRAM1 at `0x20000000` on the U575), accessible by the DMA. The 32-byte alignment is maintained as a precautionary measure — it is the cache line granularity of the Cortex-M7 — so that the buffers remain suitable for cache maintenance should the D-cache be enabled in the future.

> **Why not in TCM?** On STM32H7xx, the ITCM (`0x00000000`) and DTCM (`0x20000000`) regions are accessible only by the CPU, not by the DMA. The driver verifies this with `CA_SAFEGUARD` in `dma_h7xx.c`.

2. M2M Task — copy and verify

```
static u32 task_dma_m2m(void *arg)
{
    ca_dma_ch_t ch;
    i16 idx = ca_dma_free_channel(&ch);   /* allocate + NVIC_EnableIRQ */

    /* pattern fisso in src */
    for (u32 i = 0U; i < BUF_WORDS; i++)
        m2m_src[i] = (i * 0x55AA0011U) ^ 0xDEADBEEFU;

    while (1) {
        /* clear dst */
        ...

```

```
        __DSB();   /* no cache maintenance: D-cache off */

        ca_dma_copy_inc(ch, m2m_src, m2m_dst, BUF_WORDS, CA_DMA_WIDTH_32);
        ca_dma_wait(ch, 100U);   /* block     yield     wake-up from ISR */

        /* verifica */
        u32 errs = 0U;
        for (u32 i = 0U; i < BUF_WORDS; i++)
            if (m2m_dst[i] != m2m_src[i]) errs++;

        if (errs == 0U)
            ca_stdout_printf_n("EX31 M2M: ok #%u (1024B)", m2m_ok_count++);
        else
            ca_stdout_printf_n("EX31 M2M: ERRORS=%u  #%u", errs, m2m_err_count
    ++);

        ca_os_sleep(1000);
    }
}
```

3. Task M2P — Sine DAC

```
static u32 task_dma_dac(void *arg)
{
    ca_dma_ch_t ch;
    i16 idx = ca_dma_free_channel(&ch);   /* channel other than M2M */

    __DSB();   /* sine_table is read-only from here on */

    u32 si = 0U, waves = 0U;

    while (1) {
        /* M2M NDTR=1 trick: writes 1 word from SRAM to the DAC register */
        ca_dma_copy_inc(ch,
                        (const void *)&sine_table[si],
                        (void *)&DAC1->DHR12R1,
                        1U, CA_DMA_WIDTH_32);
        ca_dma_wait(ch, 100U);

        si++;
        if (si >= SINE_SAMPLES) {
            si = 0U;
            waves++;
            ca_stdout_printf_n("EX31 DAC: wave #%u done", waves);
        }
        ca_os_sleep(10);   /* 10 ms/sample     640 ms period */
    }
}
```

4. ca_os_configure

```
void ca_os_configure(void)
{
    /* ... stdout, log, cli ... */

    ca_dma_init();                                    /* semaphores + DMA clock
    */
    ca_dac_init(&(ca_dac_config_t){ .channel = 1 }); /* APB1L + PA4 + CR_EN1 */
}
```

54.1.6 Technical notes

DMA M2M trick for peripheral register access

The `ca_dma_copy_inc` driver uses **DIR=M2M** (bit 10 of `DMA_SxCR`), which does not require a DREQ handshake from the peripheral and does not need DMAMUX configuration. With `NDTR =1`, a single word is transferred from the source address to the destination address — in this case `&DAC1->DHR12R1` — treated as a normal memory address.

With `NDTR=1`, the `PINC` flag (destination increment) is irrelevant since only one transfer is performed.

```
M2M con NDTR=1:
  PAR  = &sine_table[i]        sorgente (SRAM)
  M0AR = &DAC1->DHR12R1        destinazione (APB1, trattato come memoria)
  NDTR = 1
  DIR  = 10 (M2M)
      1 trasferimento da 32 bit
  DAC1->DHR12R1 = sine_table[i]
      DAC CH1 (no trigger, TEN=0)
  PA4 = (sine_table[i] / 4096.0)    3.3V
```

Cache coherence: why it is not needed here

The STM32H753 **has** a 16KB data D-cache, but **caOS leaves it off**: in the entire `hw/h7xx/` there is not a single call to `SCB_EnableDCache()`. With the cache disabled, the CPU and DMA see the same physical RAM and there is no incoherence to resolve — a simple `__DSB()` is enough to flush pending writes before arming the transfer.

Calling `SCB_CleanDCache_by_Addr()` with the cache off **is not useless: it is harmful**. It is a write to `SCB->DCCMVAC` with the cache disabled, which is undefined behavior on the Cortex-M7, and on the H753 it produces an **IMPRECISERR BusFault**. This is exactly the defect removed by `eth_h7xx.c` (ETH bug of 08/19) and even earlier by `sdio_h7xx.c`: this example was the last point in the project that still did it.

> **The trap was the guard.** The calls were protected by `#if __DCACHE_PRESENT`, which seems like the right condition but is not: that macro says that the **core possesses** a cache, not that it is **on**. On the H753 it was 1 and the block was compiled anyway. The correct condition cannot be expressed at compile time with CMSIS — it depends on a system choice of the project.

On the U575, the issue does not arise at all: the Cortex-M33 has no D-cache.

If one day the D-cache were to be turned on on the H7, maintenance must be reintroduced **together** with that choice, in three points: `Clean` on `src` before the DMA reads, `CleanInvalidate` on `dst` before it writes, `Invalidate` on `dst` after. The 32-byte alignment of the buffers is already prepared for this.

Automatic ISRs

Starting from this example, the DMA driver directly defines the `DMA1_StreamX_IRQHandler` handlers in `dma_h7xx.c` (non-weak), eliminating the need to redefine them in the application. The NVIC is enabled automatically by `ca_dma_free_channel()` and disabled by `ca_dma_release()`.

DAC1 on STM32H7xx

Register	Value	Effect
`RCC->APB1LENR`	bit `DAC12EN`	DAC1 clock
`GPIOA->MODER[PA4]`	`11` (analog)	analog pin, no AF
`DAC1->CR`	`DAC_CR_EN1`	CH1 enabled, no trigger (`TEN1=0`)
`DAC1->DHR12R1`	`[11:0]`	12-bit value → immediate output

With `TEN1=0` (no trigger), the DAC updates the output immediately after every write to `DHR12R1`, without waiting for timer events or software triggers.

54.1.7 Expected output

```
EX31: DMA M2M + M2P DAC1 avviato
EX31: PA4=DAC1_OUT1     misura con oscilloscopio (seno ~1.56Hz)
EX31: M2M check 1024B every second
EX31 M2M: canale flat=0 (ctrl=1 str=0)
EX31 DAC: canale flat=1     PA4 DAC1_OUT1 seno 1.56Hz
EX31 M2M: ok #1 (1024B)
EX31 DAC: onda #1 completata
EX31 M2M: ok #2 (1024B)
EX31 DAC: onda #2 completata
...
EX31: uptime=10s  m2m_ok=10  m2m_err=0
```

54.1.8 Tasks and priorities

Task	Priority	Period	Function
`dma_m2m`	CA_TH_LEVEL3	1 s	M2M copy 1024B + verification
`dma_dac`	CA_TH_LEVEL3	10 ms/sample	Sine on DAC1 via DMA
`heartbeat`	CA_TH_LEVEL3	500 ms	Blink LED3 + uptime log

54.1.9 DMA APIs used

```c
/* Initializes the driver: semaphores + bitmask + controller clock */
void ca_dma_init(void);

/* Allocates the first free channel; enables the NVIC automatically */
i16 ca_dma_free_channel(ca_dma_ch_t *out);

/* Allocates a specific channel (flat index) */
i16 ca_dma_free_channel_index(i16 index, ca_dma_ch_t *out);

/* M2M transfer: src and dst increment, TCIE enabled */
bool ca_dma_copy_inc(ca_dma_ch_t ch, const void *src, void *dst,
                     u32 size, ca_dma_width_t width);

/* Attende completamento (sem_wait     yield scheduler) */
bool ca_dma_wait(ca_dma_ch_t ch, u32 timeout_ms);   /* false: no TC in time */

/* Releases the channel and disables the NVIC */
void ca_dma_release(ca_dma_ch_t ch);
```

```c
/* Transfer width */
typedef enum {
    CA_DMA_WIDTH_8  = 0,   /* byte */
    CA_DMA_WIDTH_16 = 1,   /* halfword */
```

```
    CA_DMA_WIDTH_32 = 2,   /* word */
} ca_dma_width_t;
```

54.1.10 DAC APIs used

```
/* Initializes the DAC channel: clock + analog GPIO + CR enable */
bool ca_dac_init(const ca_dac_config_t *cfg);   /* cfg.channel = 1|2 */

/* Direct 12-bit write (used by the CPU; DMA writes straight to DHR12R1) */
void ca_dac_write(u8 channel, u16 val);
```

54.1.11 Summary

1. **Two independent DMA channels** allocated with `ca_dma_free_channel()`; NVIC automatically enabled — no additional lines of code in the application
2. **M2M NDTR=1 trick** to write to a peripheral register (DAC) without configuring DMAMUX; works because DIR=M2M does not require DREQ from the device
3. **Cache maintenance** required on Cortex-M7: Clean before DMA reads, Invalidate after DMA writes; protected by `#if __DCACHE_PRESENT` for portability
4. **ca__dma__wait** is a true yield: the task blocks on the semaphore and the scheduler executes other tasks for the entire duration of the transfer
5. **Automatic ISRs**: `dma_h7xx.c` defines all non-weak handlers; the application no longer needs to redefine them

Chapter 55

ETH: Link UP / Link DOWN Detection

55.1 Example 32 — ETH: link UP/DOWN, packet reception and transmission

55.1.1 Introduction

This example demonstrates the caOS **ETH** driver on the NUCLEO-H753ZI with a **LAN8742A** PHY in **RMII** mode. The objectives are:

1. Automatic detection of Ethernet link state transitions (link UP / link DOWN) with notification via **callback**.
2. **Polling** reception of incoming Ethernet frames and dump to **USB CDC** via `ca_hexdump`.
3. Transmission of a **Gratuitous ARP** upon link connection to announce its MAC+IP to the network.
4. **L2 Echo**: every received frame is sent back to the sender with the source/destination MACs swapped (`swap_and_send`).

Traffic is generated by a PC connected directly to the board via an Ethernet cable. No external traffic generator is needed: the PC itself automatically generates ARP and IGMP traffic as soon as the network port becomes active.

At each link transition, a message is sent via **USB CDC** and the state of **LED1** (green, PB0) is updated. Each received frame is printed with the Ethernet header (DST/SRC/EtherType) and a hexadecimal dump.

Hardware (NUCLEO-H753ZI, MB1364)

Signal	MCU Pin	Description
LED1 (green)	PB0	On = link UP, off = link DOWN
LED3 (red)	PB14	Heartbeat 1 Hz
ETH_RMII_REF_CLK	PA1	RMII 50 MHz clock from PHY
ETH_MDIO	PA2	MDIO PHY management data
ETH_RMII_CRS_DV	PA7	Carrier Sense / Data Valid
ETH_MDC	PC1	MDIO clock
ETH_RMII_RXD0	PC4	RX data bit 0
ETH_RMII_RXD1	PC5	RX data bit 1
ETH_RMII_TX_EN	PG11	Transmission enabled

Signal	MCU Pin	Description
ETH_RMII_TXD1	PB13	TX data bit 1
ETH_RMII_TXD0	PG13	TX data bit 0

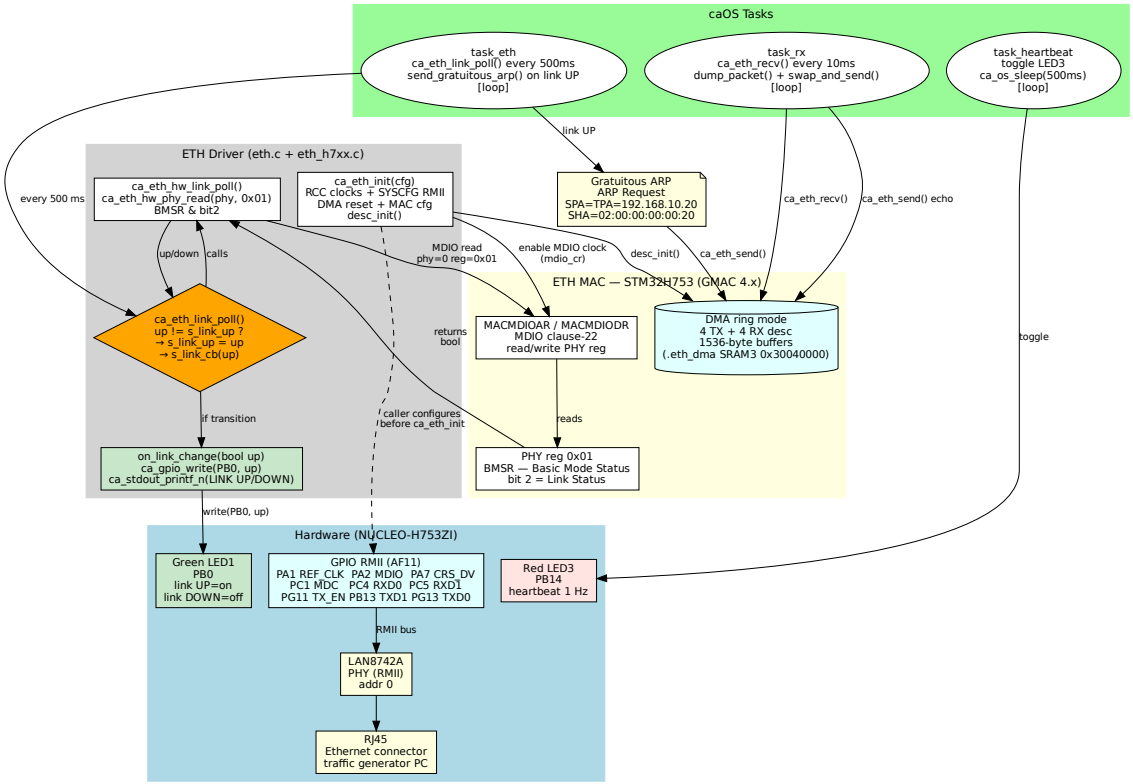
All RMII pins are configured with **AF11**, **CA_GPIO_SPEED_VERY_HIGH**, **CA_GPIO_NOPU** **CA_GPIO_OTYPE_PP**.

> **Connection**: use a straight-through Ethernet cable between the NUCLEO-H753ZI RJ45 connector (CN1) and a PC port. The traffic generator can be any tool capable of sending L2 Ethernet frames (e.g., `pktgen`, `scapy`, or simply ping).

55.1.2 Required configuration in `os_config.h`

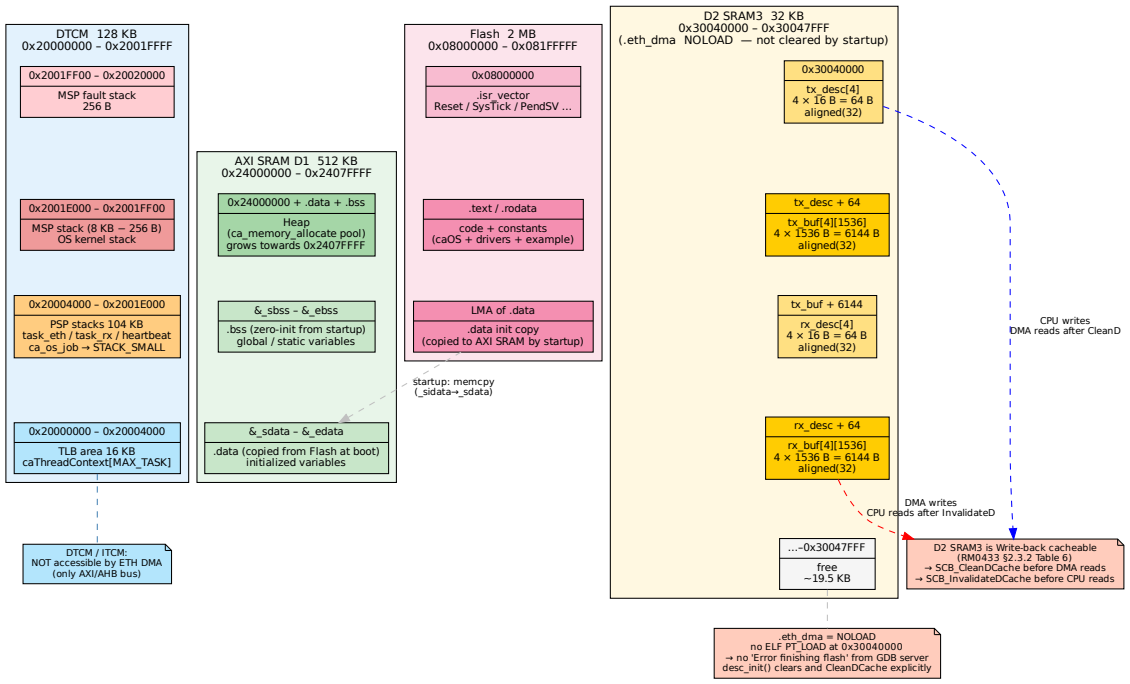
```
#define EN_ETH          1     /* Driver ETH */
#define EVAL_USB_CDC    ...   /* USB CDC for message output */
```

55.1.3 System architecture



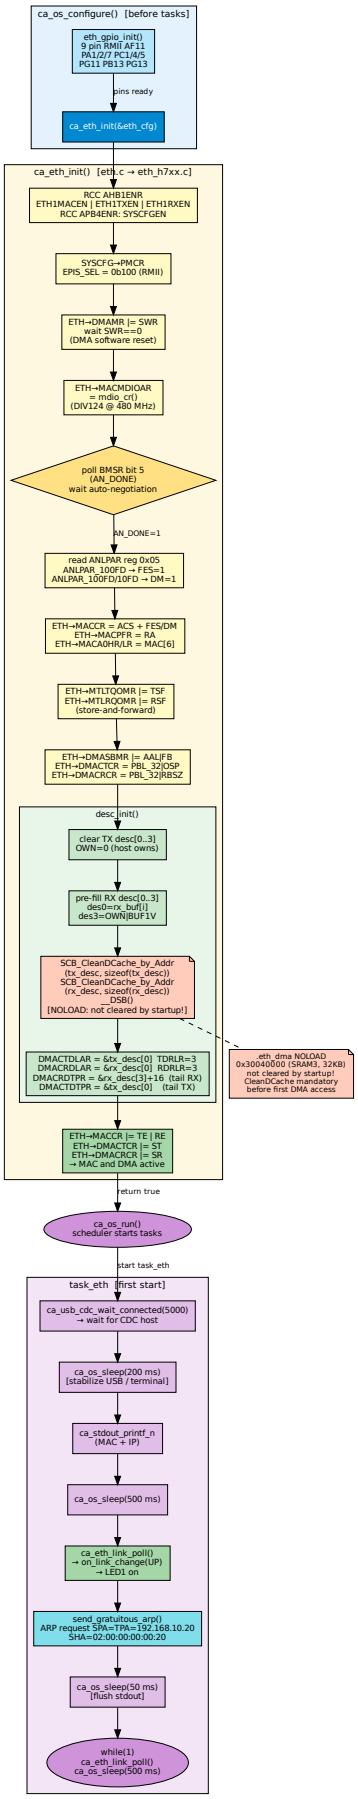
(source: `doc/diagrams/ex32_arch.dot`)

Memory map



(source: `doc/diagrams/ex32_memory.dot`)

Init flow

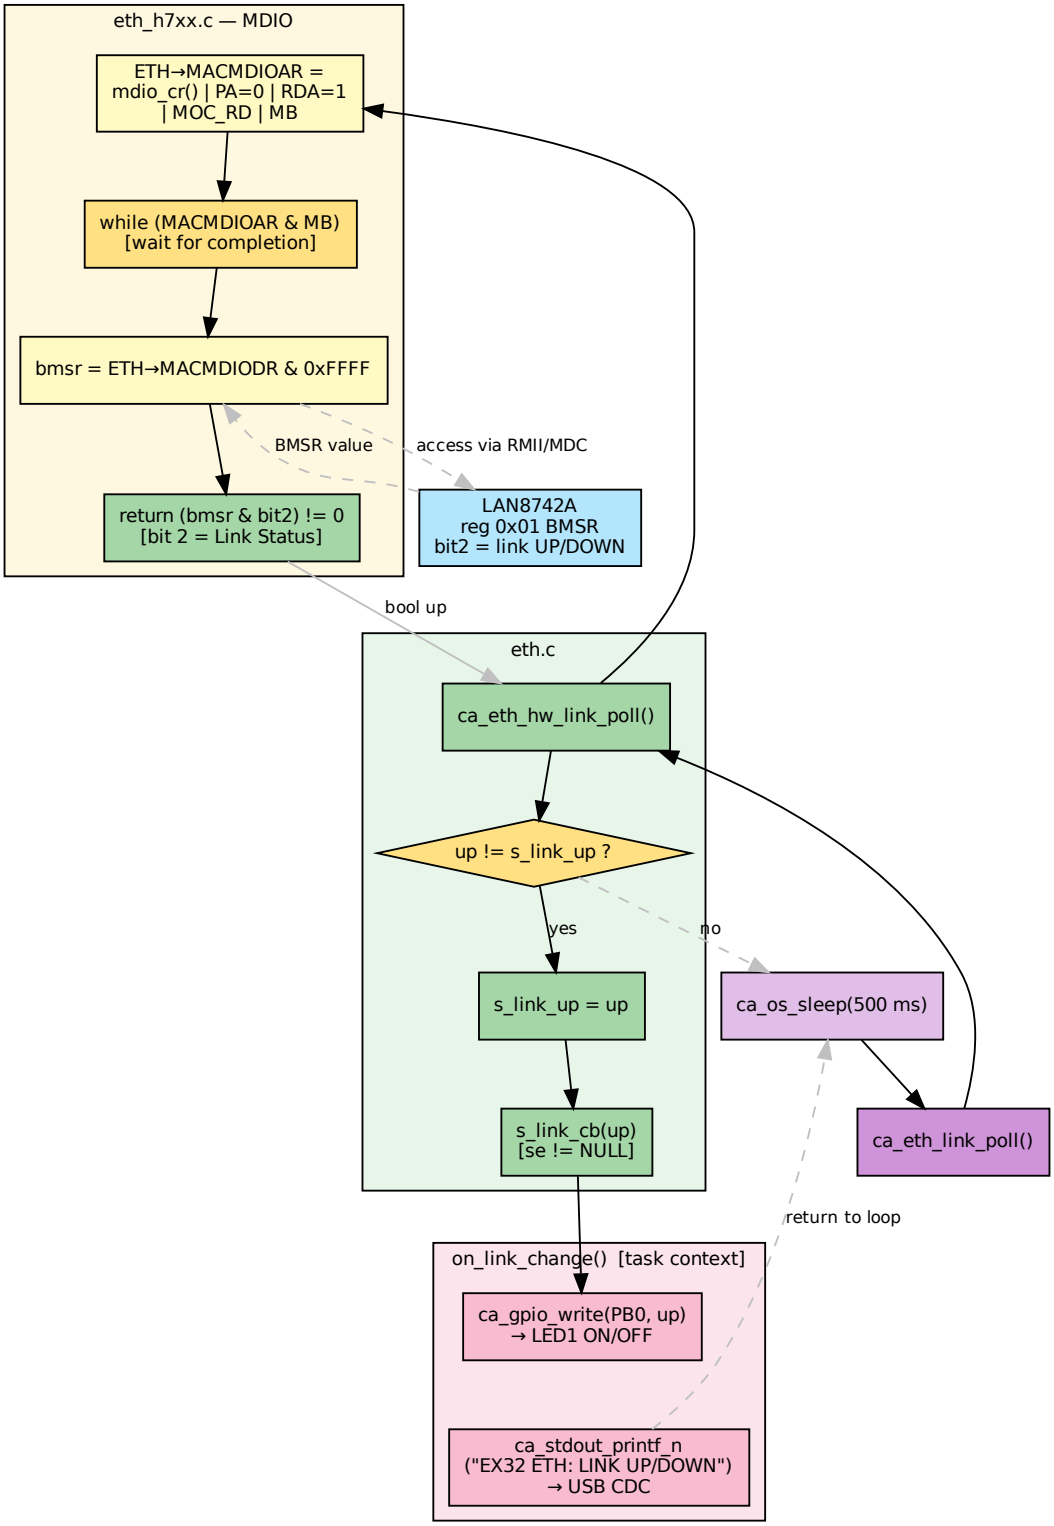


(source: `doc/diagrams/ex32_init_flow.dot`)

Why is `ca_eth_init` in `ca_os_configure` and not in the task? `ca_eth_init()` is a purely HW operation (RCC, SYSCFG, busy-wait MDIO) that does not use stdout. Executing it in `ca_os_configure` ensures that the MAC is already ready when the tasks start. Status messages are printed subsequently by `task_eth` when stdout is already active.

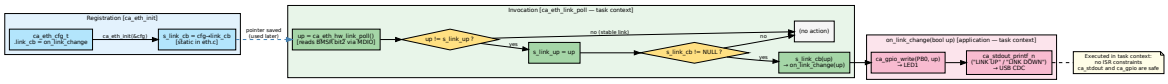
Why `ca_usb_cdc_wait_connected` + sleep in `task_eth`? The USB CDC sender silently discards messages if `tud_cdc_connected()` is false. With `wait_connected` the task waits for the host connection. The subsequent `ca_os_sleep(200)` is necessary because the busy-wait in `ca_eth_init()` (DMA reset, MDIO polling) blocks the scheduler during `ca_os_configure`: the first message would arrive too soon after the USB connection. The `ca_os_sleep(50)` before the loop gives the stdout task time to flush the message before `ca_eth_link_poll()` queues any “LINK UP”.

Link poll flow



(source: `doc/diagrams/ex32_link_poll.dot`)

Callback mechanism



(source: doc/diagrams/ex32_callback.dot)

The callback is called in **task context** (not ISR), so it is safe to invoke `ca_stdout_printf_n` and `ca_gpio_write` directly inside it.

55.1.4 The source code

The file is located in `examples/example_32/ca_os_ex32.c`.

1. `ca_eth_cfg_t` configuration and IP address

```
static void on_link_change(bool up);   /* forward declaration */

static const u8 board_ip[4] = { 192U, 168U, 10U, 20U };

static const ca_eth_cfg_t eth_cfg = {
    .phy_addr = 0U,                                          /* LAN8742A addr 0
    */
    .rmii     = true,                                        /* RMII     9 pin
    */
    .mac      = { 0x02U, 0x00U, 0x00U, 0x00U, 0x00U, 0x20U }, /* locally
    administered */
    .link_cb  = on_link_change,
};
```

The `eth_cfg` is `static const` at the file level. The forward declaration is necessary because `on_link_change` is defined after the initializer that references it as a function pointer.

The MAC address uses the `02:xx` prefix (U/L bit=1) which indicates a **locally administered** address, not assigned by the IEEE. Sufficient for L2 testing.

`board_ip` is the static IPv4 address of the board, used only for Gratuitous ARP; there is no full IP stack in this example.

2. GPIO init RMII

```
static void eth_gpio_init(void)
{
    /* PA1 REF_CLK, PA2 MDIO, PA7 CRS_DV */
    ca_gpio_configure(CA_GPIO_PORT_A, 1U,
                      CA_GPIO_MODE_AF, CA_GPIO_OTYPE_PP, CA_GPIO_SPEED_VERY_HIGH
    ,
                      CA_GPIO_NOPULL, ETH_AF);   /* ETH_AF = 11 */
    /* ... same configuration for PA2, PA7, PC1, PC4, PC5, PG11, PG12, PG13 */
}
```

> **Note**: RMII pins must be configured **before** calling `ca_eth_init()`. The ETH driver does not handle GPIOs (caOS pattern: the caller is responsible for pin configuration).

3. Link state callback

```
static void on_link_change(bool up)
{
    if (up) {
        ca_gpio_write(LED_LINK_PORT, LED_LINK_PIN, 1U);
```

```
        ca_stdout_printf_n("EX32 ETH: LINK UP");
    } else {
        ca_gpio_write(LED_LINK_PORT, LED_LINK_PIN, 0U);
        ca_stdout_printf_n("EX32 ETH: LINK DOWN");
    }
}
```

4. Task monitor link and Gratuitous ARP

```
static u32 task_eth(void *arg)
{
    (void)arg; (void)arg2;

    ca_usb_cdc_wait_connected(5000);  /* attende host; timeout 5 s */
    ca_os_sleep(200);                 /* lets USB and the host terminal settle */

    ca_stdout_printf_n("\n\nEX32: ETH INIT OK");
    ca_stdout_printf_n("PHY addr=%d RMII MAC %02X:%02X:%02X:%02X:%02X:%02X IP %u.%u.%u.%u",
        eth_cfg.phy_addr,
        eth_cfg.mac[0], eth_cfg.mac[1], eth_cfg.mac[2],
        eth_cfg.mac[3], eth_cfg.mac[4], eth_cfg.mac[5],
        board_ip[0], board_ip[1], board_ip[2], board_ip[3]);

    ca_os_sleep(500);
    ca_eth_link_poll();               /* first read; GARP from on_link_change(up) */
    ca_os_sleep(50);                  /* flush before the loop */

    while (1) {
        ca_eth_link_poll();
        ca_os_sleep(500);
    }
    return 0;
}
```

The Gratuitous ARP starts at `on_link_change(true)`, i.e., on the **rising edge** of the link and at every cable reconnection: it is used to update the ARP cache of the peers with the board's MAC. Sent blindly 500 ms after init, as in the early versions, it started ~0.9 s before the PC had the carrier and was lost, while `ca_eth_send()` responded OK anyway (measured on H563, 02/10/2026). The 500 ms period for the link poll is a good compromise between responsiveness and load on the MDIO bus.

5. Gratuitous ARP

```
static void send_gratuitous_arp(void)
{
    u16 idx = ca_net_buf_alloc();
    if (idx == NET_BUF_INVALID) { ca_stdout_printf_n("GARP: no buf"); return; }

    ca_net_buf_t *b = ca_net_buf_ptr(idx);
    u8  *arp = b->data + NET_BUF_HEADROOM;
    const u8 *mac = eth_cfg.mac.v;
    const u8 *ip  = board_ip;

    /* Ethernet header */
    for (u32 i = 0U; i < 6U; i++) arp[i]      = 0xFFU;
    for (u32 i = 0U; i < 6U; i++) arp[6U+i]   = mac[i];
    arp[12] = 0x08U; arp[13] = 0x06U;

```

```
    /* ARP payload */
    arp[14] = 0x00U; arp[15] = 0x01U;
    arp[16] = 0x08U; arp[17] = 0x00U;
    arp[18] = 6U;    arp[19] = 4U;
    arp[20] = 0x00U; arp[21] = 0x01U;

    for (u32 i = 0U; i < 6U; i++) arp[22U+i] = mac[i];
    for (u32 i = 0U; i < 4U; i++) arp[28U+i] = ip[i];
    for (u32 i = 0U; i < 6U; i++) arp[32U+i] = 0x00U;
    for (u32 i = 0U; i < 4U; i++) arp[38U+i] = ip[i];
    for (u32 i = 42U; i < 60U; i++) arp[i]   = 0x00U;

    b->data_off = NET_BUF_HEADROOM;
    b->data_len = 60U;
    i32 rc = ca_eth_send(idx);    /* driver owns buf, whatever rc says */
    if (rc == CA_ETH_SEND_OK)
        ca_stdout_printf_n("GARP %u.%u.%u.%u %02X:%02X:%02X:%02X:%02X:%02X OK",
            ip[0], ip[1], ip[2], ip[3],
            mac[0], mac[1], mac[2], mac[3], mac[4], mac[5]);
    else
        ca_stdout_printf_n("GARP FAIL %d%s", rc,
            rc == CA_ETH_SEND_ERR_LINK ? " (link down)" : " (tx ring)");
}
```

The frame is built directly in the buffer pool (NCacheable D2 SRAM1) — no copy to the DMA. The field OPER=0x0001 (Request) is correct for a Gratuitous ARP: RFC 5227 defines the GARP as an ARP Request where SPA=TPA=own IP. In case of success `ca_eth_send` owns the buffer and frees it in a deferred manner; with a negative code, it has already freed it: the caller never touches it. When the link is down `ca_eth_send` rejects the frame with `CA_ETH_SEND_ERR_LINK` (-102) instead of accepting it and losing it on the wire.

Verification with tcpdump: `sudo tcpdump -e -i eth0 arp` Expected output: `02:00:00:00:00:20 > Broadcast, ARP, length 60, ARP Request who-has 192.168.10.20 tell 192.168.10.20`

6. L2 reception and echo: `task_rx`, `dump_packet`, `swap_and_send`

```
#define DUMP_MAX  32U   /* max bytes hex-dumped per packet */

static void dump_packet(const u8 *pkt, u32 len, u32 n)
{
    ca_stdout_printf_n("PKT#%u len=%u", n, len);
    if (len < 14U) return;
    ca_stdout_printf_n(
        "  D=%02X:%02X:%02X:%02X:%02X:%02X"
        "  S=%02X:%02X:%02X:%02X:%02X:%02X"
        "  t=0x%04X",
        pkt[0],pkt[1],pkt[2],pkt[3],pkt[4],pkt[5],
        pkt[6],pkt[7],pkt[8],pkt[9],pkt[10],pkt[11],
        ((u32)pkt[12] << 8) | pkt[13]);
    u32 d = len < DUMP_MAX ? len : DUMP_MAX;
    ca_hexdump(pkt, (u16)d);
}

static void swap_and_send(u16 buf_idx)
{
    ca_net_buf_t *b = ca_net_buf_ptr(buf_idx);
    u8 *pkt = b->data + b->data_off;
    u32 len = b->data_len;
    if (len < 14U) { ca_net_buf_free(buf_idx); return; }
    /* DST = original source (unicast to the sender) */
    for (u32 i = 0U; i < 6U; i++) pkt[i] = pkt[6U + i];
```

```
    /* SRC = MAC of the board */
    for (u32 i = 0U; i < 6U; i++) pkt[6U + i] = eth_cfg.mac[i];
    i32 rc = ca_eth_send(buf_idx);   /* the driver owns buf_idx, whatever the rc
     */
    if (rc == CA_ETH_SEND_OK) ca_stdout_printf_n("TX len=%u OK", len);
    else                      ca_stdout_printf_n("TX len=%u FAIL %d", len, rc);
}

static u32 task_rx(void *arg)
{
    (void)arg; (void)arg2;
    u32 count = 0U;
    while (1) {
        u16 new_idx = ca_net_buf_alloc();
        if (new_idx == NET_BUF_INVALID) { ca_os_sleep(10); continue; }
        u16 out_idx;
        if (!ca_eth_recv(&out_idx, new_idx)) {
            ca_net_buf_free(new_idx);
            ca_os_sleep(10);
            continue;
        }
        ca_net_buf_t *b = ca_net_buf_ptr(out_idx);
        dump_packet(b->data + b->data_off, b->data_len, ++count);
        swap_and_send(out_idx);   /* trasferisce ownership a send o free */
    }
    return 0;
}
```

The static buffer `rx_pkt[1536]` no longer exists: every frame arrives already in the buffer pool (NCacheable D2 SRAM1) via **zero-copy swap**. `task_rx` allocates a replacement buffer (`new_idx`) for the RX ring, obtains the received frame (`out_idx`), and transfers its ownership to `swap_and_send`.

`swap_and_send` receives ownership of the buffer and passes it to `ca_eth_send`, which keeps it regardless of what it returns: in case of an error, the buffer has already been freed by the driver, and `swap_and_send` no longer touches it.

`ca_hexdump(pkt, d)` (from `caos/src/utils.c`) prints 16-byte lines with address, hex, and ASCII column — `hexdump -C` style format.

7. ca_os_configure and ca_os_main

```
void ca_os_configure(void)
{
    /* stdout / log / cli / USB CDC ... */
    EVAL_SENSOR(ca_temp_init();)

    ca_gpio_configure(LED_LINK_PORT, LED_LINK_PIN, CA_GPIO_MODE_OUTPUT, ...);
    ca_gpio_configure(LED_HB_PORT,   LED_HB_PIN,   CA_GPIO_MODE_OUTPUT, ...);

    /* RMII GPIOs     must be ready before ca_eth_init */
    eth_gpio_init();
    /* Zero-copy buffer pool: must be initialized BEFORE ca_eth_init
     * because desc_init() pre-allocates ETH_RX_N buffers from the pool */
    ca_net_buf_pool_init();
    if (!ca_eth_init(&eth_cfg))
        CA_SAFE_FAIL("ca_eth_init");
}

void ca_os_main(void)
{
    ca_os_job("eth_mon",   CA_TH_LEVEL3, task_eth,       NULL, STACK_SMALL, ...)
    ;
```

```
    ca_os_job("eth_rx",     CA_TH_LEVEL3, task_rx,        NULL, STACK_SMALL, ...)
    ;
    ca_os_job("heartbeat", CA_TH_LEVEL3, task_heartbeat, NULL, STACK_SMALL, ...)
    ;
    ca_os_run(true);
}
```

> **Critical order**: `ca_net_buf_pool_init()` before `ca_eth_init()`. `desc_init()` (called inside `ca_eth_hw_init`) executes `ca_net_buf_alloc()` for the 4 RX descriptors. If the pool is not yet initialized, `alloc` always returns `NET_BUF_INVALID` and the RX descriptors are loaded with NULL buffers → hard fault on the first received frame.

55.1.5 Technical notes

PHY BMSR — register 0x01

The **BMSR** (Basic Mode Status Register) register is defined by the IEEE 802.3 standard and is present on any clause-22 PHY. The bit of interest is:

Bit	Name	Description
2	Link Status	`1` = link established, `0` = link absent

Reading is performed via **MDIO** (Management Data Input/Output), a 2-wire serial protocol (MDC clock, MDIO data) managed by the `MACMDIOAR` register of the GMAC 4.x.

```
ca_eth_hw_phy_read(phy=0, reg=0x01):
    ETH->MACMDIOAR = mdio_cr()          /* divisore clock: DIV124 a 480MHz */
                   | (0 << PA_Pos)      /* phy addr = 0 */
                   | (1 << RDA_Pos)     /* reg addr = BMSR */
                   | MDIO_MOC_RD        /* clause-22 read: MOC = 0b11 */
                   | MB;                /* MB=1: starts the transaction */
    while (MACMDIOAR & MB);             /* wait for completion */
    return MACMDIODR & 0xFFFF;
```

MDIO clock on STM32H753 at 480 MHz

The MDC clock must be 2.5 MHz to be compatible with all PHYs. The `CR` field of `MACMDIOAR` selects the divider:

HCLK	Divider	Resulting MDC
< 35 MHz	DIV16	~2.2 MHz
35–60 MHz	DIV26	~2.3 MHz
60–100 MHz	DIV42	~2.4 MHz
100–150 MHz	DIV62	~2.4 MHz
150–250 MHz	DIV102	~2.4 MHz
250 MHz	DIV124	~3.9 MHz @ 480 MHz → **< 2.5 MHz**

> At 480 MHz: 480 / 124 3.9 MHz. The `DIV124` value is the maximum divider available on GMAC 4.x; the LAN8742A tolerates MDC up to 25 MHz, so it is compatible even with this frequency.

Auto-negotiation — ANLPAR

After the DMA reset, the driver waits for the PHY auto-negotiation to complete (BMSR bit 5 `AN_DONE`), then reads **ANLPAR** (reg 0x05, Link Partner Ability):

```
u16 anlpar  = ca_eth_hw_phy_read(s_phy_addr, PHY_ANLPAR);
bool speed100 = (anlpar & (PHY_ANLPAR_100FD | PHY_ANLPAR_100HD)) != 0U;
bool fulldpx  = (anlpar & (PHY_ANLPAR_100FD | PHY_ANLPAR_10FD))  != 0U;

u32 maccr = ETH_MACCR_ACS;
if (speed100) maccr |= ETH_MACCR_FES;   /* Fast Ethernet 100M */
if (fulldpx)  maccr |= ETH_MACCR_DM;    /* Duplex Mode full */
ETH->MACCR = maccr;
```

This allows the driver to operate correctly with both switches/routers and direct PC–board cables (crossover or auto-MDI/MDIX), without having to assume a fixed 100FD.

SYSCFG PMCR — RMII selection

Before the DMA reset, the `EPIS_SEL` field of `SYSCFG->PMCR` must be configured to select the physical interface:

```
/* RMII: EPIS_SEL = 0b100 = bit 23 */
SYSCFG->PMCR = (SYSCFG->PMCR & ~SYSCFG_PMCR_EPIS_SEL)
             | SYSCFG_PMCR_EPIS_SEL_2;
```

This configuration must take place **before the ETH DMA reset** (`ETH->DMAMR |= SWR`), otherwise the MAC will not synchronize correctly with the PHY.

Zero-copy architecture — memory map

With the zero-copy driver, data buffers are in the **pool** (D2 SRAM1 NCacheable) and only the DMA descriptors (128 bytes total, 4+4 × 16 bytes) remain in SRAM3:

```
D2 SRAM1  0x30000000  128 KB  NCacheable (MPU region 3)
            pool: NET_BUF_COUNT    ca_net_buf_t (2 KB ciascuno)
                  [0..3]       puntati da rx_desc[0..3].des0  (driver owned)
                  [4..7]       waiting for deferred TX free  (driver owned)
                  [8..]        free in the pool

D2 SRAM3  0x30040000  32 KB   NCacheable (MPU region 4)
            .eth_dma: tx_desc[4] + rx_desc[4]  (only 128 bytes, NOLOAD)
```

```
/* eth_h7xx.c */
__attribute__((section(".eth_dma"), aligned(32))) static eth_desc_t tx_desc[
    ETH_TX_N];
__attribute__((section(".eth_dma"), aligned(32))) static eth_desc_t rx_desc[
    ETH_RX_N];
/* There are NO more tx_buf/rx_buf: the data live in the pool */
```

In the linker script `STM32H753ZITX_FLASH.ld`:

```
MEMORY {
  ETH_SRAM3 (rw) : ORIGIN = 0x30040000, LENGTH = 32K
}

.eth_dma (NOLOAD) : { *(.eth_dma) } >ETH_SRAM3
```

> **Why NOLOAD?** The section has no initializer in flash. The driver explicitly zeroes it in `desc_init()`. It avoids a PT_LOAD ELF at 0x30040000 that the GDB server tries to verify before RCC enables the D2 SRAM clock.

Cache coherency — why the pool is NCacheable

Both the descriptors (SRAM3 `.eth_dma`) and the data buffers (SRAM1 pool) are configured as **Non-cacheable** via MPU, eliminating the need for `SCB_CleanDCache_by_Addr` / `SCB_InvalidateDCache_by_Addr` operations:

Region	MPU	Reason
Pool D2 SRAM1 (0x30000000)	Region 3, TEX=001, C=0, B=0	The ETH DMA reads/writes frames; the CPU accesses the payload. NCacheable = always coherent
Desc D2 SRAM3 (0x30040000)	Region 4, TEX=001, C=0, B=0	The ETH DMA reads/writes descriptor OWN bit; without NCacheable → IMPRECISERR (write buffer)

IMPRECISERR root cause: if the descriptors or the pool are in a Write-back cacheable region, the CPU may write the OWN bit to the D-cache without immediate flushing to physical RAM. The DMA reads the old value from RAM → failed buffer handover → asynchronous bus fault (CFSR bit 10).

The `ACTLR.DISDEFWBUF` flag (bit 1, @0xE000E008) can be used as a diagnostic tool: setting it to 1 makes all bus faults PRECISERR; if the faults disappear entirely, it means the only cause was the write buffer on a cacheable region. In production, MPU NCacheable is used instead of DISDEFWBUF (which degrades core performance).

GMAC 4.x ring details

The GMAC 4.x (present on H7xx and H5xx) uses **ring mode** with 4-word (128-bit) descriptors:

RX descriptor (pre-fill):

Word	Field	Value
DES0	Buffer 1 address	`(u32)(b->data + NET_BUF_HEADROOM)` (buffer pool)
DES1	—	0
DES2	—	0
DES3	OWN=1, BUF1V=1	DMA owned, buf1 valid

RX write-back (after reception):

DES3 Field	Bit	Description
OWN	31	0 = host can read
PL	[14:0]	Packet Length (includes 4-byte FCS)

The driver subtracts 4 bytes before returning the length to the caller.

55.1.6 Expected output

```
EX32: ETH INIT OK
PHY addr=0 RMII MAC 02:00:00:00:00:20 IP 192.168.10.20

EX32 ETH: LINK UP
GARP 192.168.10.20 02:00:00:00:00:20 OK
```

```
6
7  PKT#1 len=60
8    D=FF:FF:FF:FF:FF:FF  S=C0:25:A5:51:6C:13  t=0x0806
9  0x30040...  0xff 0xff 0xff 0xff 0xff 0xff 0xc0 0x25 ...
10 TX len=60 OK
11
12 PKT#2 len=60
13   D=01:00:5E:00:00:16  S=C0:25:A5:51:6C:13  t=0x0800
14 ...
15 TX len=60 OK
16
17 [scollega cavo]
18 EX32 ETH: LINK DOWN
19 [ricollega]
20 EX32 ETH: LINK UP
21 GARP ... OK
```

The init message appears after the 200 ms USB stabilization period. The Gratuitous ARP is sent once as soon as the link is UP. Link state messages appear within **500 ms** of the physical signal change. For every received frame, the dump and the TX confirmation (`TX len=N OK`) are printed.

> **TX LED does not blink**: at 100 Mbps RMII, a 60-byte frame lasts ~5 s — the physical ETH port LED cannot keep up with the transition.

Analysis of received packets

The board receives ordinary network traffic automatically generated by the PC — no external tool is required.

```
1  DST = FF:FF:FF:FF:FF:FF   broadcast L2
2  SRC = C0:25:A5:51:6C:13   PC Ethernet interface
3  type = 0x0806              ARP
4
5  Payload ARP (IEEE 802.3     RFC 826):
6    HTYPE = 0x0001  Ethernet
7    PTYPE = 0x0800  IPv4
8    HLEN  = 6       lunghezza MAC
9    PLEN  = 4       lunghezza IP
10   OPER  = 0x0001  ARP Request ("chi ha IP X? dimmelo a C0:25:...")
11   SHA   = C0:25:A5:51:6C:13
12   SPA   = C0:A8:0A:96       192.168.10.150  (PC IP)
```

The PC does not know the MAC associated with an IP address on the network and sends a broadcast request. The board (with filter `MACPFR = RA`, receive-all) receives it but does not respond because it does not have an IP stack.

```
1  DST = 01:00:5E:00:00:16   multicast L2     gruppo IP 224.0.0.22
2  SRC = C0:25:A5:51:6C:13   PC
3  type = 0x0800              IPv4
4
5  Header IPv4 (24 byte, IHL=6, con Router Alert option):
6    DSCP/ECN = 0xC0
7    Length   = 40
8    TTL      = 1       does not leave the local network
9    Protocol = 0x02    IGMP
10   SRC IP   = 192.168.10.150
11   DST IP   = 224.0.0.22   "All IGMPv3-capable multicast routers"
```

The PC (Windows/Linux) periodically sends **IGMP v3 Membership Reports** to the group `224.0.0.22` to notify the local router of the multicast groups it is subscribed to (e.g., mDNS `224.0.0.251`, SSDP `239.255.255.250`, etc.). With TTL=1, the packet does not cross the local segment. The board receives it because its multicast MAC `01:00:5E:xx:xx:xx` is accepted by the filter `RA`.

`len=60` for short frames Ethernet imposes a minimum length of **64 bytes** per frame (60 data + 4 FCS). Shorter frames (ARP = 42 actual bytes, IGMP = ~54 bytes) are **padded** to 60 bytes by the PC's NIC before transmission. The H7xx driver subtracts the 4 bytes of FCS → `len=60`.

55.1.7 Tasks and priorities

Task	Priority	Period	Function
`eth_mon`	CA_TH_LEVEL3	500 ms	Poll PHY BMSR, callback on link transition; send GARP on link UP
`eth_rx`	CA_TH_LEVEL3	10 ms	Drain DMA ring, dump packets, L2 echo (`swap_and_send`)
`heartbeat`	CA_TH_LEVEL3	500 ms	Blink red LED3

55.1.8 ETH APIs used

```
/* Initializes MAC + DMA, configures RMII/MII via SYSCFG.
 * GPIO pins already configured by the caller before this call.
 * Saves cfg->link_cb for link state notifications. */
bool ca_eth_init(const ca_eth_cfg_t *cfg);

/* Polls PHY BMSR; calls link_cb on an UP/DOWN transition.
 * Call periodically from a task (e.g. every 500 ms).
 * Returns true if the link is currently up. */
bool ca_eth_link_poll(void);

/* Transmits an Ethernet frame     zero-copy pool.
 * CA_ETH_SEND_OK (0): the driver owns buf_idx (deferred free).
 * CA_ETH_SEND_ERR_LINK (-102): link down.  CA_ETH_SEND_ERR_TX (-101): TX ring
 * full.  In every case the driver owns buf_idx: the caller does not free it. */
i32 ca_eth_send(u16 buf_idx);

/* Receives an Ethernet frame     zero-copy swap.
 * true:  *out_idx holds the frame (to process and then free);
 *        new_idx is now in the DMA ring (do not touch).
 * false: new_idx not consumed     ca_net_buf_free(new_idx). */
bool ca_eth_recv(u16 *out_idx, u16 new_idx);

/* Buffers legitimately held by the driver (4 fixed RX + deferred TX).
 * Use fc + held == NET_BUF_COUNT for the correct leak check. */
u16 ca_eth_pool_held_count(void);

/* Direct access to the PHY registers via MDIO (after ca_eth_init). */
u16  ca_eth_phy_read (u8 phy, u8 reg);
void ca_eth_phy_write(u8 phy, u8 reg, u16 val);
```

```c
typedef void (*ca_eth_link_cb_t)(bool up);

typedef struct {
    u8               phy_addr;  /* PHY MDIO address, 0  31   */
    bool             rmii;      /* true = RMII (9 pin), false = MII (17 pin) */
    ca_mac_t            mac;       /* MAC address (ca_mac_t with field .v[6]) */
    ca_eth_link_cb_t link_cb;   /* link state callback; NULL = disabled */
} ca_eth_cfg_t;
```

55.1.9 MCU family support

Family	ETH IP	Notes
F1xx	none	stub — always returns false
F4xx (F407/F429)	legacy GMAC	`MACMIIAR`/`MACMIIDR`, DMA TCH chained
F4xx (F446)	none	stub MCU_ID guard
F7xx	legacy GMAC	identical to F4xx, HCLK up to 216 MHz
H7xx	GMAC 4.x	ring mode, `MACMDIOAR`/`MACMDIODR`, MTL layer
H5xx	GMAC 4.x	identical to H7xx, different RCC and SBS

The application code (`ca_os_ex32.c`) is identical for all families thanks to the driver abstraction; only `os_config.h` and cmake select the correct HW implementation.

55.1.10 Summary

1. **GPIO + `ca_eth_init` in `ca_os_configure`** — synchronous HW init without stdout dependencies; tasks find the MAC ready at startup
2. **Dynamic auto-negotiation** — ANLPAR read after AN_DONE: speed/duplex configured automatically; works with switches and direct cables
3. **Gratuitous ARP on link UP** — updates peer ARP cache without requiring a ping from the PC; very useful for immediate testing with tcpdump
4. **L2 Echo (`swap_and_send`)** — end-to-end TX/RX verification at Ethernet level without IP stack; tcpdump on the PC confirms both RX and TX
5. **Descriptors in SRAM3 (.eth_dma NOLOAD)** — dedicated region 0x30040000; no problematic PT_LOAD for GDB server; no conflicts with D1 heap
6. **Cache coherency via MPU NCacheable** — pool (SRAM1) and descriptors (SRAM3) configured as Non-cacheable: no `SCB_CleanDCache` / `SCB_InvalidateDCache` in the hot path. `aligned(32)` mandatory for DMA descriptors.
7. **`ca_eth_link_poll()` in task** — polling every 500 ms on PHY BMSR bit 2; no ETH interrupt required, minimal and portable approach
8. **Synchronous callback in task context** — safe for `ca_stdout_printf_n` and GPIO; avoids ISR complexity
9. **`task_rx` total drain for burst** — loop `for(;;)` allocates `new_idx`, calls `ca_eth_recv(&out_idx , new_idx)`; if no frame, frees `new_idx` and exits; ensures that closely spaced packets are not lost
10. **TX LED does not blink at 100 Mbps** — 60-byte frame lasts ~5 s; transmission must be verified with tcpdump, not by eye

Chapter 56

caOS Net Stack: Buffer Pool, ARP Reply, ICMP Echo

56.1 Example 33 — caOS Net Stack: buffer pool, ARP reply, ICMP echo, UDP

56.1.1 Introduction

Example 33 integrates the **complete net layer** of caOS on NUCLEO-H753ZI (STM32H753ZI, PHY LAN8742A RMII). Objectives:

1. **Pool self-test**: verifies that the NCacheable DMA pool is correctly initialized (address range, exhaustion, absence of duplicates).
2. **Automatic ARP reply**: response to PC ARP requests via `ca_net_proto_init()`.
3. **ICMP echo reply**: response to pings without any additional application code.
4. **Diagnostics on request**: `eth stats` and `eth pool` from the CLI, with the leak check on `ca_eth_pool_held_count`.

Unlike example 32 (raw L2 echo), here the net stack transparently handles ARP and ICMP; the application only deals with its own UDP traffic (zero binding in this basic configuration).

Hardware (NUCLEO-H753ZI, MB1364)

Signal	MCU Pin	Description
LED1 (green)	PB0	ON = link UP
LED3 (red)	PB14	Heartbeat 500 ms
ETH_RMII_REF_CLK	PA1	RMII clock 50 MHz from PHY
ETH_MDIO	PA2	MDIO PHY management data
ETH_RMII_CRS_DV	PA7	Carrier Sense / Data Valid
ETH_MDC	PC1	MDIO clock
ETH_RMII_RXD0	PC4	RX data bit 0
ETH_RMII_RXD1	PC5	RX data bit 1
ETH_RMII_TX_EN	PG11	Transmission enabled
ETH_RMII_TXD1	PB13	TX data bit 1
ETH_RMII_TXD0	PG13	TX data bit 0

All RMII pins: **AF11**, **CA_GPIO_SPEED_VERY_HIGH**, **CA_GPIO_NOPULL**, **CA_GPIO_OTYPE_PP**.

Required configuration in `os_config.h`

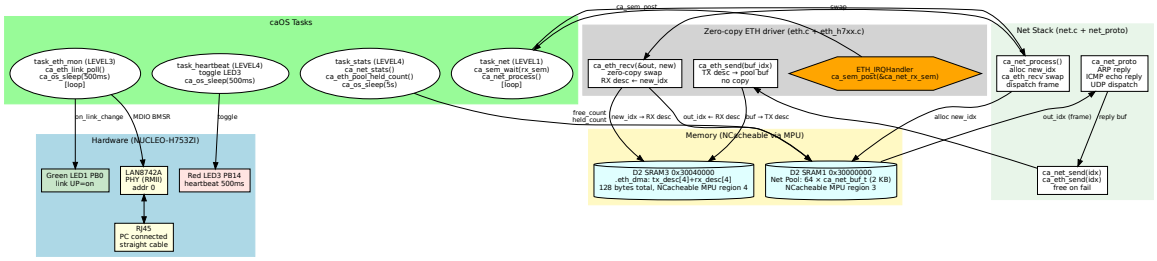
```
#define EN_ETH    1   /* driver Ethernet HW */
#define EN_NET    1   /* net_proto stack (requires EN_ETH) */
```

PC test procedure

```
sudo ip addr add 192.168.10.1/24 dev eth0
arping  -c 10  -I eth0  192.168.10.33
ping    -c 5   192.168.10.33
```

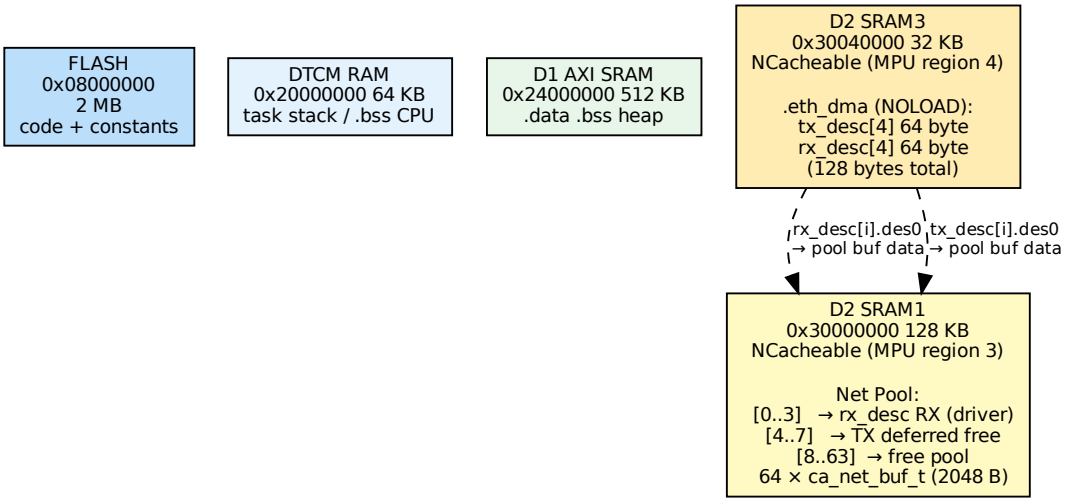
The PC must be connected directly to the board with an Ethernet cable (straight-through or crossover — LAN8742A supports Auto-MDI/MDIX).

56.1.2 System architecture



(source: `doc/diagrams/ex33_arch.dot`)

Memory map

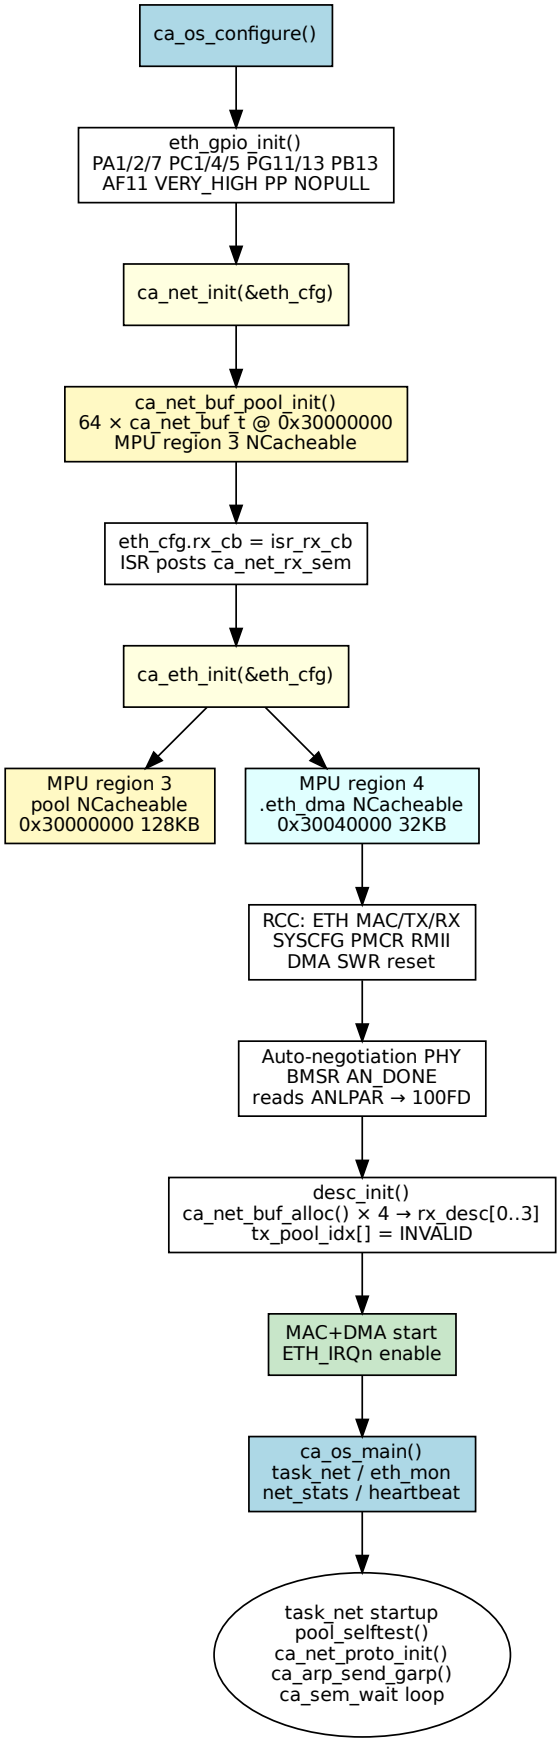


(source: `doc/diagrams/ex33_memory.dot`)

Region	Address	Size	Usage	MPU
D2 SRAM1	0x30000000	128 KB	Net pool (64 × ca_net_buf_t, 2 KB)	Region **4** NCacheable
D2 SRAM3	0x30040000	32 KB	.eth_dma: tx_desc[16] + rx_desc[8]	Region **5** NCacheable

The pool is in D2 SRAM1 NCacheable: the ETH DMA accesses the buffers directly without going through the D-cache. No cache flush/invalidate operations are necessary in the RX/TX hot path.

Initialization flow



(source: `doc/diagrams/ex33_init_flow.dot`)

56.1.3 Source code

The file is located in `examples/example_33/ca_os_ex33.c`.

1. Network configuration

```
static const ca_mac_t  s_mac = { .v = { 0x02U, 0x00U, 0x00U, 0x00U, 0x00U, 0x33U } };
static const ca_ipv4_t s_ip  = { .v = { 192U, 168U, 10U, 33U } };

static const ca_net_cfg_t net_cfg = {
    .ip  = { .v = { 192U, 168U, 10U, 33U } },
    .mac = { .v = { 0x02U, 0x00U, 0x00U, 0x00U, 0x00U, 0x33U } },
    .arp  = { .renew_ms = 30000U, .cache_size = 0U },
    .udp  = { .bindings = {{0}}, .count = 0U },
    .icmp = { .echo_reply = true },
};

static ca_eth_cfg_t eth_cfg = {
    .phy_addr = 0U,
    .rmii     = true,
    .mac      = { .v = { 0x02U, 0x00U, 0x00U, 0x00U, 0x00U, 0x33U } },
    .link_cb  = on_link_change,
    /* rx_cb / error_cb: sovrascritti da ca_net_init() */
};
```

`ca_net_cfg_t` configures the net layer: static IP, MAC, ARP parameters (no cache, renew every 30 s), no UDP binding in this demo, ICMP echo reply enabled. `ca_eth_cfg_t` has only `link_cb` set — `rx_cb` is overwritten by `ca_net_init()` which points it to its own ISR handler.

2. Pool self-test

The `pool_selftest()` function performs five checks before starting traffic:

```
static void pool_selftest(void)
{
    /* Step 1: check the physical range (must be in D2 SRAM1) */
    u32 addr = (u32)ca_net_buf_ptr(0);
    /* addr must be in [0x30000000, 0x30020000) */

    /* Step 2: allocate everything the pool can still give.
     * ca_eth_init() has already loaded ETH_RX_N buffers into the RX descriptors,
     * so the pool is NOT pristine: the expected value is NET_BUF_COUNT - held.
     */
    u16 held     = ca_eth_pool_held_count();
    u16 expected = (u16)(NET_BUF_COUNT - held);
    u16 saved[NET_BUF_COUNT];
    u16 n = 0U;
    for (; n < NET_BUF_COUNT; n++) {
        saved[n] = ca_net_buf_alloc();
        if (saved[n] == NET_BUF_INVALID) break;
    }
    /* n == expected     PASS */

    /* Step 3: the next alloc must fail (pool exhausted) */
    u16 extra = ca_net_buf_alloc();
    /* extra == NET_BUF_INVALID     PASS */

    /* Step 4: free everything, check the count */
```

```
    for (u16 i = 0U; i < n; i++) ca_net_buf_free(saved[i]);
    u16 after = ca_net_buf_free_count();
    /* after + held == NET_BUF_COUNT     PASS (no leak) */

    /* Step 5: check index uniqueness (bitmap) */
    u8 seen[NET_BUF_COUNT / 8U + 1U] = {0};
    /* allocate all, check no duplicate index     PASS */
}
```

Typical output on USB CDC:

```
--- pool selftest ---
  pool[0] @ 0x30000000  D2-SRAM1 OK
  alloc 56/56 (driver holds 8): PASS
  alloc when full: INVALID PASS
  free_count after restore: 56/56 (+8 held)  PASS
  unique indices: PASS
--- pool selftest done  free=56 ---
```

The pool is in D2 SRAM1 (`0x30000000`) — the physical address verification confirms that MPU NCacheable region 4 is active and the pool did not end up in DTCM or AXI SRAM.

3. `task_net` — RX loop

```
static u32 task_net(void *arg)
{
    (void)arg; (void)arg2;

    ca_usb_cdc_wait_connected(5000);
    ca_os_sleep(300);

    /* ... print banner, pool_selftest ... */

    ca_net_proto_init(&net_cfg);   /* registers the ARP/ICMP/UDP handlers */

    ca_os_sleep(500);
    ca_eth_link_poll();
    ca_arp_send_garp();
    ca_os_sleep(50);

    ca_stdout_printf_n("Net task ready -- waiting frames");

    while (1) {
        ca_sem_wait(&ca_net_rx_sem);   /* unblocked by the ETH ISR */
        ca_net_process();              /* swap RX, dispatch, reply */
    }
    return 0;
}
```

The task waits for the semaphore `ca_net_rx_sem` posted by the ETH ISR (connected via `rx_cb` in `ca_net_init`). `ca_net_process()` executes the RX swap loop and dispatches to the protocols: for every received frame, it allocates a replacement buffer, calls `ca_eth_recv`, delivers the frame to `net_proto` which constructs the response (ARP reply or ICMP echo), and transmits it via `ca_net_send()`.

> **Why a semaphore instead of polling sleep?** With the semaphore, the task consumes 0% CPU when no frames arrive. With a `ca_os_sleep(10)` + polling, frames would be lost during bursts and CPU would be wasted.

4. Gratuitous ARP

```
ca_arp_send_garp();
```

`ca_arp_send_garp()` (in `caos/net/src/arp_service.c`) allocates a buffer pool, constructs an ARP REQUEST frame with SPA==TPA=local IP and broadcasts it. It forces all peers on the LAN to update their ARP cache with the new MAC→IP binding of the board.

5. Pool diagnostics (on request, via CLI)

The example no longer has a periodic statistics task: counters, pool and leak check are asked of the ETH driver CLI (`caos/drivers/src/eth.c`):

Command	What it prints
`eth stats`	`rx`, `tx`, `rx_drop`, `tx_fail`, `no_hdl`, `err_bus`, `err_rbu` from `ca_net_stats()`
`eth pool`	`pool_free`, `driver_held`, historical minimum (`low_water`) and refused allocations (`alloc_fail`)
`eth dump`	registers and DMA rings (`ca_eth_dbg_dump()`)

The leak check is still the relation `pool_free + driver_held == NET_BUF_COUNT`; `eth pool` also reports a pool that ran dry and refused double frees.

6. Auxiliary tasks

```
static void on_link_change(bool up)
{
    if (up) ca_led_on(1U); else ca_led_off(1U);
    ca_stdout_printf_n("ETH LINK %s", up ? "UP" : "DOWN");
}

static u32 task_eth_mon(void *arg)
{
    (void)arg;
    while (1) {
        ca_eth_link_poll();
        ca_os_sleep(500);
    }
    return 0;
}

static u32 task_heartbeat(void *arg)
{
    (void)arg;
    while (1) {
        ca_led_toggle(3U);
        ca_os_sleep(500);
    }
    return 0;
}
```

7. ca_os_configure and ca_os_main

```
void ca_os_configure(void)
{
    EVAL_STDOUT(
        ca_stdout_init();
        ca_stdout_set_sender(STDOUT);
```

```
        ca_stdout_create_thread();
    )
    EVAL_CLI(
        ca_cli_init(2048);
        ca_cli_set_sender(STDOUT);
        ca_cli_create_thread();
    )
    EVAL_USB_CDC_STD(ca_usb_dev_mng_cdc_cli();)

    ca_led_off(1U);
    ca_led_init();
    ca_led_off(3U);

    eth_gpio_init();
    if (!ca_net_init(ca_eth_iface_get(&eth_cfg))) {
        CA_SAFE_FAIL("ca_net_init");
    }

    /* ARP replies come from net_proto's own handler, so the wire works even
     * without this - which is why its absence went unnoticed. What was missing
     * is the SERVICE: the cache, and the node that puts "arp" in the CLI
     * (arp_service.c registers it here, under EN_CLI_ARP). ca_arp_send_garp()
     * in task_net was also being called on an uninitialised service.
     * Unlike the DHCP examples, the address is known at compile time here, so
     * it is passed straight in rather than as 0.0.0.0 to be filled in later. */
    ca_arp_service_init(s_mac, s_ip);
}

void ca_os_main(void)
{
    ca_os_job("net",       CA_TH_LEVEL4, task_net,       NULL,
              STACK_SMALL, CA_JOB_STD, CA_FAULT_RESTART_THREAD);
    ca_os_job("eth_mon",   CA_TH_LEVEL3, task_eth_mon,   NULL,
              STACK_SMALL, CA_JOB_STD, CA_FAULT_RESTART_THREAD);
    ca_os_job("heartbeat", CA_TH_LEVEL4, task_heartbeat, NULL,
              STACK_SMALL, CA_JOB_STD, CA_FAULT_RESTART_THREAD);
    ca_os_run(true);
}
```

`ca_net_init()` internally executes `ca_net_buf_pool_init()` before `ca_eth_init()`: a mandatory order because `desc_init()` pre-allocates `ETH_RX_N` RX buffers (8 on H753, 4 elsewhere) from the pool. In example 32, the pool is explicitly initialized by the application; here `ca_net_init` does it transparently.

`task_net` has **CA__TH__LEVEL4**: in the weighted CFS it gets twice the CPU share of the link monitor (LEVEL3), which only does an MDIO poll every 500 ms.

56.1.4 Expected output

Startup

```
=== EX33: caOS net stack ===
Pool: 64 bufs x 2048 B = 128 KB
MAC  02:00:00:00:00:33
IP   192.168.10.33

--- pool selftest ---
  pool[0] @ 0x30000000  D2-SRAM1 OK
  alloc 56/56 (driver holds 8): PASS
  alloc when full: INVALID PASS
```

```
  free_count after restore: 56/56 (+8 held)  PASS
  unique indices: PASS
--- pool selftest done  free=56 ---

ETH LINK UP
Net task ready -- waiting frames
```

Warm restart (reset without power cycling). The PHY is not reset along with the MCU, so the link is already UP and the PC continues to send broadcasts. Two normal consequences, not to be mistaken for defects: `no_handler` counts some frames that arrived **before** `ca_net_proto_init()` registered the handlers, and `ETH LINK UP` is printed very early — during `ca_os_configure()`, therefore **above** the `=== EX33: ===` banner. The `on_link_change` callback triggers only on a state **change**: to see it again, simply unplug and replug the cable.

arping from PC

```
$ sudo arping -c 5 -I eth0 192.168.10.33
ARPING 192.168.10.33 from 192.168.10.1 eth0
Unicast reply from 192.168.10.33 [02:00:00:00:00:33]  1.23ms
Unicast reply from 192.168.10.33 [02:00:00:00:00:33]  0.98ms
...
5 packets transmitted, 5 packets received,   0% unanswered
```

ping from PC

```
$ ping -c 5 192.168.10.33
64 bytes from 192.168.10.33: icmp_seq=1 ttl=255 time=0.85 ms
64 bytes from 192.168.10.33: icmp_seq=2 ttl=255 time=0.82 ms
...
5 packets transmitted, 5 received, 0% packet loss
rtt min/avg/max = 0.82/0.85/0.89 ms
```

Statistics (`eth stats`, `eth pool`)

```
> eth stats
rx=331 tx=331 rx_drop=0 tx_fail=0 no_hdl=0 err_bus=0 err_rbu=2
> eth pool
pool_free=55/64  driver_held=9
```

`pool_free=55`: 8 fixed buffers in RX descriptors (`ETH_RX_N`) + 1 TX buffer in deferred free = 9 "held" buffers → 64 55 = 9, **no actual leak**.

The number of held buffers is not constant and depends on the part. `ETH_RX_N` is **8 on H753** and 4 on other families; `ETH_TX_N` is **16 on H753** and 4 elsewhere. The leak criterion is never the absolute value, but the relationship `pool_free + driver_held == NET_BUF_COUNT` — the same one verified by the self-test.

Moment	`pool_free`	`driver_held`	Composition
immediately after init	56	8	8 preloaded RX
at rest, after the first TX	55	9	8 RX + 1 deferred TX
after sustained traffic	**40**	**24**	8 RX + **16 TX** (full ring)

The growth up to 24 is **correct**: the *deferred free* releases the buffer of a TX slot only when that slot is **reused**, therefore at idle traffic each slot holds its own last

buffer. On H753 this immobilizes 16 2 KB buffers (**32 KB**, 25% of the pool) — with `NET_BUF_COUNT=64` there is margin, but it must be kept in mind when sizing the pool on smaller parts.

A real leak is recognized because `pool_free + driver_held` **drops below 64**, not because `pool_free` decreases.

Verified under real load (Example 44, iperf at 33 Mbps sustained): the sum remains **exactly 64** and `driver_held` stops at 24 without exceeding it. 24 is therefore a **structural ceiling**, not a progressive accumulation.

`err_rbu=2`: Ring Buffer Unavailable — the DMA had exhausted the RX buffers during an initial burst; the ISR restarts the DMA automatically.

56.1.5 Technical notes

Network init sequence

```
ca_os_configure()
            ca_net_init(&eth_cfg)
                  ca_net_buf_pool_init()            pool in D2 SRAM1 NCacheable
                  eth_cfg.rx_cb = isr_rx_cb         semaforo in ISR
                  ca_eth_init(&eth_cfg)
                        ca_eth_hw_init()
                                MPU region 3: pool NCacheable
                                MPU region 4: .eth_dma NCacheable
                                RCC, SYSCFG RMII, reset DMA
                                auto-neg PHY (BMSR AN_DONE)
                                desc_init():
                                        ca_net_buf_alloc()    4      rx_desc
    [0..3].des0
                                        SCB_CleanDCache (descriptor, NCacheable
        no-op)
                                MAC+DMA start, ETH_IRQn enable
                        return true

ca_os_main()
            task_net: ca_net_proto_init()     registra ARP/ICMP handler
```

RX semaphore and throughput

The `ca_net_rx_sem` semaphore is posted by the ETH ISR (interrupt context). `ca_net_process()` empties the RX ring in a loop (it does not stop at the first frame): a single `ca_sem_post` can unblock the processing of multiple frames accumulated between one wake-up and the next.

With a 1 ms inter-packet ping (`ping -i 0.001 -s 1472`), typical RTTs of 0.8–1.2 ms are obtained, limited primarily by the USB CDC latency of the log terminal.

Handling `err_rbu` (RX Buffer Unavailable)

`err_rbu` increments when the DMA reaches the end of the RX ring before `ca_net_process()` has swapped the buffer. The driver detects the stall via the `RBU` bit in `DMACSR` and restarts the RX DMA channel by writing `DMACRDTPR`. No frames are lost (the DMA stops, it does not overwrite): upon restart, it resumes from the next free descriptor.

To reduce `err_rbu`: increase `ETH_RX_N` (from 4 to 8) or increase the priority of `task_net`.

`ca_net_proto_init` vs `ca_net_init`

Function	Role
`ca_net_init(cfg)`	Initializes pool, ETH driver, RX ISR. Call in `ca_os_configure`.
`ca_net_proto_init(cfg)`	Registers ARP/ICMP/UDP handlers. Call at the start of the net task (after stdout is active).

The two functions are separated to allow hardware initialization (pool + MAC + DMA) in `ca_os_configure` (without the OS active) and to register protocols after the task has stdout available for debug prints.

Chapter 57

Multi-Client UDP Server on Port 7961

57.1 Example 34 — Multi-client UDP Server on port 7961

57.1.1 Introduction

Example 34 adds a **multi-client UDP server** to the caOS net layer, again on NUCLEO-H753ZI (STM32H753ZI, PHY LAN8742A RMII). Objectives:

1. **UDP server** listening on port 7961 with up to 4 simultaneous clients.
2. **Echo** of received data with prefix `"ECHO: "`.
3. **Automatic disconnection** after 10 s of client inactivity.
4. **Integrated ARP service**: automatic MAC resolution for UDP responses.
5. **CLI** integrated into the `ca_udp_server` service — commands `udp stats`, `udp list`, `udp kick`, `udp send` available automatically.

Unlike example 33 (passive ARP + ICMP), here a UDP client sends data to the server which responds actively; each client gets a dedicated worker thread managed internally by `ca_udp_server` .

Hardware (NUCLEO-H753ZI, MB1364)

Identical to example 33 — same RMII pinout, same LEDs.

Signal	MCU Pin	Description
LED1 (green)	PB0	ON = link UP
LED3 (red)	PB14	Heartbeat 500 ms
ETH_RMII_REF_CLK	PA1	RMII 50 MHz clock from PHY
ETH_MDIO	PA2	MDIO PHY management data
ETH_RMII_CRS_DV	PA7	Carrier Sense / Data Valid
ETH_MDC	PC1	MDIO clock
ETH_RMII_RXD0	PC4	RX data bit 0
ETH_RMII_RXD1	PC5	RX data bit 1
ETH_RMII_TX_EN	PG11	Transmission enabled
ETH_RMII_TXD1	PB13	TX data bit 1
ETH_RMII_TXD0	PG13	TX data bit 0

Required configuration in `os_config.h`

```
#define EN_ETH           1   /* driver Ethernet HW */
#define EN_NET           1   /* net_proto stack (requires EN_ETH) */
#define EN_ARP_SERVICE   1   /* ARP cache + automatic resolution */
#define EN_UDP_SERVER    1   /* UDP server multi-client */
```

PC test procedure

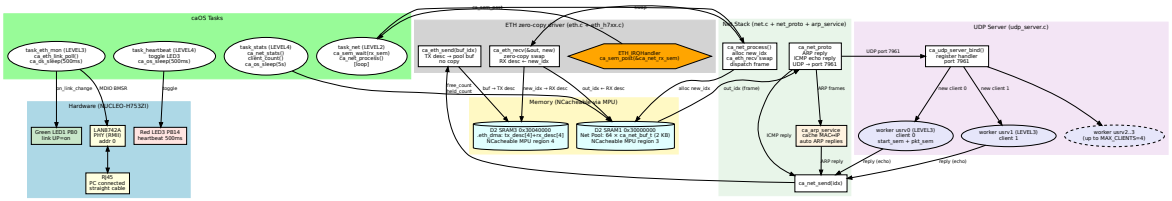
```
sudo ip addr add 192.168.10.1/24 dev eth0

# Single packet test:
echo "hello" | nc -u -q1 192.168.10.34 7961

# Interactive session (CTRL+C to quit):
nc -u 192.168.10.34 7961
```

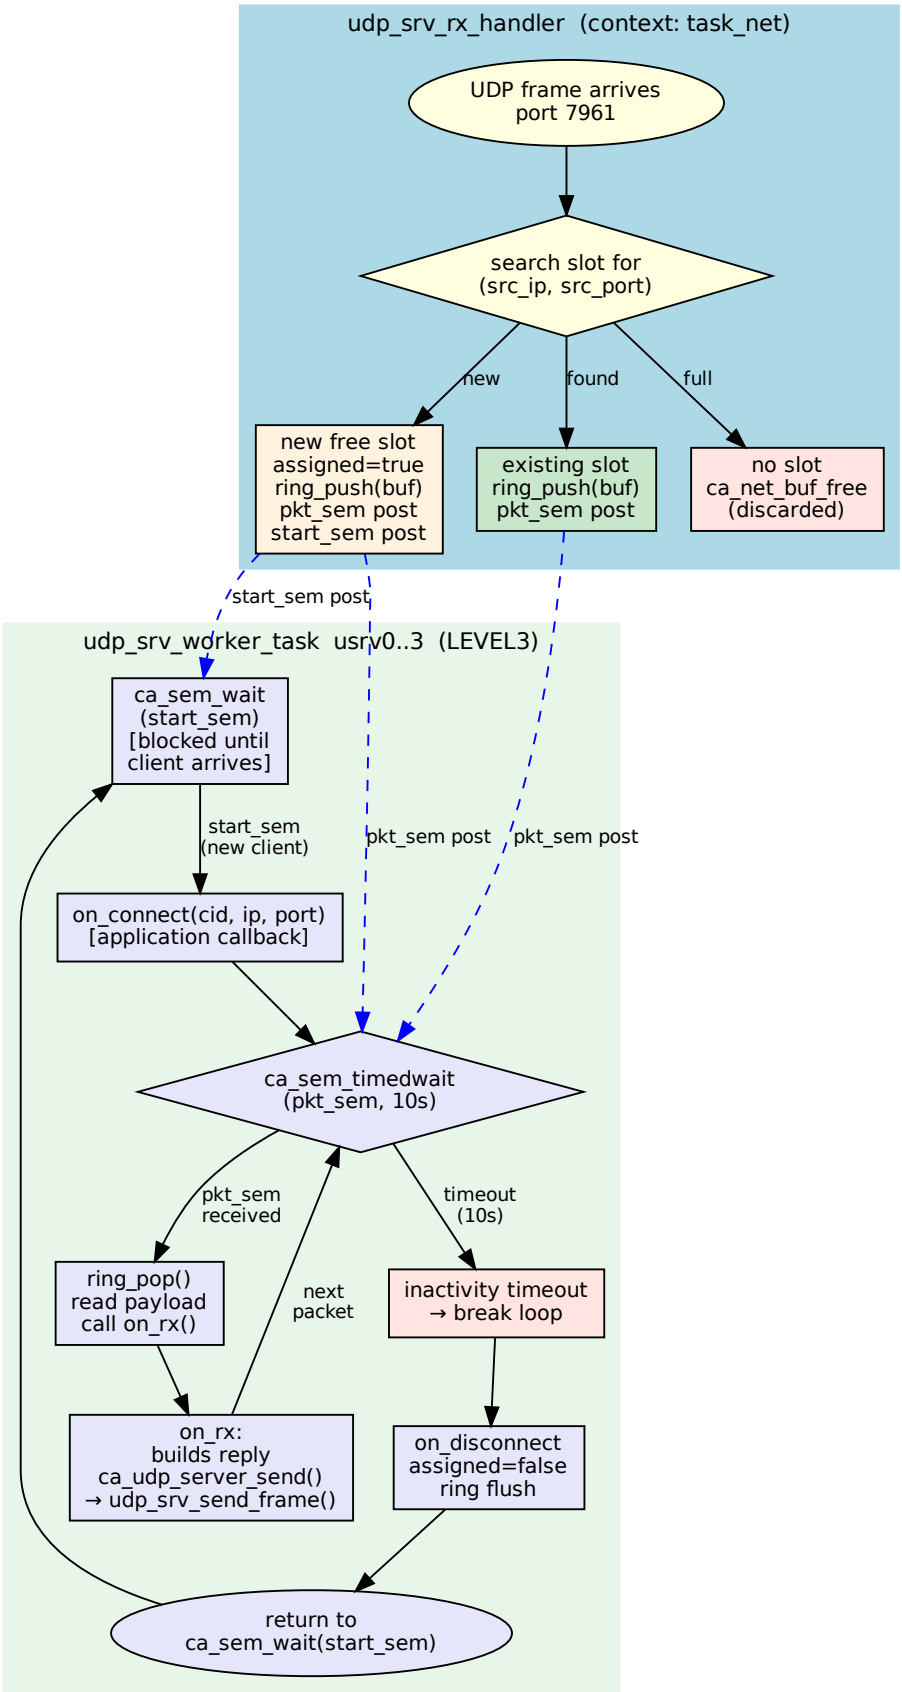
The server responds with `ECHO: <message>`. After 10 s without packets, the connection is closed (on_disconnect printed to console).

57.1.2 System architecture



(source: `doc/diagrams/ex34_arch.dot`)

UDP server worker flow



(source: `doc/diagrams/ex34_worker_flow.dot`)

Memory map

Identical to example 33:

Region	Address	Size	Usage	MPU
D2 SRAM1	0x30000000	128 KB	Net pool (64 × ca_net_buf_t, 2 KB)	Region 3 NCacheable
D2 SRAM3	0x30040000	32 KB	.eth_dma: tx_desc[4]+rx_desc[4]	Region 4 NCacheable

Differences compared to example 33

Aspect	Ex 33	Ex 34
Additional dependencies	—	EN_ARP_SERVICE, EN_UDP_SERVER
UDP port	none (no binding)	7961 (server)
Simultaneous clients	—	up to 4
ARP service	no	yes (`ca_arp_service`)
task_net priority	LEVEL1	LEVEL2
Worker thread	—	usrv0..3 (LEVEL3)
CLI	—	via integrated `ca_udp_server`

`task_net` is at LEVEL2 (not LEVEL1 as in ex33) because UDP workers must be able to respond to clients without having to wait for RX processing.

57.1.3 Source code

The file is located in `examples/example_34/ca_os_ex34.c`.

1. Network configuration

```
static const ca_mac_t  s_mac = { .v = { 0x02U, 0x00U, 0x00U, 0x00U, 0x00U, 0x34U } };
static const ca_ipv4_t s_ip  = { .v = { 192U, 168U, 10U, 34U } };

static ca_eth_cfg_t eth_cfg = {
    .phy_addr = 0U,
    .rmii     = true,
    .mac      = { .v = { 0x02U, 0x00U, 0x00U, 0x00U, 0x00U, 0x34U } },
    .link_cb  = on_link_change,
};

static const ca_net_cfg_t net_cfg = {
    .ip   = { .v = { 192U, 168U, 10U, 34U } },
    .mac  = { .v = { 0x02U, 0x00U, 0x00U, 0x00U, 0x00U, 0x34U } },
    .arp  = { .renew_ms = 30000U },
    .udp  = { .bindings = { {0U, NULL} }, .count = 0U },
    .icmp = { .echo_reply = true },
};
```

`s_mac` and `s_ip` are passed to `ca_arp_service_init()` and used in the construction of the GARP. Initialization with `.v = {}` is mandatory: the first member of `ca_ipv4_t` is `u32 addr` and the first of `ca_mac_t` is the struct `raw` — without `.v` only the first field would be initialized.

2. UDP server configuration

```
#define UDP_SRV_PORT       7961U
#define MAX_CLIENTS        4U
#define CLIENT_TIMEOUT_MS  10000U

static const ca_udp_server_cfg_t srv_cfg = {
    .port              = UDP_SRV_PORT,
    .max_clients       = MAX_CLIENTS,
    .client_timeout_ms = CLIENT_TIMEOUT_MS,
    .local_mac         = { .v = { 0x02U, 0x00U, 0x00U, 0x00U, 0x00U, 0x34U } },
    .local_ip          = { .v = { 192U, 168U, 10U, 34U } },
    .on_rx             = on_rx,
    .on_connect        = on_connect,
    .on_disconnect     = on_disconnect,
};
```

`local_mac` and `local_ip` in the server configuration are used to build the TX frames of UDP responses (Ethernet + IP header).

3. Callbacks

```
static void on_connect(u8 cid, ca_ipv4_t ip, u16 port)
{
    ca_stdout_printf_n("UDP[7961] client %u: %u.%u.%u.%u:%u connected",
        (u32)cid, ip.v[0], ip.v[1], ip.v[2], ip.v[3], (u32)port);
}

static void on_disconnect(u8 cid, ca_ipv4_t ip, u16 port)
{
    ca_stdout_printf_n("UDP[7961] client %u: %u.%u.%u.%u:%u disconnected",
        (u32)cid, ip.v[0], ip.v[1], ip.v[2], ip.v[3], (u32)port);
}

static void on_rx(u8 cid, ca_ipv4_t ip, u16 port,
                  const u8 *pld, u16 len)
{
    u8 reply[256U];
    static const u8 pfx[] = "ECHO: ";
    const u16 pfxlen = (u16)(sizeof(pfx) - 1U);
    u16 rlen = pfxlen + len;
    if (rlen > (u16)sizeof(reply)) rlen = (u16)sizeof(reply);
    for (u16 i = 0U; i < pfxlen; i++) reply[i] = pfx[i];
    u16 dlen = rlen - pfxlen;
    for (u16 i = 0U; i < dlen; i++) reply[pfxlen + i] = pld[i];

    ca_udp_server_send(cid, reply, rlen);
}
```

Callbacks are called in the context of the **worker task** `usrv<N>` — not the task_net. This allows performing blocking operations (e.g., wait on a resource) without blocking the RX processing of other clients.

`on_rx` builds the response on the stack (local buffer `reply[256]`) and sends it with `ca_udp_server_send(cid, ...)` which allocates a buffer pool and calls `ca_net_send()`.

4. `task_net` — RX loop

```
static u32 task_net(void *arg)
{
    ca_net_proto_init(&net_cfg);   /* registers the ARP/ICMP handler */
    ca_udp_server_bind();          /* registers the port 7961 handler */
```

```
5
6       ca_eth_link_poll();
7       ca_arp_send_garp();
8
9       while (1) {
10          ca_sem_wait(&ca_net_rx_sem);
11          ca_net_process();
12      }
13  }
```

`ca_udp_server_bind()` must be called **after** `ca_net_proto_init()`: it registers its own handler in the protocol stack's UDP table. Packets on port 7961 are delivered directly to the `udp_srv_rx_handler` which handles demultiplexing for clients.

5. ca_os_configure and ca_os_main

```
1   void ca_os_configure(void)
2   {
3       /* ... stdout, CLI, USB CDC, GPIO, ETH ... */
4       if (!ca_net_init(&eth_cfg))
5           CA_SAFE_FAIL("ca_net_init");
6
7       ca_arp_service_init(s_mac, s_ip);  /* init ARP cache */
8       /* CLI udp* commands registered automatically by ca_udp_server_start() */
9   }
10
11  void ca_os_main(void)
12  {
13      ca_arp_service_start();             /* avvia task ARP */
14      ca_udp_server_start(&srv_cfg);      /* starts workers usrv0..3 */
15
16      ca_os_job("net",       CA_TH_LEVEL2, task_net,    ...);
17      ca_os_job("eth_mon",   CA_TH_LEVEL3, task_eth_mon, ...);
18      ca_os_job("net_stats", CA_TH_LEVEL4, task_stats,  ...);
19      ca_os_job("heartbeat", CA_TH_LEVEL4, task_heartbeat, ...);
20      ca_os_run(true);
21  }
```

Mandatory order: 1. `ca_net_init()` (in `ca_os_configure`) — initialize pool + ETH + ISR 2. `ca_arp_service_init()` (in `ca_os_configure`) — init ARP cache (no OS yet) 3. `ca_arp_service_start()` (in `ca_os_main`) — start ARP task (OS active) 4. `ca_udp_server_start()` (in `ca_os_main`) — create worker thread (OS active) 5. `ca_net_proto_init()` + `ca_udp_server_bind()` (in `task_net`) — register handler

6. UDP CLI commands

CLI commands are automatically registered by `ca_udp_server_start()` via `ca_cli_register()` — they do not require hooks in the example code.

Command	caOS function	Description
`udp stats`	`ca_net_stats()`, `ca_udp_server_client_count()`	Network counters + active clients
`udp list`	`ca_udp_server_get_client(i, &info)`	IP/port/ring for each slot
`udp kick <id>`	`ca_udp_server_disconnect(id)`	Force slot closure (0–3)
`udp send <id> <msg>`	`ca_udp_server_send(id, ...)`	Send data to active client

57.1.4 Multi-client model — UDP Server API

Opening a connection (server-side)

A "client" is identified by the `(src_ip, src_port)` pair of the first UDP packet received. There is no TCP handshake: any packet from a new source opens a slot. Free slots: `MAX_CLIENTS - ca_udp_server_client_count()`.

Worker thread model

Each `[0..MAX_CLIENTS-1]` slot has its own `usrv<N>` task created by `ca_udp_server_start()`. Workers are **always running**: blocked on `start_sem` when free, active in the `pkt_sem` loop when they have a client.

```
free slot:
  usrv<N>       ca_sem_wait(start_sem)  [blocked]

new packet from an unknown IP:
  udp_srv_rx_handler:
    assegna slot N
    ring_push(buf)
    ca_sem_post(&pkt_sem)
    ca_sem_post(&start_sem)       unblocks the worker

  usrv<N>       on_connect(N, ip, port)
                loop: ca_sem_timedwait(pkt_sem, 10s)
                     ring_pop()     on_rx()     ca_udp_server_send()

timeout 10s:
  usrv<N>       on_disconnect(N, ip, port)
                assigned=false
                ca_sem_wait(start_sem)  [blocked, ready for a new client]
```

Public API

```
/* Avvia i worker thread (chiamare in ca_os_main, OS attivo) */
bool ca_udp_server_start(const ca_udp_server_cfg_t *cfg);

/* Registers the UDP handler (call in task_net after ca_net_proto_init) */
bool ca_udp_server_bind(void);

/* Sends data to the active client (call from the on_rx callback or another task
   ) */
bool ca_udp_server_send(u8 client_id, const u8 *payload, u16 len);

/* Forces a client to disconnect */
void ca_udp_server_disconnect(u8 client_id);

/* Number of clients currently assigned */
u8 ca_udp_server_client_count(void);

/* Info on a slot (returns false if not assigned) */
bool ca_udp_server_get_client(u8 client_id, ca_udp_srv_client_info_t *info);
```

57.1.5 Expected output

Startup

```
=== EX34: UDP server porta 7961 ===
MAC  02:00:00:00:00:34
IP   192.168.10.34
ETH LINK UP
GARP 192.168.10.34  pool_free=59  OK
UDP server ready
```

Client connection

```
$ echo "hello caos" | nc -u -q1 192.168.10.34 7961
ECHO: hello caos
```

MCU Console:

```
UDP[7961] client 0: 192.168.10.1:54321 connesso
UDP[7961] client 0: rx 10 bytes from 192.168.10.1:54321
UDP[7961] client 0: 192.168.10.1:54321 disconnesso
```

Multi-client session (CLI)

```
> udp stats
NET  rx=47 drop=0 tx=23
POOL free=59/64 held=5
UDP  port=7961 clients=2/4

> udp list
  [0] 192.168.10.1:54321  ring=0
  [1] 192.168.10.2:48102  ring=1

> udp kick 1
client 1 disconnesso

> udp send 0 hello from the server
send client 0: ok
```

Statistics (every 5 s)

```
STATS pool_free=59/64 rx=134 drop_pool=0 tx=67 clients=1
```

57.1.6 Technical notes

ARP service vs ARP in net_proto

`ca_net_proto_init()` already handles unicast ARP responses directed to the board. `ca_arp_service` adds a **MACIP cache**: when the server needs to send a UDP response to a client, it already has the resolving MAC in the cache without having to perform a blocking ARP request.

Without `EN_ARP_SERVICE`, the server might use the broadcast MAC as a fallback (less efficient, discards unnecessary traffic on the LAN).

Client timeout and concurrency

The 10 s timeout is implemented with `ca_sem_timedwait` in the worker: if no packets arrive within the timeout, the loop exits, calls `on_disconnect`, and the slot is freed for a new client.

Concurrency between `udp_srv_rx_handler` (task_net context) and the worker (task usrv context) is protected by `s_srv_mtx`. The ring buffer is the only shared data structure and is always accessed under a mutex.

Task priorities

```
LEVEL1: (not used in ex34     reserved for more urgent tasks)
LEVEL2: task_net            processing frame RX
LEVEL3: task_eth_mon        link PHY poll
         usrv0..3           worker UDP (creati da ca_udp_server_start)
LEVEL4: task_stats          statistiche
         task_heartbeat     LED
```

`task_net` at LEVEL2 yields the CPU to workers at LEVEL3 as soon as it posts `pkt_sem`: workers respond to the client with minimal latency.

Reply sizes

The local buffer `reply[256]` in the callback `on_rx` is on the worker's `usrv<N>` **stack**. The stack is `STACK_SMALL` (configurable in `os_config.h`). For UDP payloads > 250 bytes, increase the reply buffer size or use a direct buffer pool.

Conditional compilation

```
#if EN_ETH && EN_NET && EN_UDP_SERVER
/* ... all the ex34 code ... */
#endif
```

`EVAL_ARP_SVC(expr)` and `EVAL_UDP_SRV(expr)` are macros that execute `expr` only if `EN_ARP_SERVICE` and `EN_UDP_SERVER` are both enabled.

Chapter 58

DHCP Client + ARP + ICMP Ping + UDP Server with 2 Clients

58.1 Example 35 — DHCP client + ARP + ICMP ping + UDP server 2 client

58.1.1 Introduction

Example 35 adds the **DHCP client** to the caOS net layer, still on NUCLEO-H753ZI (STM32H753ZI, PHY LAN8742A RMII). Objectives:

1. **DHCP client**: obtains IP, mask, gateway, and DNS automatically via DORA protocol (Discover → Offer → Request → Ack).
2. **Lease renewal**: T1/T2/rebinding state machine compliant with RFC 2131.
3. **ARP service**: MACIP cache, updated with the new IP after every BOUND.
4. **ICMP echo reply** (ping) — functional as soon as DHCP is BOUND.
5. **UDP server** on port 7961 with up to 2 simultaneous clients — echo with prefix `"ECHO: "`.
6. **GARP** (Gratuitous ARP) sent after every DHCP bound/renew.
7. **CLI** integrated into services — commands `dhcp info/renew` from `ca_dhcp_service`, `udp stats /list/kick/send` from `ca_udp_server`, available automatically.

Unlike example 34 (static IP), here the network address is not known a priori: the stack starts with `0.0.0.0` and updates all layers (net_proto, udp_server, arp_service) in the `on_dhcp_bound` callback.

Hardware (NUCLEO-H753ZI, MB1364)

Identical to examples 33 and 34 — same RMII pinout, same LEDs.

Signal	MCU Pin	Description
LED1 (green)	PB0	ON = link UP
LED3 (red)	PB14	Heartbeat 500 ms
ETH_RMII_REF_CLK	PA1	RMII 50 MHz clock from PHY
ETH_MDIO	PA2	MDIO PHY management data
ETH_RMII_CRS_DV	PA7	Carrier Sense / Data Valid
ETH_MDC	PC1	MDIO clock
ETH_RMII_RXD0	PC4	RX data bit 0
ETH_RMII_RXD1	PC5	RX data bit 1
ETH_RMII_TX_EN	PG11	Transmission enabled

Signal	MCU Pin	Description
ETH_RMII_TXD1	PB13	TX data bit 1
ETH_RMII_TXD0	PG13	TX data bit 0

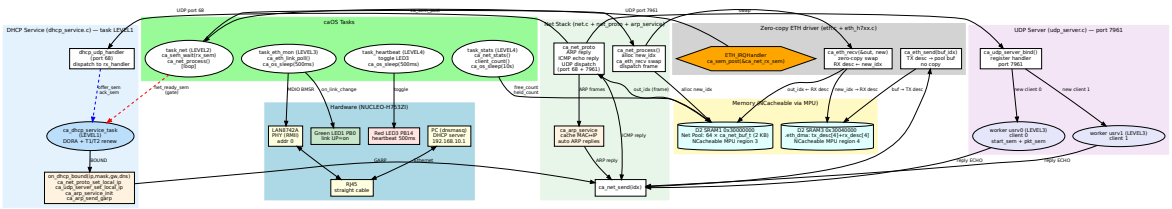
Required configuration in `os_config.h`

```
#define EN_ETH           1   /* driver Ethernet HW */
#define EN_NET           1   /* net_proto stack (requires EN_ETH) */
#define EN_NET_DHCP      1   /* DHCP parser in the proto stack */
#define EN_ARP_SERVICE   1   /* ARP cache + automatic resolution */
#define EN_UDP_SERVER    1   /* UDP server multi-client */
#define EN_DHCP_SERVICE  1   /* DHCP client DORA + T1/T2 renew */
```

DHCP parameters (modifiable in `os_config.h`):

Macro	Default	Meaning
`DHCP_DISCOVER_RETRY_N`	3	DISCOVER attempts before backoff
`DHCP_OFFER_TIMEOUT_MS`	4000	Wait for OFFER per attempt
`DHCP_REQUEST_TIMEOUT_MS`	4000	Wait for ACK after REQUEST
`DHCP_RENEW_TIMEOUT_MS`	10000	Unicast interval in RENEWING/REBINDING
`DHCP_RETRY_BACKOFF_MS`	5000	Pause before restarting DORA
`DHCP_BIND_TIMEOUT_MS`	60000	Max timeout of `ca_dhcp_service_bind()`

58.1.2 System architecture

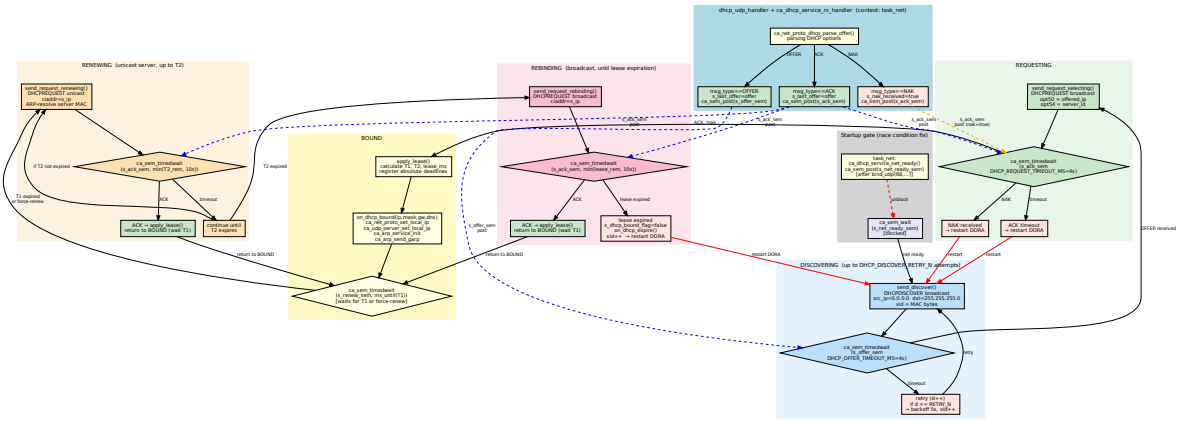


(source: doc/diagrams/ex35_arch.dot)

Initialization flow

(source: doc/diagrams/ex35_init_flow.dot)

DHCP DORA + renew state machine



(source: `doc/diagrams/ex35_dhcp_flow.dot`)

Memory map

Identical to examples 33 and 34:

Region	Address	Size	Usage	MPU
D2 SRAM1	0x30000000	128 KB	Net pool (64 × ca_net_buf_t, 2 KB)	Region 3 NCacheable
D2 SRAM3	0x30040000	32 KB	.eth_dma: tx_desc[4]+rx_desc[4]	Region 4 NCacheable

Differences compared to example 34

Aspect	Ex 34	Ex 35
IP address	static (192.168.10.34)	dynamic DHCP
Additional dependencies	EN_ARP_SERVICE, EN_UDP_SERVER	+ EN_NET_DHCP, EN_DHCP_SERVICE
LEVEL1 task	—	task_dhcp (DORA + renew)
Concurrent clients	4	2 (`MAX_CLIENTS`)
ARP init	static ip	ip=0, updated in `on_dhcp_bound`
local_ip udp server	static	0, updated in `on_dhcp_bound`
CLI	via `ca_udp_server`	+ integrated `ca_dhcp_service`
GARP	at startup	after every DHCP BOUND/renew

`task_net` remains at LEVEL2; `task_dhcp` is LEVEL1 to react to the OFFER before another task consumes the semaphore.

58.1.3 Source code

The file is located in `examples/example_35/ca_os_ex35.c`.

1. Network configuration — Dynamic IP

```
static const ca_mac_t s_mac = { .v = { 0x02U,0x00U,0x00U,0x00U,0x00U,0x35U } };

/* Dynamic IP     written by on_bound, read by task_net and the CLI */
static volatile ca_ipv4_t s_ip   = { .addr = 0U };
static volatile ca_ipv4_t s_mask = { .addr = 0U };
static volatile ca_ipv4_t s_gw   = { .addr = 0U };
static volatile ca_ipv4_t s_dns  = { .addr = 0U };
static volatile bool   s_dhcp_bound = false;

static const ca_net_cfg_t net_cfg = {
    .ip   = { .addr = 0U },   /* 0.0.0.0     updated after DHCP */
    .mac  = { .v = { 0x02U,0x00U,0x00U,0x00U,0x00U,0x35U } },
    .arp  = { .renew_ms = 30000U },
    .udp  = { .bindings = { {0U, NULL} }, .count = 0U },
    .icmp = { .echo_reply = true },
};
```

The stack starts with `IP=0.0.0.0`; the field is updated by `ca_net_proto_set_local_ip()` inside `on_dhcp_bound`.

2. UDP server configuration — dynamic local_ip

```
static ca_udp_server_cfg_t srv_cfg = {
    .port              = UDP_SRV_PORT,      /* 7961 */
    .max_clients       = MAX_CLIENTS,       /* 2 */
    .client_timeout_ms = CLIENT_TIMEOUT_MS, /* 15 s */
    .local_mac         = { .v = { 0x02U,0x00U,0x00U,0x00U,0x00U,0x35U } },
    .local_ip          = { .addr = 0U },    /* updated after DHCP */
    .on_rx             = on_rx,
    .on_connect        = on_connect,
    .on_disconnect     = on_disconnect,
};
```

`local_ip` is `0` at the time of the `ca_udp_server_start()` call; it is updated with `ca_udp_server_set_local_ip(ip)` in the DHCP callback. Without this update, UDP response frames would have `src_ip=0.0.0.0` and would be discarded by the PC.

3. Adapter for the UDP dispatcher (port 68)

```
static void dhcp_udp_handler(u16 buf_idx)
{
    ca_net_buf_t *b = ca_net_buf_ptr(buf_idx);
    u8 *frame = b->data + b->data_off;
    u16 l4_off = b->meta.rx.l4_off;
    const ca_udp_frame_t *udp = (const ca_udp_frame_t *)(frame + l4_off);
    u16 udp_total = (u16)(b->data_len - l4_off);
    ca_dhcp_service_rx_handler(udp, udp_total);
    ca_net_buf_free(buf_idx);
}
```

The dispatcher `ca_net_proto` calls UDP handlers with the signature `void handler(u16 buf_idx)`. The DHCP service instead exposes `ca_dhcp_service_rx_handler(const ca_udp_frame_t *udp, u16 len)`: this small adapter performs the conversion and frees the buffer.

4. DHCP Callback — multilayer update

```
static void on_dhcp_bound(ca_ipv4_t ip, ca_ipv4_t mask, ca_ipv4_t gw, ca_ipv4_t
    dns)
{
    s_ip = ip;  s_mask = mask;  s_gw = gw;  s_dns = dns;
    s_dhcp_bound = true;

    ca_net_proto_set_local_ip(ip);            /* proto stack */
    EVAL_UDP_SRV(ca_udp_server_set_local_ip(ip);)  /* UDP server TX */

#if EN_ARP_SERVICE
    ca_arp_service_update_local_ip(ip);       /* aggiorna local_ip ARP (no
    reinit) */
#endif

    ca_stdout_printf_n("\nDHCP BOUND  IP=%u.%u.%u.%u  mask=%u.%u.%u.%u",
        ip.v[0],ip.v[1],ip.v[2],ip.v[3],
        mask.v[0],mask.v[1],mask.v[2],mask.v[3]);
    ca_stdout_printf_n("            GW=%u.%u.%u.%u  DNS=%u.%u.%u.%u",
        gw.v[0],gw.v[1],gw.v[2],gw.v[3],
        dns.v[0],dns.v[1],dns.v[2],dns.v[3]);

    ca_arp_send_garp();
}
```

Three layers are updated in sequence: proto stack, UDP server, ARP service. The order is important: the GARP must start with the IP already set in the proto stack (otherwise, ARP response frames would still use `0.0.0.0`).

> **Note**: `ca_arp_service_update_local_ip(ip)` is used and **not** `ca_arp_service_init(s_mac, ip)`. The latter reinitializes the ARP service's internal semaphores while the task is running, causing a SAFEGUARD semaphore overflow upon the second DHCP bound.

5. task_net — gate and RX loop

```
static u32 task_net(void *arg)
{
    ca_usb_cdc_wait_connected(5000);
    ca_os_sleep(300);

    ca_net_proto_init(&net_cfg);
    ca_net_proto_bind_udp(DHCP_CLIENT_PORT, dhcp_udp_handler);
    EVAL_UDP_SRV(ca_udp_server_bind();)

    ca_eth_link_poll();
    ca_os_sleep(200);

    /* Unblocks the DHCP task     from here port 68 is ready */
    EVAL_DHCP_SVC(ca_dhcp_service_net_ready();)

    while (1) {
        ca_sem_wait(&ca_net_rx_sem);
        ca_net_process();
    }
}
```

Critical point: `ca_dhcp_service_net_ready()` must be called **after** `ca_net_proto_bind_udp(68, ...)`. Before this call, the DHCP task is blocked on `s_net_ready_sem` and cannot send a DISCOVER. Without this gate (race condition), the DHCP task (LEVEL1, highest priority) would

wake up first, send the DISCOVER, but port 68 would not yet be registered in the dispatcher → the OFFER would be silently discarded.

The task_net **does not call** `ca_dhcp_service_bind()`: that function is blocking and would freeze the net task → the `ca_net_process()` loop would not run → the OFFER/ACK packets would never be processed → deadlock. The IP arrives via the `on_dhcp_bound` callback from the DHCP task.

6. ca_os_configure and ca_os_main

```
void ca_os_configure(void)
{
    /* stdout, CLI, USB CDC, GPIO, ETH ... */
    if (!ca_net_init(&eth_cfg)) CA_SAFE_FAIL("ca_net_init");

    /* ARP service with a provisional IP; updated in on_dhcp_bound */
    EVAL_ARP_SVC({
        ca_ipv4_t zero = { .addr = 0U };
        ca_arp_service_init(s_mac, zero);
    })

    /* DHCP service: registers callbacks, inits semaphores */
    EVAL_DHCP_SVC(ca_dhcp_service_init(s_mac, on_dhcp_bound, on_dhcp_expire);)

    /* CLI dhcp commands */renew, udp*/list/kick/send registrati automaticamente
     * da ca_dhcp_service_init() e ca_udp_server_start() */
}

void ca_os_main(void)
{
    EVAL_ARP_SVC(ca_arp_service_start();)       /* task ARP (LEVEL1) */
    EVAL_DHCP_SVC(ca_dhcp_service_start();)     /* task dhcp (LEVEL1) */
    EVAL_UDP_SRV(ca_udp_server_start(&srv_cfg);) /* usrv0, usrv1 (LEVEL3) */

    ca_os_job("net",       CA_TH_LEVEL2, task_net,       ...);
    ca_os_job("eth_mon",   CA_TH_LEVEL3, task_eth_mon,   ...);
    ca_os_job("net_stats", CA_TH_LEVEL4, task_stats,     ...);
    ca_os_job("heartbeat", CA_TH_LEVEL4, task_heartbeat, ...);
    ca_os_run(true);
}
```

Mandatory order:

Step	Function	Where	Notes
1	`ca_net_init()`	`ca_os_configure`	pool + ETH + ISR
2	`ca_arp_service_init()`	`ca_os_configure`	init cache, no OS
3	`ca_dhcp_service_init()`	`ca_os_configure`	inits semaphores, no OS
4	`ca_arp_service_start()`	`ca_os_main`	create task (OS active)
5	`ca_dhcp_service_start()`	`ca_os_main`	create LEVEL1 task (blocked)
6	`ca_udp_server_start()`	`ca_os_main`	create usrv0..1 (blocked)
7	`ca_net_proto_init()`	`task_net`	register ARP/ICMP/UDP handler
8	`bind_udp(68)` + `udp_server_bind()`	`task_net`	register ports
9	`ca_dhcp_service_net_ready()`	`task_net`	unblock DHCP task

7. DHCP Service — internal state

```
typedef enum {
    DHCP_ST_INIT, DHCP_ST_DISCOVERING, DHCP_ST_REQUESTING,
```

```
    DHCP_ST_BOUND, DHCP_ST_RENEWING, DHCP_ST_REBINDING,
} dhcp_state_t;
```

Internal semaphores:

Semaphore	Producer	Consumer	Purpose
`s_net_ready_sem`	`task_net`	`task_dhcp`	gate: port 68 ready
`s_offer_sem`	`rx_handler`	`task_dhcp`	OFFER received
`s_ack_sem`	`rx_handler`	`task_dhcp`	ACK or NAK received
`s_renew_sem`	CLI (`dhcp renew`)	`task_dhcp`	force-renew
`s_dhcp_bound_flag_sem`	`task_dhcp`	`ca_dhcp_service_bind()`	BOUND event

8. Available CLI commands

Commands are automatically registered by services via `ca_cli_register()`. No hooks in the example.

Command	Service	Description
`dhcp info`	`ca_dhcp_service`	Current lease status (IP, mask, GW, DNS, T1/T2 timer)
`dhcp renew`	`ca_dhcp_service`	Force early renew
`udp stats`	`ca_udp_server`	Pool + active clients
`udp list`	`ca_udp_server`	IP:port + ring of each slot
`udp kick <id>`	`ca_udp_server`	Force slot closure
`udp send <id> <msg>`	`ca_udp_server`	Send data to active client

58.1.4 Test procedure from PC

The `examples/example_35/test_dhcp_pc.sh` script automates the entire procedure. It requires `dnsmasq`, `ip`, `ping`, `nc` (netcat-openbsd).

```
sudo ./examples/example_35/test_dhcp_pc.sh enp7s0
```

The script: 1. Assigns `192.168.10.1/24` to the specified interface. 2. Starts `dnsmasq` with pool `192.168.10.100 200`, 1 h lease. 3. Waits up to 60 s for `DHCPACK` to appear in the dnsmasq log. 4. Executes `ping -c4` to the board. 5. Sends `hello caOS` on UDP port 7961 and verifies the `ECHO:` response. 6. Launches 2 simultaneous UDP clients. 7. Prints the complete dnsmasq DHCP log. 8. Upon pressing Ctrl+C, performs cleanup (stop dnsmasq, remove IP).

Equivalent manual test:

```
# Setup PC
sudo ip addr add 192.168.10.1/24 dev eth0
# (starts dnsmasq or uses an existing DHCP server)

# Ping
ping <ip_assegnato>

# Echo UDP
echo "hello caOS" | nc -u -w2 <ip_assegnato> 7961

# 2 simultaneous clients
echo -n "client_one" | nc -u -w2 <ip_assegnato> 7961 &
echo -n "client_two" | nc -u -w2 <ip_assegnato> 7961 &
wait
```

58.1.5 Expected output

MCU Console (USB CDC)

```

58.1.6 Technical notes

Race conditions and gate `s_net_ready_sem`

The DHCP task is at LEVEL1 (more urgent than the task_net at LEVEL2). Without explicit synchronization, the DHCP task would wake up before the task_net and send the DISCOVER when port 68 is not yet registered in the dispatcher. The OFFER from the DHCP server would be silently discarded.

The solution is a gate semaphore (`s_net_ready_sem`) with an initial value of 0: the DHCP task blocks on `ca_sem_wait(&s_net_ready_sem)` and resumes only when the task_net calls `ca_dhcp_service_net_ready()` after completing `ca_net_proto_bind_udp(68, ...)`.

Deadlock and prohibition of `ca_dhcp_service_bind()` in task_net

`ca_dhcp_service_bind()` blocks the caller until the BOUND arrives or `DHCP_BIND_TIMEOUT_MS` expires. If called by `task_net`, it freezes the `ca_net_process()` loop: the OFFER and ACK packets are never processed → the BOUND semaphore is never posted → permanent deadlock.

The function can only be used by application tasks that are not part of the RX path (e.g., a configuration task that waits for the IP before opening a TCP connection).

Updating `local_ip` of the UDP server

`ca_udp_server_start()` copies the passed configuration. The `s_srv_cfg.local_ip` field is used in every TX frame to construct the source IP header. If it remains `0.0.0.0`, the PC receives responses with an invalid source IP and discards them (or the kernel fails to deliver them to the UDP socket).

`ca_udp_server_set_local_ip()` is a `static inline` that updates `s_udp_srv_cfg.local_ip` directly via the extern variable exposed by the header. It is not necessary to reinitialize the server.

Task priorities

```
LEVEL1: task_dhcp       DORA + T1/T2 renew (alta priorit      reagisce subito
    all'OFFER)
         task_arp       ARP cache (same priority, does not interfere)
LEVEL2: task_net        processing frame RX
LEVEL3: task_eth_mon     link PHY poll
         usrv0, usrv1     worker UDP
LEVEL4: task_stats      statistics every 10 s
         task_heartbeat     LED
```

T1/T2 and lease renewal

By default, the dnsmasq server sends T1 = lease/2, T2 = lease×7/8. If the optional fields are absent, the DHCP service calculates them autonomously:

```
u32 t1_s = (s_last_offer.t1 != 0U) ? s_last_offer.t1 : (lease_s / 2U);
u32 t2_s = (s_last_offer.t2 != 0U) ? s_last_offer.t2
                                   : (lease_s - lease_s / 8U);
```

The force-renew from CLI (`dhcp renew`) posts `s_renew_sem` which interrupts the `ca_sem_timedwait` of the T1 wait → the task immediately transitions to RENEWING.

Conditional compilation

```
#if EN_ETH && EN_NET && EN_NET_DHCP && EN_DHCP_SERVICE && EN_UDP_SERVER
/* ... all the ex35 code ... */
#endif
```

`EVAL_DHCP_SVC(expr)`, `EVAL_ARP_SVC(expr)`, `EVAL_UDP_SRV(expr)` are macros defined in `os_config.h` that execute `expr` only if the respective service is enabled.

Chapter 59

DHCP + NTP + ARP + ICMP Ping + UDP Server

59.1 Example 36 — DHCP + NTP + ARP + ICMP ping + UDP server

59.1.1 Introduction

Example 36 adds the **NTP client** to the caOS network stack, still on the NUCLEO-H753ZI (STM32H753ZI, PHY LAN8742A RMII). Objectives:

1. **DHCP client**: obtains IP automatically (DORA + T1/T2 renew).
2. **NTP client**: synchronizes unix time with the server indicated by DHCP (option 42) or with the gateway as a fallback.
3. **ARP service**: MACIP cache, updated with the new IP after every BOUND.
4. **ICMP echo reply** (ping) — functional as soon as DHCP is BOUND.
5. **UDP server** on port 7961 with up to 2 simultaneous clients.
6. **GARP** sent after every DHCP bound/renew.
7. **CLI** integrated into the services — commands automatically registered by `ca_dhcp_service`, `ca_ntp_service`, `ca_arp_service`, `ca_udp_server`.

Compared to example 35, the new element is the NTP task synchronized via a second gate: `ca_ntp_service_net_ready()` is called by `on_dhcp_bound` after the IP has been assigned, ensuring that the NTP task does not send requests with IP=0.

Hardware (NUCLEO-H753ZI, MB1364)

Identical to examples 33–35 — same RMII pinout, same LEDs.

Signal	MCU Pin	Description
LED1 (green)	PB0	On = link UP
LED3 (red)	PB14	Heartbeat 500 ms
ETH_RMII_REF_CLK	PA1	RMII 50 MHz clock from PHY
ETH_MDIO	PA2	MDIO PHY management data
ETH_RMII_CRS_DV	PA7	Carrier Sense / Data Valid
ETH_MDC	PC1	MDIO clock
ETH_RMII_RXD0	PC4	RX data bit 0
ETH_RMII_RXD1	PC5	RX data bit 1

Signal	MCU Pin	Description
ETH_RMII_TX_EN	PG11	Transmission enabled
ETH_RMII_TXD1	PB13	TX data bit 1
ETH_RMII_TXD0	PG13	TX data bit 0

Configuration required in `os_config.h`

```
#define EN_ETH          1   /* driver Ethernet HW */
#define EN_NET          1   /* stack net_proto */
#define EN_NET_DHCP     1   /* parser DHCP */
#define EN_NET_NTP      1   /* parser NTP */
#define EN_ARP_SERVICE  1   /* ARP cache + resolve */
#define EN_UDP_SERVER   1   /* UDP server multi-client */
#define EN_DHCP_SERVICE 1   /* DHCP client DORA + T1/T2 renew */
#define EN_NTP_SERVICE  1   /* NTP client with polling */
```

59.1.2 System architecture

Differences compared to example 35

Aspect	Ex 35	Ex 36
NTP client	no	yes (`ca_ntp_service`)
Additional dependencies	—	+`EN_NET_NTP`, `EN_NTP_SERVICE`
Additional tasks	—	`task_ntp` (LEVEL1, blocked on `s_ntp_ev_q`)
NTP gate	—	`ca_ntp_service_net_ready()` in `on_dhcp_bound`
CLI	integrated dhcp+udp	+`ntp info/sync`, `arp info` integrated
STATS	`dhcp=%s`	`dhcp=%s ntp=%s`

Init flow

```
ca_os_configure():
  ca_net_init()
  ca_arp_service_init(mac, 0.0.0.0)
  ca_dhcp_service_init(mac, on_bound, on_expire)
  ca_ntp_service_init(fallback_ip, mac, on_sync, on_fail)

ca_os_main():
  ca_arp_service_start()    -- task LEVEL0 (blocked on req_q)
  ca_dhcp_service_start()   -- task LEVEL1 (blocked on net_ready_sem)
  ca_ntp_service_start()    -- task LEVEL1 (blocked on ev_q)
  ca_udp_server_start()     -- usrv0..1 (LEVEL3, blocked)

task_net:
  ca_net_proto_init()
  ca_net_proto_bind_udp(68)     -- DHCP
  ca_udp_server_bind()          -- porta 7961
  ca_ntp_service_bind()         -- porta 123
  ca_dhcp_service_net_ready()   -- sblocca DHCP
  [loop: ca_sem_wait + ca_net_process]

on_dhcp_bound():
  ca_net_proto_set_local_ip(ip)
  ca_udp_server_set_local_ip(ip)
```

```
  ca_arp_service_update_local_ip(ip)
  ca_arp_send_garp()
  ca_ntp_service_set_server(opt42 o gw)
  ca_ntp_service_net_ready()    -- sblocca NTP
```

Task priorities

```
LEVEL0: task_arp         cache ARP (slot pool + queue)
LEVEL1: task_dhcp        DORA + T1/T2 renew
         task_ntp         NTP polling (blocked on ev_q between polls)
LEVEL2: task_net         processing frame RX
LEVEL3: task_eth_mon      link PHY poll
         usrv0, usrv1      worker UDP
LEVEL4: task_stats       statistics every 10 s
         task_heartbeat      LED
```

59.1.3 The source code

The file is located in `examples/example_36/ca_os_ex36.c`.

1. NTP server — from DHCP option 42

```c
static void on_dhcp_bound(ca_ipv4_t ip, ca_ipv4_t mask, ca_ipv4_t gw, ca_ipv4_t
    dns)
{
    /* update the proto stack, UDP server, ARP service */
    ca_net_proto_set_local_ip(ip);
    EVAL_UDP_SRV(ca_udp_server_set_local_ip(ip);)
    EVAL_ARP_SVC(ca_arp_service_update_local_ip(ip);)

    ca_arp_send_garp();

    /* Update the NTP IP: use opt42 from DHCP, fall back to the gateway */
    EVAL_NTP_SVC({
        ca_ipv4_t ntp_ip = ca_dhcp_service_get_ntp_server();
        if (ntp_ip.addr == 0U) ntp_ip = gw;
        ca_ntp_service_set_server(ntp_ip);
        ca_ntp_service_net_ready();   /* sblocca task NTP */
    })
}
```

`ca_dhcp_service_get_ntp_server()` returns the IP from the option 42 field of the ACK. If the DHCP server does not provide option 42 (common with simple dnsmasq), the gateway is used as a fallback NTP server.

`ca_ntp_service_net_ready()` is the gate for the NTP task: without this call, the task would remain blocked on the event queue and would never send requests.

2. NTP Callbacks

```c
static void on_ntp_sync(u32 unix_time)
{
    u16 yr; u8 mo, dy, hh, mm, ss;
    unix_to_dt(unix_time, &yr, &mo, &dy, &hh, &mm, &ss);
    ca_stdout_printf_n(
        "NTP SYNC  unix=%u  %04u-%02u-%02u %02u:%02u:%02u UTC", ...);
}

```

```
static void on_ntp_fail(void)
{
    ca_stdout_put_n("NTP FAIL  server unreachable");
}
```

Callbacks are called in the context of the **NTP task** (LEVEL1), not in `task_net`. They can perform blocking operations without impacting the RX path.

`unix_to_dt()` converts the UNIX timestamp into year/month/day/hour/minute/second, handling leap years and months with 28/30/31 days.

3. NTP Configuration

```
/* ca_os_configure(): server placeholder, aggiornato da on_dhcp_bound */
EVAL_NTP_SVC(ca_ntp_service_init(
    NTP_SERVER_IP_FALLBACK,   /* { 192, 168, 10, 1 } */
    s_mac,
    on_ntp_sync,
    on_ntp_fail
);)
```

The fallback `192.168.10.1` is the test PC gateway — usually the PC has an active NTP server (either ntpd or systemd-timesyncd).

4. `task_net` — port binding

```
ca_net_proto_bind_udp(DHCP_CLIENT_PORT, dhcp_udp_handler);  /* 68 */
EVAL_UDP_SRV(ca_udp_server_bind();)                          /* 7961 */
EVAL_NTP_SVC(ca_ntp_service_bind();)                         /* 123 */
```

The NTP port (123) must be registered before unlocking DHCP, otherwise the NTP task might send a request before the port is in the dispatcher and lose the response.

5. Available CLI commands

Automatically registered by services via `ca_cli_register()`. No hooks in the example.

Command	Service	Description
`dhcp info`	`ca_dhcp_service`	Lease status: IP, MASK, GW, DNS, T1/T2 timers
`dhcp renew`	`ca_dhcp_service`	Force early renew
`ntp info`	`ca_ntp_service`	Unix timestamp + formatted date/time
`ntp sync`	`ca_ntp_service`	Force immediate sync
`arp info`	`ca_arp_service`	Print ARP cache with age
`udp stats`	`ca_udp_server`	Pool + active clients
`udp list`	`ca_udp_server`	IP:port + ring usage for each slot
`udp kick <id>`	`ca_udp_server`	Disconnect client
`udp send <id> <msg>`	`ca_udp_server`	Send data to active client

59.1.4 Test procedure from PC

The `examples/example_36/test_dhcp_ntp_pc.sh` script executes the complete procedure. It requires `dnsmasq`, `ntp` (or `ntpdate`).

```
sudo ./examples/example_36/test_dhcp_ntp_pc.sh enp7s0
```

Manual test:

```
# Setup PC
sudo ip addr add 192.168.10.1/24 dev eth0
# start dnsmasq
sudo dnsmasq --no-daemon --interface=eth0 \
  --dhcp-range=192.168.10.100,192.168.10.200,1h \
  --dhcp-option=option:ntp-server,192.168.10.1

# Ping (after DHCP bound)
ping <ip_assegnato>

# NTP check: ntpd or chronyd must be running on the PC
# The board queries it on port 123 of the PC
```

59.1.5 Expected output

```
=== EX36: DHCP + NTP + ARP + ping + UDP server ===
MAC  02:00:00:00:00:36
IP   --- (waiting for DHCP)
DHCP: avvio DORA...

DHCP BOUND  IP=192.168.10.136  mask=255.255.255.0
            GW=192.168.10.1  DNS=192.168.10.1

NTP SYNC  unix=1745000000  2025-04-18 12:33:20 UTC

STATS dhcp=BOUND ntp=SYNC pool=56/64 held=8 rx=34 drop=0 tx=12 cli=0
```

CLI

```
> ntp info

NTP sync forzato

> arp cache
ARP cache:
  192.168.10.1  C0:25:A5:51:6C:13  age=4500ms
```

59.1.6 Technical notes

Two-level gate: DHCP then NTP

The NTP task must wait for two events in sequence: 1. **DHCP BOUND** — to have a valid source IP in the NTP request frames 2. **NTP server available** — to know the server IP

The gate `s_net_ready_sem` (inside `ca_ntp_service_net_ready()`) covers both: it is called only by `on_dhcp_bound`, which has already updated the IP and the NTP server. Before this call, the NTP task is blocked on the event queue.

Port 123 and `ca_ntp_service_bind()`

Port 123 (UDP) must be registered in the dispatcher **before** the NTP task sends the first request. If the binding were to happen later, the server response would arrive on port 123 but there would be no handler → `rx_no_handler++` and the response is discarded. The NTP task would time out and retry at the next poll.

Conditional compilation

```
#if EN_ETH && EN_NET && EN_NET_DHCP && EN_NET_NTP && \
    EN_DHCP_SERVICE && EN_NTP_SERVICE && EN_UDP_SERVER
```

`EVAL_NTP_SVC(expr)` is a macro defined in `os_config.h` that executes `expr` only if `EN_NTP_SERVICE=1`.

Chapter 60

DHCP + NTP + DNS + ARP + ICMP Ping + UDP Server

60.1 Example 37 — DHCP + NTP + DNS + ARP + ICMP ping + UDP server

60.1.1 Introduction

Example 37 adds the **DNS client** to the network stack of caOS, on NUCLEO-H753ZI (STM32H753ZI, PHY LAN8742A RMII). Objectives:

1. **DHCP client**: automatically obtains IP, gateway and DNS server.
2. **NTP client**: synchronizes the clock via DHCP option 42 or fallback to gateway.
3. **DNS client**: resolves hostnames to IPv4 addresses using the DNS server from DHCP (opt 6).
4. **ARP service**: MACIP cache with pool slots and queue — queue-based version.
5. **ICMP echo reply** (ping).
6. **UDP server** on port 7961 with up to 2 simultaneous clients.
7. **task_dns_demo**: at startup resolves a list of demo hostnames; the built-in CLI in `ca_dns_service` allows interactive resolutions with `dns resolve <hostname>`.

Compared to example 36, the new element is the DNS service. The task `task_dns_demo` demonstrates how to use `ca_dns_resolve()` in a blocking manner from an application task.

Hardware (NUCLEO-H753ZI, MB1364)

Identical to examples 33–36 — same RMII pinout, same LEDs.

Required configuration in `os_config.h`

```
#define EN_ETH          1
#define EN_NET          1
#define EN_NET_DHCP     1
#define EN_NET_NTP      1
#define EN_NET_DNS      1
#define EN_ARP_SERVICE  1
#define EN_UDP_SERVER   1
#define EN_DHCP_SERVICE 1
#define EN_NTP_SERVICE  1
#define EN_DNS_SERVICE  1
```

60.1.2 System Architecture

Differences from example 36

Aspect	Ex 36	Ex 37
DNS client	no	yes (`ca_dns_service`)
Additional dependencies	—	+`EN_NET_DNS`, `EN_DNS_SERVICE`
Additional tasks	—	`task_dns_demo` (LEVEL3), `task_dns` (LEVEL1)
DNS Gate	—	`ca_dns_service_net_ready()` in `on_dhcp_bound`
Demo semaphore	—	`s_dns_demo_sem`: DHCP→task_dns_demo
CLI	integrated dhcp/ntp/arp/udp	+`dns resolve`, `dns server` integrated

Flow `on_dhcp_bound`

```
static void on_dhcp_bound(ca_ipv4_t ip, ca_ipv4_t mask, ca_ipv4_t gw, ca_ipv4_t
    dns)
{
    ca_net_proto_set_local_ip(ip);
    EVAL_UDP_SRV(ca_udp_server_set_local_ip(ip);)
    EVAL_ARP_SVC(ca_arp_service_update_local_ip(ip);)
    ca_arp_send_garp();

    /* NTP: option 42 or gateway fallback */
    EVAL_NTP_SVC({
        ca_ipv4_t ntp_ip = ca_dhcp_service_get_ntp_server();
        if (ntp_ip.addr == 0U) ntp_ip = gw;
        ca_ntp_service_set_server(ntp_ip);
        ca_ntp_service_net_ready();
    })

    /* DNS: option 6 or gateway fallback */
    EVAL_DNS_SVC({
        ca_ipv4_t dns_ip = dns;
        if (dns_ip.addr == 0U) dns_ip = gw;
        ca_dns_service_set_server(dns_ip);
        ca_dns_service_net_ready();
        ca_sem_trywait(&s_dns_demo_sem);   /* drain */
        ca_sem_post(&s_dns_demo_sem);      /* sblocca task_dns_demo */
    })
}
```

Two independent gates: NTP and DNS are both unlocked by `on_dhcp_bound`, but remain separate tasks that operate concurrently.

Task Priority

```
LEVEL0: task_arp          cache ARP
LEVEL1: task_dhcp         DORA + T1/T2
         task_ntp          polling NTP
         task_dns          gestione query DNS
LEVEL2: task_net          processing frame RX
LEVEL3: task_eth_mon      link PHY poll
         usrv0..1         worker UDP
         task_dns_demo     risoluzioni demo all'avvio
LEVEL4: task_stats        statistiche
         task_heartbeat     LED
```

60.1.3 Source code

The file is located in `examples/example_37/ca_os_ex37.c`.

1. DNS demo semaphore

```
static ca_semaphore_t s_dns_demo_sem;   /* on_dhcp_bound     task_dns_demo */
```

Initialized in `ca_os_configure()` with value 0 (blocking). It is posted by `on_dhcp_bound` at the time of BOUND. `task_dns_demo` waits for this semaphore before starting the resolutions.

The `trywait + post` pattern ensures that if DHCP makes multiple renews, the semaphore does not accumulate posts: `trywait` drains the previous value before posting again.

2. task_dns_demo

```
static const char * const s_demo_hosts[] = {
    "test.caos.local",
    "gateway.caos.local",
    "pool.ntp.org",
};

static u32 task_dns_demo(void *arg)
{
    ca_sem_wait(&s_dns_demo_sem);   /* waits for DHCP BOUND */

    for (u32 h = 0U; h < DEMO_HOSTS_N; h++) {
        ca_ipv4_t ip = { .addr = 0U };
        bool ok = ca_dns_resolve(s_demo_hosts[h], &ip, 10000U);
        if (ok) {
            ca_stdout_printf_n("DNS  %-24s  ->  %u.%u.%u.%u", ...);
        } else {
            ca_stdout_printf_n("DNS  %-24s  ->  FAILED", s_demo_hosts[h]);
        }
        ca_os_sleep(500U);
    }
    ca_stdout_put_n("DNS: demo done - use the CLI 'dns resolve <hostname>'");
    return 0U;   /* task termina */
}
```

`ca_dns_resolve()` is blocking: the caller suspends until the response arrives or the timeout expires. It does not block `task_net` because it runs on a separate task (LEVEL3).

The hostname `.caos.local` usually fails on external DNS servers (NXDOMAIN) — this is to test error handling. `pool.ntp.org` requires that the PC has internet access or a DNS server that responds.

3. Available CLI commands

Automatically registered by services via `ca_cli_register()`. No hook in the example.

Command	Service	Description
`dhcp info`	`ca_dhcp_service`	Current lease status
`dhcp renew`	`ca_dhcp_service`	Force early renew
`ntp info`	`ca_ntp_service`	Unix timestamp + date/time
`ntp sync`	`ca_ntp_service`	Force immediate sync
`dns resolve <host>`	`ca_dns_service`	Resolve hostname to IPv4 (blocking max 10 s)
`dns server`	`ca_dns_service`	Show current DNS server IP

Command	Service	Description
`arp info`	`ca_arp_service`	Print ARP cache with age
`ip info`	`ca_net_proto`	IP, mask, GW, MTU

Warning: `dns resolve` blocks the CLI task until response (max 10 s).

4. `ca_os_configure` and `ca_os_main`

```c
void ca_os_configure(void)
{
    /* ... stdout, CLI, USB CDC, GPIO, ETH ... */
    ca_sem_init(&s_dns_demo_sem, "DNSDMO", 0U, 1U);

    ca_arp_service_init(s_mac, zero);          /* IP=0, aggiornato in on_bound
    */
    ca_dhcp_service_init(s_mac, on_bound, on_expire);
    ca_ntp_service_init(NTP_FALLBACK, s_mac, on_sync, on_fail);
    ca_dns_service_init(DNS_FALLBACK, s_mac);
}

void ca_os_main(void)
{
    ca_arp_service_start();
    ca_dhcp_service_start();
    ca_ntp_service_start();
    ca_dns_service_start();
    ca_udp_server_start(&srv_cfg);

    ca_os_job("net",        CA_TH_LEVEL2, task_net,       ...);
    ca_os_job("dns_demo",   CA_TH_LEVEL3, task_dns_demo,  ...);
    ca_os_job("eth_mon",    CA_TH_LEVEL3, task_eth_mon,   ...);
    ca_os_job("net_stats",  CA_TH_LEVEL4, task_stats,     ...);
    ca_os_job("heartbeat",  CA_TH_LEVEL4, task_heartbeat,...);
    ca_os_run(true);
}
```

5. Port binding in `task_net`

```c
ca_net_proto_bind_udp(DHCP_CLIENT_PORT, dhcp_udp_handler);  /* 68 */
EVAL_UDP_SRV(ca_udp_server_bind();)                          /* 7961 */
EVAL_NTP_SVC(ca_ntp_service_bind();)                         /* 123 */
EVAL_DNS_SVC(ca_dns_service_bind();)                         /* 53 */
```

All bindings occur **before** `ca_dhcp_service_net_ready()`: ensuring that ports 123 and 53 are registered in the dispatcher before the NTP/DNS tasks begin sending requests.

60.1.4 Testing procedure from PC

```bash
# Interface setup
sudo ip addr add 192.168.10.1/24 dev eth0

# DHCP server with NTP and DNS
sudo dnsmasq --no-daemon --interface=eth0 \
  --dhcp-range=192.168.10.100,192.168.10.200,1h \
  --dhcp-option=option:ntp-server,192.168.10.1 \
  --dhcp-option=option:dns-server,192.168.10.1
```

```

# Simple local DNS     answers for *.caos.local
# (aggiungere in /etc/hosts o usare dnsmasq address=/.caos.local/192.168.10.1)
```

60.1.5 Expected Output

```
=== EX37: DHCP + NTP + DNS + ARP + ping + UDP server ===

DNS  pool.ntp.org       185.125.190.58

> dns server
DNS server: 192.168.10.1

> arp cache
ARP cache:
  192.168.10.1  C0:25:A5:51:6C:13  age=2300ms
```

60.1.6 Technical Notes

`ca_dns_resolve()` — Internal operation

`ca_dns_resolve(hostname, &ip, timeout_ms)` is blocking:

1. Searches internal DNS cache (hit → returns immediately)
2. Cache miss: allocates a request slot, sends UDP query to DNS server
3. Waits for response on slot semaphore (max `timeout_ms`)
4. Response received: updates cache, writes `*ip`, returns `true`
5. Timeout: frees slot, returns `false`

The DNS service uses the same slot-pool architecture as the ARP service: up to `DNS_PENDING_MAX` concurrent callers, each with dedicated semaphores.

Conditional compilation

```
#if EN_ETH && EN_NET && EN_NET_DHCP && EN_NET_NTP && EN_NET_DNS && \
    EN_DHCP_SERVICE && EN_NTP_SERVICE && EN_DNS_SERVICE && EN_UDP_SERVER
```

Chapter 61

DHCP + mDNS Responder + ARP + ICMP Ping + UDP Server

61.1 Example 38 — DHCP + mDNS responder + ARP + ICMP ping + UDP server

61.1.1 Introduction

Example 38 introduces the **mDNS responder** (Multicast DNS, RFC 6762) in caOS, on NUCLEO-H753ZI (STM32H753ZI, PHY LAN8742A RMII). Objectives:

1. **DHCP client**: automatically obtains IP (DORA + T1/T2 renew).
2. **mDNS responder**: the board announces itself as `caos-board.local` and responds to multicast queries on `224.0.0.251:5353` without any DNS server.
3. **ARP service**: MACIP cache for UDP replies.
4. **ICMP echo reply** (ping).
5. **UDP server** on port 7961 with up to 2 simultaneous clients.
6. **GARP + mDNS announce** sent after every DHCP bound.
7. **Integrated CLI** in services — commands `dhcp info/renew`, `mdns info`, `arp info` automatically registered by `ca_dhcp_service`, `ca_mdns_service`, `ca_arp_service`.

With mDNS active, it is not necessary to know the dynamic IP assigned by DHCP: `ping caos-board.local` and `nc -u caos-board.local 7961` work directly from the PC as soon as the board is BOUND.

Hardware (NUCLEO-H753ZI, MB1364)

Identical to examples 33–37 — same RMII pinout, same LEDs.

Required Configuration in `os_config.h`

```
#define EN_ETH           1
#define EN_NET           1
#define EN_NET_DHCP      1
#define EN_NET_MDNS      1
#define EN_ARP_SERVICE   1
#define EN_UDP_SERVER    1
#define EN_DHCP_SERVICE  1
#define EN_MDNS_SERVICE  1
```

61.1.2 System Architecture

Differences from example 35

Aspect	Ex 35	Ex 38
mDNS responder	no	yes (`ca_mdns_service`)
Hostname .local	—	`caos-board.local`
Additional dependencies	—	+`EN_NET_MDNS`, `EN_MDNS_SERVICE`
Additional tasks	—	`task_mdns` (LEVEL1)
mDNS Gate	—	`ca_mdns_service_net_ready(ip)` in `on_dhcp_bound`
Additional UDP port	—	5353 (multicast 224.0.0.251)
NTP/DNS	no	no
CLI	integrated dhcp+udp	`dhcp info/renew`, `mdns info`, `arp info` integrated

---

mDNS Service Architecture

```
task_mdns (LEVEL1)
         ca_sem_wait(s_announce_sem)               sbloccato da
    ca_mdns_service_net_ready()
         send_announce()                           gratuitous announce all'avvio
         loop: ca_sem_timedwait(s_query_sem)
                   unblocked by ca_mdns_service_rx_handler() for each query

task_net (LEVEL2)
         ca_net_process():
       porta 5353     mdns_udp_rx()
             ca_net_proto_mdns_parse_query()
             is_for_us?     ca_sem_post(s_query_sem)
```

Two semaphores separate the startup flow (announce one-shot) from the continuing flow (query response): - `s_announce_sem` (max=1): `ca_mdns_service_net_ready()` → task - `s_query_sem` (max=8): `ca_mdns_service_rx_handler()` → task

Multicast Flow

```
Ethernet: dst=01:00:5E:00:00:FB (gruppo mDNS)
IPv4:     dst=224.0.0.251  TTL=255
UDP:      src=5353  dst=5353
DNS:      ID=0  QR=1  AA=1  ANCOUNT=1
Answer:   caos-board.local     A     <ip_board>  (CLASS|CACHE_FLUSH)
```

The ETH `MACPFR_RA` MAC filter (Receive All) is required to receive multicast mDNS frames; it is already configured in `eth_h7xx.c`.

Task Priority

```
LEVEL0: task_arp         cache ARP
LEVEL1: task_dhcp        DORA + T1/T2
         task_mdns       announce + query reply
LEVEL2: task_net         processing frame RX (include porta 5353)
LEVEL3: task_eth_mon     link PHY poll
         usrv0..1        worker UDP
LEVEL4: task_stats       statistiche
         task_heartbeat     LED
```

61.1.3 Source code

The file is located in `examples/example_38/ca_os_ex38.c`.

1. Hostname mDNS

```
#define MDNS_HOSTNAME  "caos-board"   /* risponde a caos-board.local */
```

Must match the name used by the PC tests. Editable without recompiling the service: it is a string passed to `ca_mdns_service_init()`.

2. `on_dhcp_bound` — update sequence

The `on_dhcp_bound` update sequence is a critical process in the caOS real-time operating system, designed to ensure safe and reliable firmware updates for STM32 microcontroller-based systems. This sequence is implemented to prevent system crashes or corrupted states during the update process, which could otherwise lead to device lockups or data loss.

The update sequence begins with the initialization of the update mechanism, where the system verifies the integrity of the new firmware image. This verification includes checking the image's checksum and ensuring it is compatible with the target hardware. Once the verification is complete, the system prepares the necessary resources for the update, including allocating memory and configuring the required peripherals.

The actual update process involves writing the new firmware to the device's flash memory. This is done in a manner that ensures atomicity, meaning that either the entire update succeeds or it fails completely, preventing partial updates that could corrupt the system. The system also implements a rollback mechanism, which allows the device to revert to the previous firmware version if the update fails or is deemed unstable.

During the update, the system maintains a watchdog timer to monitor the progress and ensure that the update does not hang or get stuck. If the watchdog timer expires, the system will trigger a reset to prevent indefinite hanging.

Finally, after a successful update, the system performs a verification step to confirm that the new firmware is correctly installed and operational. This step includes running a basic self-test to ensure that all system components are functioning as expected. If all tests pass, the system proceeds to normal operation with the updated firmware.

The `on_dhcp_bound` update sequence is designed to be robust and fault-tolerant, ensuring that even in the event of unexpected errors or power failures during the update process, the system remains stable and recoverable. This is particularly important in embedded systems where reliability and uptime are critical factors.

```
static void on_dhcp_bound(ca_ipv4_t ip, ca_ipv4_t mask, ca_ipv4_t gw, ca_ipv4_t
    dns)
{
    (void)dns;   /* not used in ex38 */
    s_ip = ip;  s_mask = mask;  s_gw = gw;
    s_dhcp_bound = true;

    ca_net_proto_set_local_ip(ip);
    EVAL_UDP_SRV(ca_udp_server_set_local_ip(ip);)
    EVAL_ARP_SVC(ca_arp_service_update_local_ip(ip);)

    ca_arp_send_garp();

    /* unblocks the mDNS task and sends the gratuitous announce */
    EVAL_MDNS_SVC(ca_mdns_service_net_ready(ip);)
}
```

The order is critical: `ca_net_proto_set_local_ip(ip)` must precede `ca_mdns_service_net_ready(ip)` because the mDNS task (LEVEL1, more urgent than `task_net` LEVEL2) will be scheduled immediately and use `build_announce()` which reads the IP from the parameter passed, not from the proto stack.

3. Init mDNS in `ca_os_configure`

```
EVAL_MDNS_SVC(ca_mdns_service_init(s_mac, MDNS_HOSTNAME);)
```

`ca_mdns_service_init()` saves MAC and hostname, initializes the semaphores. It does not create the task — that is done by `ca_mdns_service_start()` in `ca_os_main()`.

4. Binding port 5353 in `task_net`

```
ca_net_proto_bind_udp(DHCP_CLIENT_PORT, dhcp_udp_handler);  /* 68 */
EVAL_UDP_SRV(ca_udp_server_bind();)                          /* 7961 */
EVAL_MDNS_SVC(ca_mdns_service_bind();)                       /* 5353 */
```

`ca_mdns_service_bind()` registers the handler `mdns_udp_rx` on port 5353. The dispatcher accepts the frame because the MAC `01:00:5E:00:00:FB` is multicast (I/G bit=1) and is accepted by the `CA_L2_ACCEPT_MULTICAST` filter.

5. `ca_os_main`

```
void ca_os_main(void)
{
    EVAL_ARP_SVC(ca_arp_service_start();)
    EVAL_DHCP_SVC(ca_dhcp_service_start();)
    EVAL_MDNS_SVC(ca_mdns_service_start();)
    EVAL_UDP_SRV(ca_udp_server_start(&srv_cfg);)

    ca_os_job("net",       CA_TH_LEVEL2, task_net,       ...);
    ca_os_job("eth_mon",   CA_TH_LEVEL3, task_eth_mon,   ...);
    ca_os_job("net_stats", CA_TH_LEVEL4, task_stats,     ...);
    ca_os_job("heartbeat", CA_TH_LEVEL4, task_heartbeat, ...);
    ca_os_run(true);
}
```

61.1.4 PC Test Procedure

The script `examples/example_38/test_mdns_pc.sh` automates the procedure. Requires: `dnsmasq`, `avahi-utils`, `python3`.

```
sudo ./examples/example_38/test_mdns_pc.sh
# or with a specific interface:
sudo IFACE=enp7s0 ./examples/example_38/test_mdns_pc.sh
```

The script runs three tests:

1. **avahi-resolve** — uses the PC's `avahi-daemon` to resolve `caos-board.local`
2. **ping .local** — `ping -c3 caos-board.local`
3. **mDNS raw** — Python script that sends a UDP multicast query on 224.0.0.251:5353 bypassing avahi, verifies that the board responds directly

Equivalent manual test:

```
# Setup PC
sudo ip addr add 192.168.10.1/24 dev eth0
sudo dnsmasq --no-daemon --interface=eth0 \
  --dhcp-range=192.168.10.100,192.168.10.200,1h

# After the board's DHCP bound:
avahi-resolve -n caos-board.local
ping -c3 caos-board.local
echo "hello" | nc -u caos-board.local 7961

# Monitor mDNS
sudo tcpdump -i eth0 udp port 5353 -vvv
```

61.1.5 Expected Output

Console MCU (USB CDC)

```
=== EX38: DHCP + mDNS + ARP + ping + UDP server ===

```

61.1.6 Technical Notes

Gratuitous announce vs query response

The mDNS task distinguishes two behaviors:

- **Gratuitous announce** (at startup): sends an unsolicited `QR=1` response with `QDCOUNT=0` and `ANCOUNT=1`. All peers on the LAN learn the hostname→IP association without having to perform a query. Avahi receives this immediately.
- **Query response** (loop): when `ca_net_proto_mdns_parse_query()` returns `is_for_us=true`, the task posts `s_query_sem` and the mDNS task sends an identical response. Typical latency: ~500 µs from query to response.

RFC 6762 — Transaction ID always 0

mDNS requires `txid=0` in all messages (request and response). A different value causes the response to be rejected by avahi and other stacks. `ca_net_proto_mdns_build_announce()` sets `ID=0` correctly.

Multicast reception — `MACPFR_RA`

The mDNS frame has `dst_mac=01:00:5E:00:00:FB`. The GMAC 4.x (H7xx) must be configured with the `ETH_MACPFR_RA` bit (Receive All) or with the multicast hash filter to accept this group. `eth_h7xx.c` sets `RA` for simplicity — the board receives all multicast, including IGMP and mDNS.

Conditional Compilation

```
#if EN_ETH && EN_NET && EN_NET_DHCP && EN_NET_MDNS && \
    EN_DHCP_SERVICE && EN_MDNS_SERVICE && EN_UDP_SERVER
```

`EVAL_MDNS_SVC(expr)` executes `expr` only if `EN_MDNS_SERVICE=1`.

Chapter 62

UDP Syslog Client (RFC 3164)

62.1 Example 39 — DHCP + Syslog Service

62.1.1 Introduction

Example 39 shows how to integrate the **Syslog service** of caOS into a real networked application on Ethernet. The service sends log messages to a remote server via UDP port 514 (RFC 3164), with a fire-and-forget architecture: any task calling `ca_syslog_send()` does not block, delivery occurs in the background by the lowest priority task.

Objectives:

1. **DHCP client**: automatically obtains IP (DORA + T1/T2 renew).
2. **Syslog service**: sends messages with variable severity (DEBUG, INFO, WARN) to the syslog server on the PC.
3. **ARP service**: resolves the syslog server's MAC address (only the first time, then cached).
4. **ICMP echo reply** (ping from the board).
5. **Integrated CLI**: `syslog info`, `arp info`, `dhcp info/renew`.

Hardware (NUCLEO-H753ZI, MB1364)

Identical to examples 33–38 — same RMII pinout, same LEDs.

Required configuration in `os_config.h`

```
#define EN_ETH           1
#define EN_NET           1
#define EN_NET_SYSLOG    1
#define EN_NET_DHCP      1
#define EN_ARP_SERVICE   1
#define EN_DHCP_SERVICE  1
#define EN_SYSLOG_SERVICE 1
```

62.1.2 System Architecture

Differences from example 38

Aspect	Ex 38	Ex 39
mDNS responder	yes	no
UDP server port 7961	yes	no
Syslog service	no	**yes**
Log sources	—	4 (hb, stats, dhcp, link)
Severity levels used	—	DEBUG, INFO, WARN
PC test script	`test_mdns_pc.sh`	`syslog_server.py`
Additional ENs	`EN_NET_MDNS`, `EN_MDNS_SERVICE`	`EN_NET_SYSLOG`, `EN_SYSLOG_SERVICE`

Task Priorities

```
LEVEL0: task_arp            cache ARP + resolve
LEVEL1: task_dhcp           DORA + T1/T2
LEVEL2: task_net            processing frame RX
LEVEL3: task_eth_mon        link PHY poll
         task_heartbeat      LED + syslog DEBUG every 30s
LEVEL4: task_stats          statistics + syslog INFO every 60s
         task_syslog        drena queue + invia UDP 514
```

The syslog task is at LEVEL4 (the lowest priority) in order not to interfere with the critical RX/TX path. Messages are delivered in idle windows.

62.1.3 The source code

The file is located in `examples/example_39/ca_os_ex39.c`.

1. Syslog server IP

```
#define SYSLOG_SERVER_IP    { 192U, 168U, 10U, 1U }
```

Modify with the IP of the PC where `syslog_server.py` is running. The IP is passed to `ca_syslog_service_init()` in `ca_os_configure()`. It can be updated at runtime with `ca_syslog_service_set_server(new_ip)`.

2. ca_os_configure — initialization

```
void ca_os_configure(void)
{
    /* ... GPIO, ETH, ARP, DHCP init ... */
    {
        ca_ipv4_t zero = { .addr = 0U };
        ca_arp_service_init(s_mac, zero);      /* provisional IP 0 */
    }
    ca_dhcp_service_init(s_mac, on_dhcp_bound, on_dhcp_expire);

    {
        ca_ipv4_t srv = { .v = SYSLOG_SERVER_IP };
        ca_syslog_service_init(srv, s_mac, SYSLOG_FAC_LOCAL0);
    }
}
```

`ca_syslog_service_init()` initializes the queue, registers the CLI (`syslog info`), and saves the server's MAC and IP address. The task has not yet been created.

3. ca_os_main — task start

```
void ca_os_main(void)
{
    ca_arp_service_start();
    ca_dhcp_service_start();
    ca_syslog_service_start();   /* crea task LEVEL4 */
    /* ... ca_os_job for net, eth_mon, heartbeat, stats ... */
    ca_os_run(true);
}
```

The syslog task blocks immediately on `s_net_ready` — waits for the gate.

4. on_dhcp_bound — unlock and first message

```
static void on_dhcp_bound(ca_ipv4_t ip, ca_ipv4_t mask, ca_ipv4_t gw, ca_ipv4_t
    dns)
{
    s_ip = ip; s_mask = mask; s_gw = gw; s_dhcp_bound = true;

    ca_net_proto_set_local_ip(ip);         /* update the proto stack */
    ca_arp_service_update_local_ip(ip);    /* update ARP */

    ca_arp_send_garp();

    ca_syslog_service_net_ready();         /* unblocks the syslog task */

    char msg[64];
    ca_snprintf(msg, sizeof(msg),
                "EX39 BOUND IP=%u.%u.%u.%u",
                (u32)ip.v[0], (u32)ip.v[1], (u32)ip.v[2], (u32)ip.v[3]);
    ca_syslog_send(SYSLOG_SEV_INFO, msg);
}
```

Critical order: `ca_net_proto_set_local_ip(ip)` before `ca_syslog_service_net_ready()`. The syslog task uses `s_net_proto_local_ip` as `src_ip` of the UDP frame: if it is still 0.0.0.0 the frame will be discarded by the server.

5. task_heartbeat — periodic log

```c
static u32 task_heartbeat(void *arg)
{
    u32 seq = 0U;
    while (1) {
        ca_os_delay_ms(HEARTBEAT_PERIOD_MS);   /* 30 s */
        ca_gpio_toggle(LED_HB_PORT, LED_HB_PIN);
        if (!s_dhcp_bound) continue;
        char msg[64];
        ca_snprintf(msg, sizeof(msg),
                    "EX39 heartbeat seq=%u pool=%u/%u",
                    seq, (u32)ca_net_buf_free_count(), (u32)NET_BUF_COUNT);
        ca_syslog_send(SYSLOG_SEV_DEBUG, msg);
        seq++;
    }
    return 0U;
}
```

Check `s_dhcp_bound` before sending: if DHCP is not yet bound, the syslog does not have a valid IP and the messages would be discarded.

6. `ca_syslog_send` — fire-and-forget semantics

```c
ca_syslog_send(SYSLOG_SEV_WARN, "EX39 ETH link DOWN");
```

- **Non blocking**: copies the message to the queue and returns immediately.
- **Silent drop**: if the queue is full (8 slots) the message is lost and `ca_syslog_dropped()` increments the counter.
- **Safe from ISR**: does not acquire mutex — uses `ca_queue_static_trysend()`.

62.1.4 Test procedure from PC

1. Start the syslog server (DHCP included)

`syslog_server.py` automatically starts the DHCP server (`dnsmasq`) and configures the interface to `192.168.10.1/24`. At completion it restores the initial conditions.

```
# Needs sudo (port 514 + dnsmasq + ip)
sudo python3 examples/example_39/syslog_server.py --iface enp7s0
```

Main options:

Option	Default	Description
`--iface <eth>`	—	Network interface (required for DHCP)
`--pc-ip <ip>`	`192.168.10.1`	PC IP (must match `SYSLOG_SERVER_IP`)
`--port <n>`	`514`	UDP syslog port
`--no-dhcp`	off	Syslog only, do not start dnsmasq

Output on startup:

```
[*] enp7s0 configurato     192.168.10.1/24
[*] dnsmasq avviato (pid 12358)
[*] DHCP log: tail -f /tmp/dnsmasq-caos39.log
============================================================
 caOS EX39     syslog server  192.168.10.1:514
 DHCP pool  192.168.10.100     192.168.10.200
============================================================
 Ctrl+C per terminare (cleanup automatico).
------------------------------------------------------------
```

2. Programming the board and monitoring

On the serial monitor (USB CDC):

```
=== EX39: DHCP + Syslog service ===
MAC           02:00:00:00:00:39
IP            --- (waiting for DHCP)
Syslog        -> 192.168.10.1:514
DHCP: avvio DORA...

DHCP BOUND  IP=192.168.10.139  mask=255.255.255.0
            GW=192.168.10.1
```

On the syslog server (PC), the messages appear immediately after the bind:

```
[18:51:35.738] 192.168.10.139:514  [INFO  ]  EX39 ETH link UP
[18:51:35.738] 192.168.10.139:514  [INFO  ]  EX39 BOUND IP=192.168.10.139
[18:52:05.040] 192.168.10.139:514  [DEBUG ]  EX39 heartbeat seq=0 pool=56/64
[18:52:34.936] 192.168.10.139:514  [INFO  ]  EX39 stats rx=3 tx=6 drop=0
    slg_drop=0
[18:52:34.943] 192.168.10.139:514  [DEBUG ]  EX39 heartbeat seq=1 pool=56/64
```

3. Simulate a link change

Unplug and replug the Ethernet cable:

```
[HH:MM:SS.mmm] 192.168.10.139:514  [WARN  ]  EX39 ETH link DOWN
[HH:MM:SS.mmm] 192.168.10.139:514  [INFO  ]  EX39 ETH link UP
[HH:MM:SS.mmm] 192.168.10.139:514  [INFO  ]  EX39 BOUND IP=192.168.10.139
```

4. CLI from the board

```
c.a.O.S > syslog info
syslog server : 192.168.10.1:514
facility      : 16
net ready     : yes
dropped msgs  : 0

c.a.O.S > arp info
slot  IP               MAC                age(ms)
[0]   192.168.10.1     AA:BB:CC:11:22:33  3241
```

62.1.5 Expected output (verified on NUCLEO-H753ZI)

MCU Console (USB CDC)

```
=== EX39: DHCP + Syslog service ===

Syslog        -> 192.168.10.1:514
DHCP: avvio DORA...

DHCP BOUND  IP=192.168.10.139  mask=255.255.255.0
            GW=192.168.10.1

STATS dhcp=BOUND pool=56/64 held=8 rx=3 drop=0 tx=6 syslog_drop=0
```

Syslog Server PC (`syslog_server.py`)

```
[18:51:35.738] 192.168.10.139:514  [INFO  ]  EX39 ETH link UP
[18:51:35.738] 192.168.10.139:514  [INFO  ]  EX39 BOUND IP=192.168.10.139
[18:52:05.040] 192.168.10.139:514  [DEBUG ]  EX39 heartbeat seq=0 pool=56/64
[18:52:34.936] 192.168.10.139:514  [INFO  ]  EX39 stats rx=3 tx=6 drop=0
    slg_drop=0
[18:52:34.943] 192.168.10.139:514  [DEBUG ]  EX39 heartbeat seq=1 pool=56/64
```

62.1.6 Technical Notes

Gate `s_net_ready` — why it is necessary

The syslog task runs at LEVEL4 (the lowest priority). At system creation (before DHCP binds), there is no valid local IP yet: the UDP frame would have `src_ip=0.0.0.0` and would be dropped by the server. The gate prevents wasting ARP requests and buffers before the network is operational.

ARP — resolve and cache

The first `ca_syslog_send()` after the gate triggers an `ca_net_resolve_mac()` to obtain the MAC address of the syslog server. The result is kept in `s_server_mac` (`s_have_server_mac = true`): all subsequent messages do not re-do ARP.

If the server changes IP (`ca_syslog_service_set_server(new_ip)`), the cache is invalidated (`s_have_server_mac = false`) and ARP is re-done.

`ca_syslog_send()` from ISR

`ca_syslog_send()` uses `ca_queue_static_trysend()` which is ISR-safe (no mutexes, no suspension). It can be called from interrupt handlers, provided the string `msg` is in the data segment (not in the ephemeral ISR stack).

Dropped messages

If tasks produce messages faster than the syslog task delivers them (e.g. burst of high-priority events), the queue becomes saturated. `ca_syslog_dropped()` counts the lost messages. Increase `SYSLOG_QUEUE_SIZE` in `os_config.h` if the value is > 0 at steady state.

Wire format (RFC 3164)

```
UDP payload: <PRI>message
PRI = facility * 8 + severity
```

With `facility=SYSLOG_FAC_LOCAL0=16` and `severity=SYSLOG_SEV_INFO=6`: `PRI = 16*8+6 = 134` → `<134>EX39 BOUND IP=192.168.10.139`

The format does not include timestamp (no RTC in the example): the PC server adds the local timestamp upon receipt.

Chapter 63

TCP Client HTTP GET

63.1 Example 40 — TCP Client HTTP GET

63.1.1 Introduction

Application example of the caOS TCP client service: the NUCLEO-H753ZI board obtains an IP via DHCP, establishes a TCP connection to a Python server on the LAN, sends an HTTP GET request and reads the response.

The example **does not start by itself**: after the DHCP lease it remains idle and announces (`ex40: idle`). The `e40 start` command executes **one** request and closes it with a verdict that the test bench reads:

```
RUN RESULT : OK   (1/1)       connected, GET sent, non-empty reply read
RUN RESULT : FAIL  (0/1)      one of the three things did not happen
```

`e40 info` indicates whether the client is ready and how many requests have succeeded.

> **Why not a loop anymore.** Until 10/04, the client repeated the request every 30 s from boot. The test bench could not ask it to connect: it had to wait for the loop to arrive, on average almost a full period (~29 s for the connection phase alone), and count events within time windows twice the period wide. With `e40 start`, the same test lasts about a second and the criterion is a verdict line, not a count.

Demonstrative objectives:

Feature	Notes
DHCP client	DORA + T1/T2 renew, gate semaphore
ARP service	resolve server MAC, GARP at bind
Blocking TCP client	`ca_tcp_connect()` + `ca_tcp_send()` + `ca_tcp_recv()`
HTTP GET / HTTP 1.0	minimal request, connection close
ICMP echo reply	ping from the board during the test
Task stats	pool buffer, rx/tx frame

63.1.2 Hardware

Component	Value
Board	NUCLEO-H753ZI (STM32H753ZI)
PHY	LAN8742A (RMII, addr 0)

Component	Value
LED link	PB0
LED heartbeat	PB14
MAC	02:00:00:00:00:40
IP	assigned by DHCP
TCP Server	192.168.10.1 : 8080 (configurable)

63.1.3 os_config.h Configuration

```
#define EN_ETH            1
#define EN_NET            1
#define EN_ARP_SERVICE    1
#define EN_DHCP_SERVICE   1
#define EN_NET_DHCP       1
#define EN_TCP_SERVICE    1
/* TCP_MAX_CONN 8, TCP_MAX_INFLIGHT 16, TCP_RX_RING_DEPTH 8: model defaults */
```

63.1.4 Architettura

         TCP timer task        RTO retransmit
LEVEL4: task_stats            statistics every 20 s
```

Architecture diagram

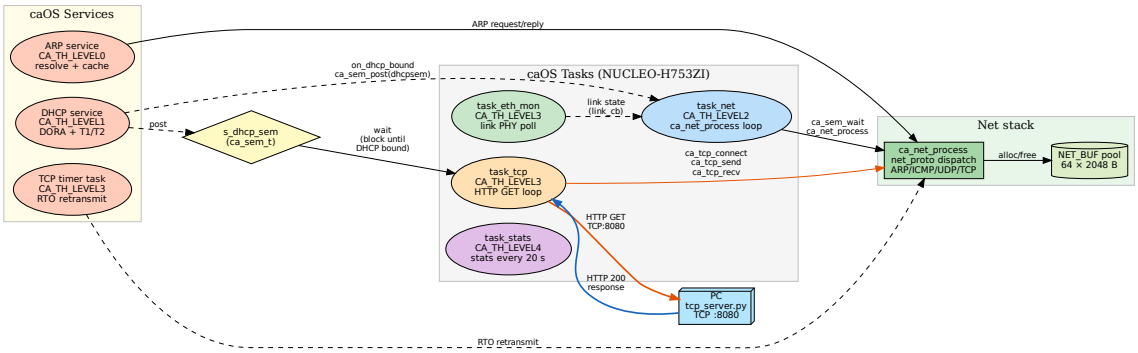

Figure 63.1: Example architecture 40

Task_tcp flow

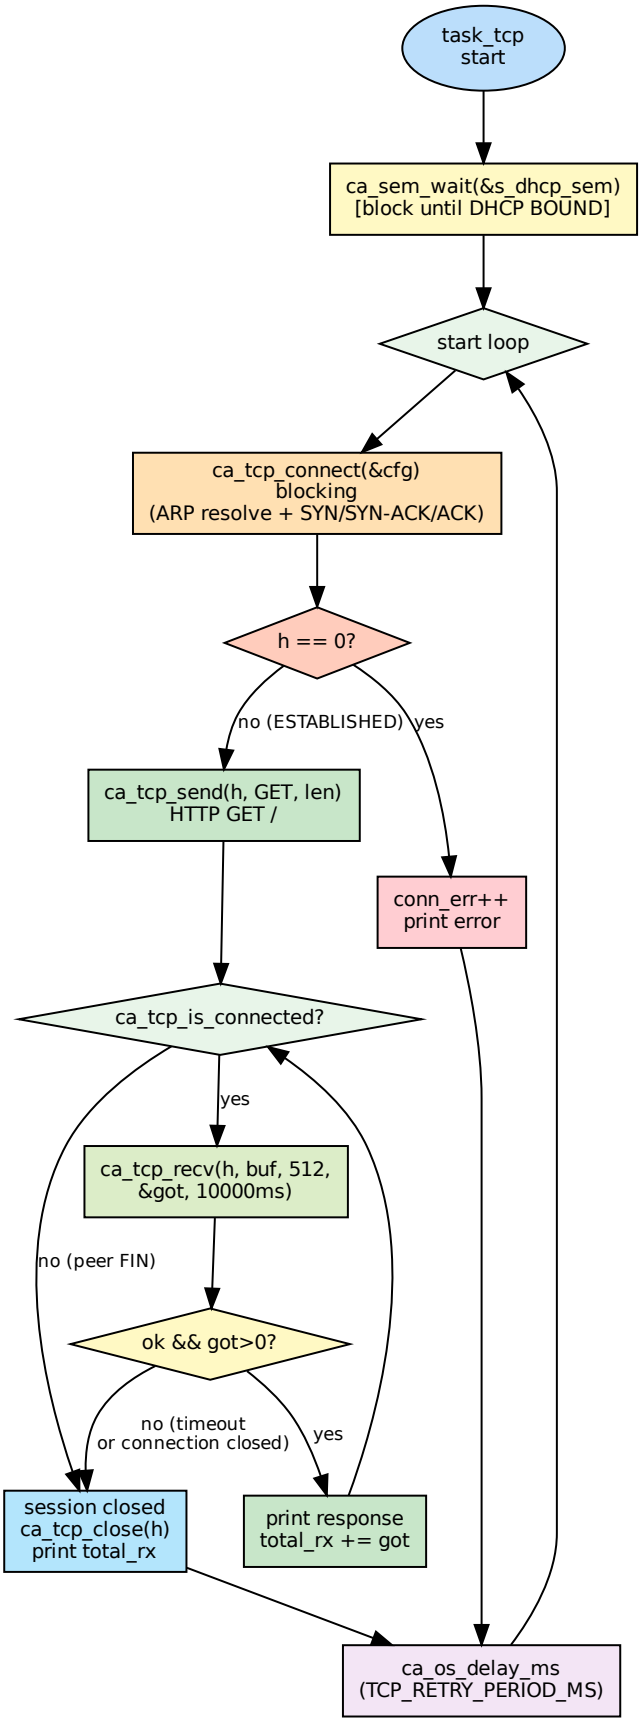

Figure 63.2: TCP client flow

63.1.5 Code — key points

Gate DHCP → TCP

The `task_tcp` must wait for the IP to be valid before attempting any connection. Synchronization is done via a semaphore:

```
/* ca_os_configure: */
ca_sem_init(&s_dhcp_sem, "DHCPBND", 0U, 1U);

/* on_dhcp_bound: */
ca_net_proto_set_local_ip(ip);
ca_arp_service_update_local_ip(ip);
ca_arp_send_garp();
ca_sem_post(&s_dhcp_sem);    /* sblocca task_tcp */

/* task_tcp: */
ca_sem_wait(&s_dhcp_sem);    /* waits for the bind */
```

Blocking Connection

```
ca_tcp_connect_cfg_t cfg = {
    .remote_ip          = srv_ip,
    .remote_port        = TCP_SERVER_PORT,
    .local_ip           = s_ip,
    .local_mac          = s_mac,
    .arp_timeout_ms     = 0U,   /* default TCP_ARP_TIMEOUT_MS  = 2000 ms */
    .connect_timeout_ms = 0U,   /* default TCP_CONNECT_TIMEOUT_MS = 5000 ms */
    .on_rx              = NULL, /* blocking mode ca_tcp_recv() */
    .on_connected       = NULL, /* blocks on connect */
    .on_closed          = NULL,
};

u8 h = ca_tcp_connect(&cfg);
/* h == 0     error (ARP timeout, SYN timeout, pool full) */
/* h >= 1     valid handle, connection ESTABLISHED */
```

Internally `ca_tcp_connect()` executes: 1. ARP resolution of the server's MAC (from cache or request) 2. Allocates a PCB from the pool (4 slots) 3. Sends SYN, waits for SYN-ACK, sends ACK

Send HTTP GET

```
static const char http_get[] =
    "GET / HTTP/1.0\r\n"
    "Host: caOS-board\r\n"
    "Connection: close\r\n"
    "\r\n";

bool ok = ca_tcp_send(h, (const u8 *)http_get, (u16)(sizeof(http_get) - 1U));
```

`ca_tcp_send()` segments the payload into chunks of MSS size; each segment is kept in a buffer pool until the peer's ACK is received (retransmit store-and-send).

Response Reception

```
u16  got = 0U;
bool ok  = ca_tcp_recv(h, rx_buf, sizeof(rx_buf) - 1U, &got, 10000U);
```

The loop continues while `ca_tcp_is_connected(h)` is true and `ca_tcp_recv()` returns data. When the peer closes (FIN), `ca_tcp_is_connected()` becomes `false` and the loop terminates.

63.1.6 Test from PC (verified on NUCLEO-H753ZI)

Start the server (DHCP included)

`tcp_server.py` automatically starts `dnsmasq` and configures the interface to `192.168.10.1/24`. At completion it restores the initial conditions.

```
cd examples/example_40
sudo python3 tcp_server.py --iface enp7s0
```

Main options:

Option	Default	Description
`--iface <eth>`	—	Network interface (required for DHCP)
`--pc-ip <ip>`	`192.168.10.1`	PC IP (must match `TCP_SERVER_IP`)
`--port <n>`	8080	TCP port
`--no-dhcp`	off	TCP server only, without dnsmasq

PC side output:

```
[*] enp7s0 already configured with 192.168.10.1
[*] dnsmasq avviato (pid 20147)
[*] DHCP log: tail -f /tmp/dnsmasq-caos40.log
============================================================
 caOS EX40     TCP server  192.168.10.1:8080
 DHCP pool  192.168.10.100     192.168.10.200
============================================================
 Ctrl+C per terminare (cleanup automatico).
------------------------------------------------------------
[19:11:41] connect from 192.168.10.146:49200
  >> GET / HTTP/1.0
  << 167 byte sent
[19:12:21] connect from 192.168.10.146:49200
  >> GET / HTTP/1.0
  << 167 byte sent
```

Output board (stdout/USB) — verified on NUCLEO-H753ZI

```
=== EX40: TCP client HTTP GET ===
MAC          02:00:00:00:00:40
TCP server   192.168.10.1:8080
DHCP: avvio DORA...

DHCP BOUND  IP=192.168.10.146
ex40: idle - "e40 start" fetches once from the server
e40 start

TCP connect -> 192.168.10.1:8080
TCP ESTABLISHED  h=1  ok=1
TCP send GET  OK
TCP rx 167 byte:
HTTP/1.0 200 OK
Content-Type: text/plain
Content-Length: 83
```

```
Connection: close

caOS EX40 TCP server reply
time=2026-0
TCP session done  total_rx=167 byte
  RUN RESULT : OK  (1/1)
```

Display note — `time=2026-0`

The HTTP response uses `\r\n` as line terminator (RFC 2616). The board prints the raw buffer with `ca_stdout_put_n()`, which sends the bytes as they are to the USB CDC terminal. The `\r` character (CR, ASCII 13) orders the terminal to return to **column 0 of the current line** without advancing to the next line. The next line of the body (`client=192.168.10.146:...`) is then printed starting from column 0 of the same line, overwriting the end part of the data. Only `time=2026-0` remains visible because the string `client=` (7 characters) covers the first 7 characters of what was there.

The data **is received correctly** (`total_rx=167`): this is a terminal display artifact, not a caOS bug.

63.1.7 Technical notes

Blocking vs callback mode

With `on_connected=NULL` and `on_rx=NULL` (blocking mode), the calling task blocks during connect and recv. This is the simplest way for sequential code. To handle multiple concurrent connections, use callbacks (`on_connected`, `on_rx`) in separate tasks.

Ephemeral ports

The implementation automatically assigns the local port starting from `49200 + slot` (one per PCB). It is not necessary to configure it.

Reconnect and PCB

After `ca_tcp_close()` the PCB enters TIME_WAIT (`TCP_TIME_WAIT_MS` = 4 s) before being released. A second `e40 start` immediately after the first does not wait: with `TCP_MAX_CONN` = 4 the new connection takes another PCB. While a request is in progress, `e40 start` responds `a fetch is already running` instead of queuing another one.

Buffer pool and TCP

Each in-flight TX segment occupies a buffer pool until ACK. With `TCP_MAX_INFLIGHT=4` and `TCP_MAX_CONN=4`, TCP can keep at most 16 buffers occupied. Check `NET_BUF_COUNT >= 16 + margine_rx` .

Garanzia sequenza on_dhcp_bound

```
ca_net_proto_set_local_ip(ip)          proto usa IP corretto nei frame TCP
ca_arp_service_update_local_ip(ip)      ARP usa IP corretto per richieste
ca_arp_send_garp()                      updates the peers' caches on the LAN
ca_sem_post(&s_dhcp_sem)                unblocks task_tcp only after all of the
    above
```

Chapter 64

TCP Server (Echo Server, RFC 862)

64.1 Example 41 — TCP Server (echo server RFC 862)

64.1.1 Introduction

Example of the caOS TCP server in **passive open** mode: the NUCLEO-H753ZI board listens on TCP port 7 (echo, RFC 862), accepts one connection at a time, and returns any received data to the client.

Demonstration objectives:

Feature	Notes
TCP server passive open	`ca_tcp_listen` + `ca_tcp_accept` blocking
3-way handshake	SYN → SYN-ACK → ACK handled automatically
Echo loop	`ca_tcp_recv` → `ca_tcp_send`
DHCP client	IP assigned dynamically, listen updated post-bind
ARP service	client MAC resolution + GARP
ICMP echo reply	ping from the board during the test

64.1.2 Hardware

Component	Value
Board	NUCLEO-H753ZI (STM32H753ZI)
PHY	LAN8742A (RMII, addr 0)
Link LED	PB0
Heartbeat LED	PB14 (toggled at each closed connection)
MAC	02:00:00:00:00:41
IP	assigned by DHCP
Server port	TCP 7 (echo RFC 862)

64.1.3 Configuration os_config.h

```
#define EN_ETH           1
#define EN_NET           1
#define EN_ARP_SERVICE   1
```

```
#define EN_DHCP_SERVICE  1
#define EN_NET_DHCP      1
#define EN_TCP_SERVICE   1
/* TCP_MAX_LISTEN default 2     1 is enough for this example */
```

64.1.5 Code — key points

Opening the listen

The listen is created in `ca_os_main()` with `local_ip=0.0.0.0` before DHCP has assigned an IP. When `on_dhcp_bound` arrives, it is updated with the real IP:

```
/* ca_os_main: */
ca_tcp_listen_cfg_t lcfg = {
    .local_port = TCP_ECHO_PORT,
    .local_ip   = { .addr = 0U },   /* provisional IP */
    .local_mac  = s_mac,
    .on_accept  = NULL,             /* blocking mode */
    .on_rx      = NULL,
    .on_closed  = NULL,
};
s_lh = ca_tcp_listen(&lcfg);

/* on_dhcp_bound: */
ca_tcp_unlisten(s_lh);     /* removes the listen with IP=0 */
lcfg.local_ip = ip;
s_lh = ca_tcp_listen(&lcfg);   /* re-registers with the real IP */
ca_sem_post(&s_dhcp_sem);       /* sblocca task_server */
```

Blocking accept

```
u8 h = ca_tcp_accept(s_lh, TCP_TCP_ACCEPT_TIMEOUT_MS);
/* h == 0     timeout, riprova */
/* h >= 1     connection ESTABLISHED */
```

`ca_tcp_accept` blocks on `accept_sem` until the 3-way handshake completes. The flow in the net task is:

```
SYN ricevuto su porta 7
      alloc PCB, state = SYN_RECEIVED
      send SYN-ACK
ACK ricevuto
      state = ESTABLISHED
      ls->last_handle = h
      ca_sem_post(&ls->accept_sem)       sblocca ca_tcp_accept()
```

Echo loop

```
while (ca_tcp_is_connected(h)) {
    u16  got = 0U;
    bool ok  = ca_tcp_recv(h, buf, sizeof(buf)-1U, &got, ECHO_RECV_TIMEOUT);
    if (!ok) {
        if (ca_tcp_is_connected(h)) continue;  /* timeout: riprova */
        break;                                  /* peer has closed */
    }
    if (got == 0U) continue;
    ca_tcp_send(h, buf, got);
}
ca_tcp_close(h);
```

`ca_tcp_recv` can return `false` due to timeout (no data within `ECHO_RECV_TIMEOUT`) or disconnection. Distinguishing between the two cases with `ca_tcp_is_connected()` allows the echo server to wait for the peer indefinitely without closing due to inactivity.

64.1.6 Test from PC (verified on NUCLEO-H753ZI)

Start the client (DHCP included)

`tcp_client.py` starts `dnsmasq`, configures the interface to `192.168.10.1/24`, automatically detects the IP assigned to the board from the DHCP log, and connects.

```
cd examples/example_41
sudo python3 tcp_client.py --iface enp7s0
```

Main options:

Option	Default	Description
`--iface <eth>`	—	Network interface (mandatory for DHCP)
`--pc-ip <ip>`	`192.168.10.1`	PC IP on the interface
`--port <n>`	`7`	TCP echo port on the board
`--host <ip>`	—	Direct board IP (skips DHCP auto-detect)
`--no-dhcp`	off	Client only, without dnsmasq (requires `--host`)

PC-side output (verified):

```
[*] enp7s0 already configured with 192.168.10.1
[*] dnsmasq avviato (pid 26173)
[*] DHCP log: tail -f /tmp/dnsmasq-caos41.log
[*] Waiting for DHCP ACK from the board (max 60s)...
============================================================
 caOS EX41     TCP echo client       192.168.10.147:7
============================================================
[*] Connessione a 192.168.10.147:7 ...
[*] Connesso. Digita testo + Invio. 'quit' per uscire.

> hello world
[19:34:22] echo (12B): hello world
> quit
[*] Connessione chiusa.
```

Output board (stdout/USB) — verified

```
=== EX41: TCP echo server ===
MAC     02:00:00:00:00:41
Port    TCP:7  (RFC 862 echo)
DHCP: avvio DORA...

DHCP BOUND  IP=192.168.10.147
TCP echo server on port 7
TCP server: listening on port 7
TCP accept  h=1  conn#1
  echo 12 byte: hello world

STATS dhcp=BOUND pool=56/64 held=8 rx=7 drop=0 tx=7
```

Test with netcat (alternative)

```
echo -n "Hello from nc" | nc 192.168.10.147 7
```

64.1.7 Technical notes

SYN_RECEIVED and SYN-ACK retransmit

The timer task handles the SYN-ACK retransmit exactly like the SYN retransmit for the client: exponential backoff up to `TCP_MAX_RETRIES`, then the PCB is freed.

One connection at a time

The `task_server` uses `ca_tcp_accept` in blocking mode: while an echo session is in progress, a new SYN connection is accepted at the IP level (PCB allocated, SYN-ACK sent), but `ca_tcp_accept` will only return when the current session ends. If the PCB pool is full, the new SYN is discarded with RST.

To handle concurrent connections, use `on_accept` callback + separate tasks for data handling.

IP listen update after DHCP

The SYN-ACK frame uses `local_ip` taken from the PCB at the time of acceptance. Since `on_dhcp_bound` updates the listen slot with the real IP before unblocking `task_server`, all subsequent SYNs will use the correct IP.

`ca_tcp_listen` before `ca_os_run`

`ca_tcp_listen` and `ca_tcp_unlisten` use a dedicated IRQ spinlock (`s_listen_lock`) instead of the blocking mutex `s_mtx`. This allows calling them in `ca_os_main()` before the scheduler is started, without causing the SAFEGUARD `current != NULL` of `ca_mutex_lock`.

Recv timeout in the echo loop

`ca_tcp_recv` with `ECHO_RECV_TIMEOUT` can expire before the peer sends data (e.g., slow user in interactive mode). The loop distinguishes timeout (`continue`) from disconnection (`break`) via `ca_tcp_is_connected()`.

Chapter 65

MQTT Client

65.1 Example 42 — MQTT Client

65.1.1 Introduction

Application example of the caOS MQTT client service: the NUCLEO-H753ZI board obtains an IP via DHCP, connects to an MQTT broker on the LAN and establishes an MQTT v3.1.1 session. The board periodically publishes its status on the topic `caos/status` and receives LED commands on the topic `caos/led`. All network management is performed via callbacks — no blocking polling in the MQTT task.

Demonstration objectives:

Feature	Notes
DHCP client	DORA + T1/T2 renew, gate semaphore
ARP service	resolve broker MAC, GARP at bind
MQTT v3.1.1 client	QoS 0, CONNECT/PUBLISH/SUBSCRIBE/PING
Asynchronous mode	all callback-driven on TCP layer, no dedicated MQTT task
Periodic publish	`caos/status` every 5 s with JSON payload
Subscribe + command	`caos/led` → `on`/`off` → GPIO LED green
Application keepalive	`ca_mqtt_ping()` every 30 s (< MQTT_KEEPALIVE_SEC=60)
Automatic reconnection	retry TCP+MQTT every 8 s after disconnection
ICMP echo reply	ping from board during test
Task stats	pool buffer, MQTT up/down status, session counter

65.1.2 Hardware

Component	Value
Board	NUCLEO-H753ZI (STM32H753ZI)
PHY	LAN8742A (RMII, addr 0)
Link LED	PB0 (red)
Green LED	PB0 — controlled by `caos/led`

Component	Value
Heartbeat LED	PB14 (blue — toggle stats)
MAC	02:00:00:00:00:42
IP	assigned by DHCP
MQTT Broker	DHCP gateway : 1883 — PC IP automatically detected

65.1.3 os_config.h Configuration

```
#define EN_ETH            1
#define EN_NET            1
#define EN_ARP_SERVICE    1
#define EN_DHCP_SERVICE   1
#define EN_NET_DHCP       1
#define EN_TCP_SERVICE    1
#define EN_MQTT_SERVICE   1
/* MQTT_RX_BUF_SIZE    default 256      max payload RX */
/* MQTT_KEEPALIVE_SEC  default 60       advertised to the broker */
```

65.1.4 Architecture

Tasks and priorities

```
LEVEL0: ARP service             cache + blocking resolve
LEVEL1: DHCP service            DORA + T1/T2
LEVEL2: task_net                ca_net_process loop
LEVEL3: task_eth_mon            link PHY poll
         task_mqtt               publish + ping + reconnect
         TCP timer task          RTO retransmit
LEVEL4: task_stats              statistics every 20 s
```

Architecture diagram

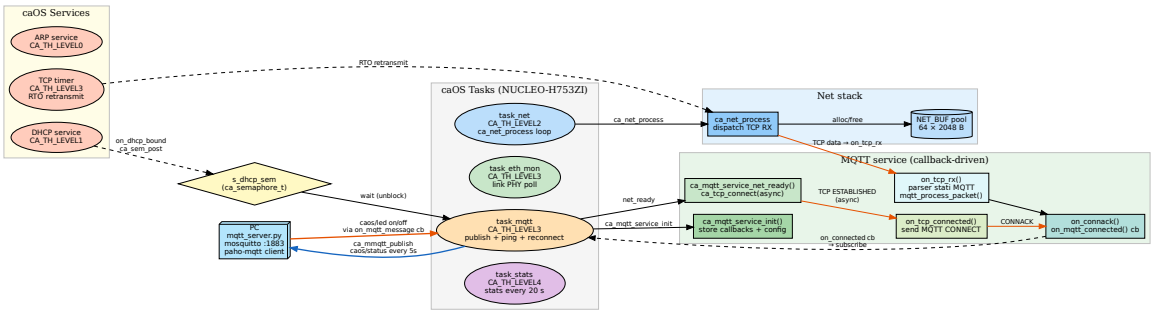

Figure 65.1: Example architecture 42

Task_mqtt flow

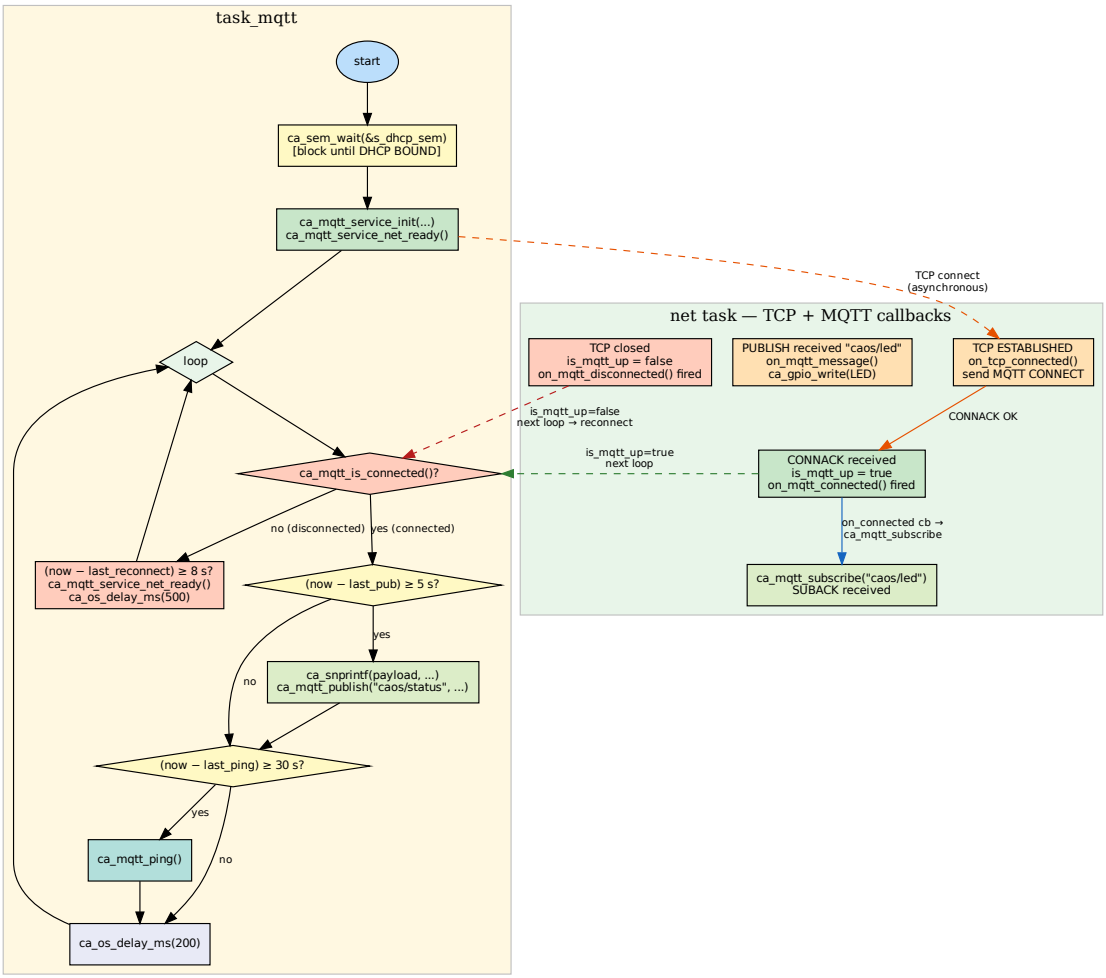

Figure 65.2: MQTT client flow

65.1.5 Code — key points

MQTT service initialization

The service is configured by `ca_os_configure()` before the network is available. At this stage the three application callbacks are registered and the broker configuration is saved. The TCP connection is not opened yet.

```
ca_mqtt_service_init(broker_ip, MQTT_BROKER_PORT,
                     local_ip, s_mac,
                     MQTT_CLIENT_ID,
                     on_mqtt_connected,
                     on_mqtt_message,
                     on_mqtt_disconnected);
```

Gate DHCP → MQTT

`task_mqtt` blocks on `s_dhcp_sem` until `on_dhcp_bound` signals that the IP is valid. Only at that point the TCP connection to the broker is opened:

```
/* on_dhcp_bound: */
ca_net_proto_set_local_ip(ip);
ca_arp_service_update_local_ip(ip);
ca_arp_send_garp();
ca_sem_post(&s_dhcp_sem);    /* sblocca task_mqtt */

/* task_mqtt: */
ca_sem_wait(&s_dhcp_sem);
ca_mqtt_service_net_ready(); /* opens asynchronous TCP     automatic CONNECT */
```

Automatic CONNECT

When the TCP 3-way handshake completes, `on_tcp_connected()` in the service automatically sends the MQTT CONNECT packet. The application does not need to handle this step: it only receives the `on_mqtt_connected()` callback when the CONNACK with return code 0 arrives.

```
static void on_mqtt_connected(void)
{
    s_mqtt_conn++;
    ca_mqtt_subscribe(MQTT_TOPIC_LED);   /* subscribe in reply to CONNACK */
}
```

Periodic publish

The `task_mqtt` loop checks the time elapsed since the last publication and builds a JSON payload with sequence number, uptime in seconds and current IP address:

```
ca_snprintf(payload, sizeof(payload),
    "{\"seq\":%u,\"up\":%u,\"ip\":\"%u.%u.%u.%u\"}",
    pub_seq++,
    now / 1000U,
    (u32)ip.v[0], (u32)ip.v[1], (u32)ip.v[2], (u32)ip.v[3]);

ca_mqtt_publish(MQTT_TOPIC_STATUS, (const u8 *)payload, (u16)ca_strlen(payload))
    ;
```

LED Command Reception

The callback `on_mqtt_message` is invoked in the context of the net task. The topic and payload are **not** null-terminated: it is necessary to use the explicit lengths.

```
static void on_mqtt_message(const char *topic, u16 topic_len,
                            const char *payload, u16 payload_len)
{
    if (topic_len == (u16)(sizeof(MQTT_TOPIC_LED) - 1U) &&
        ca_memcmp(topic, MQTT_TOPIC_LED, topic_len) == 0)
    {
        bool on = (payload_len >= 2U &&
                   payload[0] == 'o' && payload[1] == 'n');
        ca_gpio_write(LED_GREEN_PORT, LED_GREEN_PIN, on ? 1U : 0U);
    }
}
```

Keepalive and Reconnection

The keepalive PINGREQ is the responsibility of the application. The task sends `ca_mqtt_ping()` every `MQTT_PING_PERIOD_MS` (30 s), well below the limit of `MQTT_KEEPALIVE_SEC` (60 s) advertised to the broker.

If the connection fails (`on_mqtt_disconnected` fired → `mqtt_up=false`), the task attempts a new connection every `MQTT_RECONNECT_MS` (8 s). Before reopening the connection, it calls `ca_mqtt_service_init()` again to update the local IP (useful after a DHCP renewal).

```
if (!ca_mqtt_is_connected()) {
    if ((now - last_reconnect) >= MQTT_RECONNECT_MS) {
        last_reconnect = now;
        local_ip = s_ip;            /* IP updated by DHCP */
        ca_mqtt_service_init(...);
        ca_mqtt_service_net_ready();
    }
    ca_os_delay_ms(500U);
    continue;
}
```

65.1.6 Test from PC

Start the server (broker + DHCP)

`mqtt_server.py` starts `dnsmasq` for DHCP, `mosquitto` as MQTT broker and a client `paho-mqtt` that prints incoming messages. At the end it restores the initial conditions of the interface.

```
cd examples/example_42
sudo python3 mqtt_server.py --iface enp7s0
```

Main options:

Option	Default	Description
`--iface <eth>`	—	Network interface (required for DHCP)
`--pc-ip <ip>`	`192.168.10.1`	PC IP — becomes both DHCP gateway and MQTT broker
`--no-dhcp`	off	Broker only, without dnsmasq

> **Note**: the IP broker is not hardcoded. The board reads the gateway from the DHCP ACK (`on_dhcp_bound`) and uses it as the broker address. It is sufficient that `--pc-ip` matches the physical IP of the PC on the interface.

PC Dependencies:

```
sudo apt install mosquitto dnsmasq
pip3 install paho-mqtt
```

PC side output:

```
[*] enp7s0 configurato     192.168.10.70/24
[*] dnsmasq avviato (pid 28959)
[*] DHCP pool 192.168.10.100     192.168.10.200
[*] DHCP log: tail -f /tmp/dnsmasq-caos42.log
[*] Waiting for DHCP ACK from the board (max 60s)...
[*] Board IP: 192.168.10.148
[*] mosquitto avviato (pid 28965)  192.168.10.70:1883
[*] Paho connesso al broker
[*] Sottoscritto a caos/status
============================================================
```

```
 caOS EX42     MQTT broker  192.168.10.70:1883
 Board IP:  192.168.10.148
 Subscribe: caos/status
 Publish:   caos/led
 DHCP pool  192.168.10.100     192.168.10.200
============================================================
 Commands: on | off | q
------------------------------------------------------------
>   [caos/status] {"seq":0,"up":8,"ip":"192.168.10.148"}
> off
  -> [caos/led] off
> on
  -> [caos/led] on
>   [caos/status] {"seq":2,"up":18,"ip":"192.168.10.148"}
```

> **Note**: The script waits for the DHCP ACK from the board (max 60 s) before starting mosquitto. This ensures that the board has a valid IP before the broker is reachable.

Board output (stdout/USB)

```
=== EX42: MQTT client ===

```

65.1.7 Technical Notes

No dedicated MQTT task

Unlike NTP or Syslog (which have a dedicated task for polling or draining the queue), the MQTT service is entirely callback-driven: RX packets are processed by `on_tcp_rx()` in the context of the net task, without additional buffering. `task_mqtt` exists only for application timers (publish, ping, reconnect) and has no synchronization dependencies with the net task.

Stateful RX parser

TCP is a stream: an MQTT packet can arrive in multiple segments, or multiple packets can arrive in the same TCP segment. The service uses a three-state machine to correctly reassemble each packet before processing it:

```
state 0: waiting for fixed header (1 byte)
state 1: decodes remaining length (1-4 bytes, 7-bit varlen encoding)
state 2: accumulating payload in rx_buf up to rem_len bytes
             mqtt_process_packet()
```

Packets with payload > `MQTT_RX_BUF_SIZE` (256 B) are silently discarded, resetting the state parser to 0.

Automatic CONNECT on TCP established

When the 3-way handshake completes, `on_tcp_connected()` is called from the TCP layer in the context of the net task and immediately sends MQTT CONNECT. The application does not need to handle the timing between TCP connect and MQTT connect: just wait for `on_mqtt_connected()`.

Topics and payload in on_mqtt_message callback

The pointers `topic` and `payload` passed to `on_mqtt_message` point directly to `rx_buf` inside the service. They are valid **only during the callback**. If the data must survive the callback (e.g. passing to another task), copy them before returning.

on_dhcp_bound sequence

```
ca_net_proto_set_local_ip(ip)          proto usa IP corretto nei frame TCP
ca_arp_service_update_local_ip(ip)     ARP usa IP corretto per resolve broker
ca_arp_send_garp()                     updates the peers' caches on the LAN
ca_sem_post(&s_dhcp_sem)               unblocks task_mqtt only after all of the
    above
```

Pool buffer and persistent connection

The TCP connection remains open for the entire duration of the MQTT session. The pool buffers are only occupied during TX (`ca_mqtt_publish`) and released on ACK. In idle, the connection does not hold buffers.

Broker IP from DHCP gateway

The broker IP is not hardcoded: `on_dhcp_bound` saves the `gw` field and passes it to `ca_mqtt_service_init`. This makes the code independent from the PC's IP: just make sure the PC is configured as a DHCP gateway (`--pc-ip` option).

```
static void on_dhcp_bound(ca_ipv4_t ip, ca_ipv4_t mask, ca_ipv4_t gw, ca_ipv4_t
    dns)
{
    s_ip = ip;
    s_gw = gw;   /* broker = gateway */
    ca_sem_post(&s_dhcp_sem);
}
/* task_mqtt: */
ca_ipv4_t broker_ip = s_gw;
ca_mqtt_service_init(broker_ip, MQTT_BROKER_PORT, ...);
```

65.1.8 Fixes implemented during HW testing

The following fixes were introduced during testing on NUCLEO-H753ZI and are permanent part of the TCP/MQTT layer.

1 — Mutex deadlock in `tcp_service.c` (callback `on_connected`)

Problem: `on_tcp_connected` was called from the net task while `s_mtx` was still acquired. The callback called `ca_tcp_send` → `ca_mutex_lock(&s_mtx)` → deadlock detected by SAFEGUARD with `RESTART`.

Fix: in `TCP_STATE_SYN_SENT`, the mutex is released before the callback, using the same pattern as `on_rx` and `on_accept`.

2 — SEM OVERFLOW on conn_sem (reused PCB slot)

Problem: conn_sem (max=1) was not reset between one connection and the next on the same slot. In async mode (callback on_connected set), nobody consumes the semaphore after the post. On the second connection the post caused overflow (cnt=1 2).

Fix: ca_sem_init(&p->conn_sem, 0, 1) reinitialized in ca_tcp_connect before SYN. The post of conn_sem now happens only in blocking mode (on_connected == NULL).

3 — TIME_WAIT on Linux (fixed ephemeral port)

Problem: on every reconnection the board used the same local port (49200 + slot). The Linux server, with the old 4-tuple in TIME_WAIT (60 s), responded with challenge ACK instead of SYN-ACK.

Fix: s_ephemeral_ctr counter rotates ports on 49200..49399. Every ca_tcp_connect assigns a different port from the previous one.

4 — MQTT CONNECT truncated (inflight slots exhausted)

Problem: send_connect() called ca_tcp_send 4 separate times (fixed, rem_len, proto, vhdr), saturating the 4 inflight slots (TCP_MAX_INFLIGHT=4). The fifth call for client_id failed silently; mosquitto did not respond with CONNACK.

Fix: send_connect, ca_mqtt_publish and ca_mqtt_subscribe now build the complete packet in a local buffer (MQTT_TX_BUF_SIZE=128) and call ca_tcp_send only once.

5 — %lX in ca_vsnprintf

Problem: length modifiers l/h (%lX, %lu) were not supported in ca_vsnprintf and caused literal printing of the format.

Fix: l and h are now ignored in the format options loop (ARM32: u32/i32 = 4 bytes, no functional difference).

Chapter 66

Modbus TCP Client

66.1 Example 43 — Modbus TCP Client

66.1.1 Introduction

Application example of the caOS Modbus TCP client on NUCLEO-H753ZI (STM32H753ZI).

The board obtains an IP address via DHCP, opens a TCP connection to a Modbus server on port 502 and performs a periodic cycle of reading and writing using function codes FC01, FC03, FC06, FC16. An interactive CLI allows executing on-demand transactions without waiting for the automatic cycle.

Feature	Notes
DHCP client	DORA + synchronization semaphore towards task_modbus
ARP service	GARP at bind, gateway MAC resolution
Modbus TCP client	MBAP framing, serialization with mutex
FC03 Read Holding Registers	4 registers (addr 0..3)
FC06 Write Single Register	setpoint (addr 4)
FC16 Write Multiple Registers	2 config registers (addr 5..6)
FC01 Read Coils	8 coils (addr 0..7)
Interactive CLI	`rdreg`, `wrreg`, `rdcoil`, `stat`
Automatic reconnection	retry every 5 s
ICMP echo reply	ping from board during test
Task stats	pool, OK/ERR counters, connection status

66.1.2 Hardware

Board: NUCLEO-H753ZI (STM32H753ZI, Cortex-M7 @ 480 MHz)
PHY: LAN8742A (RMII, phy_addr=0)

Pin	Function
PB0	Red LED — ETH link up/down
PE1	Green LED — Modbus cycle OK
PB14	Blue LED — heartbeat stats
PA1, PA2, PA7, PC1, PC4, PC5, PG11, PB13, PG13	ETH RMII (AF11)

66.1.3 os_config.h Configuration

```
#define EN_ETH                1
#define EN_NET                1
#define EN_ARP_SERVICE        1
#define EN_DHCP_SERVICE       1
#define EN_NET_DHCP           1
#define EN_TCP_SERVICE        1
#define EN_MODBUS_SERVICE     1
#define MODBUS_TIMEOUT_MS     1000
#define MODBUS_RX_BUF_SIZE    270
```

For the CLI add `ENABLE_CLI 1` and `EN_CLI_MODBUS 1`.

66.1.4 Architecture

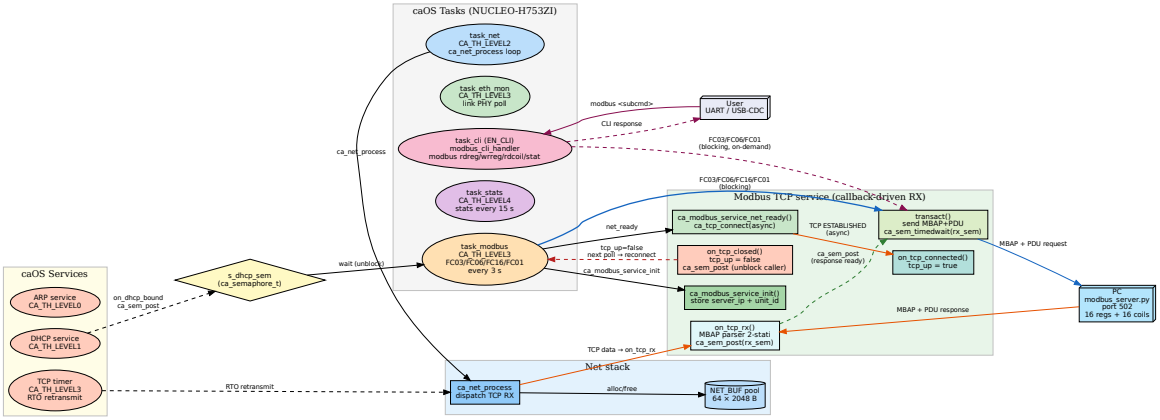

Figure 66.1: Example architecture 43

The system starts 4 tasks:

Task	Priority	Function
`task_net`	LEVEL2	RX loop: `ca_sem_wait` + `ca_net_process`
`task_eth_mon`	LEVEL3	ETH link polling every 500 ms
`task_modbus`	LEVEL3	Modbus loop + reconnection
`task_stats`	LEVEL4	print statistics every 15 s

The DHCP gateway is used as the Modbus server address: `s_gw` is captured in the callback `on_dhcp_bound` and passed to `ca_modbus_service_init`.

66.1.5 task_modbus flow

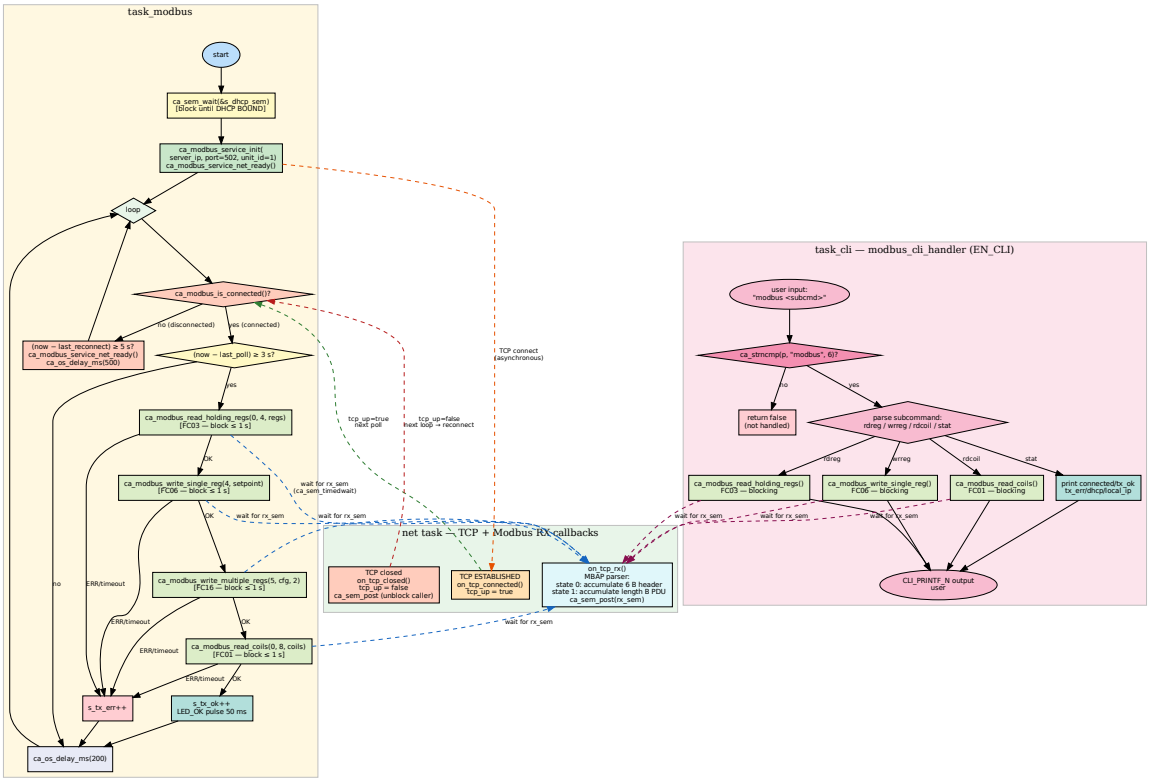

Figure 66.2: task_modbus flow

```
ca_sem_wait(&s_dhcp_sem)              sblocca on_dhcp_bound
ca_modbus_service_init(...)
ca_modbus_service_net_ready()         invia SYN

loop:
  if !connected:
    if timeout 5s: reinit + reconnect
    delay 500ms; continue

  if poll timeout 3s:
    FC03 leggi 4 registri
    FC06 scrivi setpoint
    FC16 scrivi 2 config
    FC01 leggi 8 coil
        ok++  o  err++

  delay 200ms
```

66.1.6 Interactive CLI

With `EN_CLI_MODBUS 1` and `ENABLE_CLI 1` the `modbus_cli_handler` node is available.

Command	Description
`modbus help`	lists sub-commands

Command	Description
`modbus rdreg <addr> [count]`	FC03 — reads 1..4 holding registers
`modbus wrreg <addr> <val>`	FC06 — writes a register
`modbus rdcoil <addr> [count]`	FC01 — reads 1..8 coil
`modbus stat`	connection status, local IP, OK/ERR counters

CLI and automatic task are serialized by the internal `tx_mtx` in the Modbus service: if the automatic task is waiting for a response, the CLI command blocks until the current transaction completes (at most `MODBUS_TIMEOUT_MS`).

Sample session

```
> modbus stat
  connected : YES
  tx_ok     : 3
  tx_err    : 0
  dhcp      : BOUND
  local_ip  : 192.168.10.149

> modbus rdreg 0 4
  reg[0] = 101 (0x0065)
  reg[1] = 201 (0x00C9)
  reg[2] = 301 (0x012D)
  reg[3] = 401 (0x0191)

> modbus wrreg 4 9999
  reg[4] <- 9999 OK

> modbus rdcoil 0 8
  coil[0] = 1
  coil[1] = 0
  coil[2] = 1
  coil[3] = 0
  coil[4] = 1
  coil[5] = 0
  coil[6] = 1
  coil[7] = 0
```

66.1.7 Test PC — modbus_server.py

The Python server in the example directory simulates a Modbus TCP device with 16 holding registers and 16 coils, automatically updated every 5 s.

```
sudo python3 examples/example_43/modbus_server.py --iface enp7s0
```

The server: 1. Configures `enp7s0` with IP `192.168.10.1/24` 2. Starts `dnsmasq` as DHCP server (pool `192.168.10.100..200`) 3. Waits for the board's DHCP ACK (max 60 s) 4. Listens for Modbus TCP server on `192.168.10.1:502`

Optional arguments:

Argument	Default	Description
`--iface`	`enp7s0`	Ethernet interface
`--pc-ip`	`192.168.10.1`	PC IP (Modbus server)
`--port`	`502`	TCP port
`--no-dhcp`	—	skip IP/DHCP setup (IP already configured)

Expected output from the server:

```
[+] client 192.168.10.149:49201
  RX tid=1 unit=1 FC=0x03
  RX tid=2 unit=1 FC=0x06
  [WR] reg[4] = 100
  RX tid=3 unit=1 FC=0x10
  [WR] reg[5..6] = [1, 2]
  RX tid=4 unit=1 FC=0x01
  RX tid=5 unit=1 FC=0x03
  ...
```

66.1.8 Expected UART Output

```
=== EX43: Modbus TCP client ===
MAC     02:00:00:00:00:43
Server  192.168.10.1:502  unit_id=1
DHCP: avvio DORA...
DHCP BOUND  IP=192.168.10.149
MODBUS server 192.168.10.1:502
MODBUS: avvio connessione TCP...
FC03 regs[0..3]= 100 200 300 400
FC06 setpoint=100 OK
FC16 config OK
FC01 coils=0x55
FC03 regs[0..3]= 100 200 300 400
FC06 setpoint=200 OK
FC16 config OK
FC01 coils=0x55
STATS dhcp=BOUND modbus=UP ok=2 err=0 pool=56/64 held=8 rx=21 tx=38
```

`held=8` is the normal value in steady state: 4 RX DMA slots + 4 TX DMA slots occupied by the ETH H7xx driver.

66.1.9 Technical Notes

Three-segment TCP Framing

`send_request` sends the Modbus ADU with three separate calls to `ca_tcp_send`: MBAP header (6 bytes), unit_id (1 byte), PDU body (N bytes). Each call occupies a slot inflight in the TCP service. The server receives the segments in order and reassembles them in the socket buffer before passing them to the application.

CLI Serialization + automatic task

The internal mutex `tx_mtx` prevents overlaps between the automatic task and the CLI. The pattern in `transact()`:

```
ca_mutex_lock(&s.tx_mtx);
/* drain stale rx_sem */
while (ca_sem_trywait(&s.rx_sem)) {}
send_request(tid, ...);
ok = ca_sem_timedwait(&s.rx_sem, MODBUS_TIMEOUT_MS);
ca_mutex_unlock(&s.tx_mtx);
```

Callback stale after reconnection

The old connection (TIME_WAIT) can invoke `on_tcp_closed` after the new one is already ESTABLISHED. The check `handle != s.tcp_handle` at the entrance of each callback ignores these events:

```
static void on_tcp_closed(u8 handle)
{
    if (handle != s.tcp_handle) return;
    s.tcp_up = false;
    ca_sem_post(&s.rx_sem);
}
```

Timeout and Reconnection

If the server does not respond within `MODBUS_TIMEOUT_MS` (default 1000 ms), `transact()` returns `false`. The TCP connection remains open; the task retries on the next cycle. If `ca_modbus_is_connected()` returns `false` (TCP closed by RST or FIN), the task reinitializes and reconnects after 5 s.

66.1.10 TCP CLI command sequence during testing

```
tcp list              1  ESTABLISHED  49201  502  192.168.10.1
tcp info 1            snd_wnd=64240 inflight=0/4
modbus stat           connected=YES ok=N err=0
modbus rdreg 0 4      reg[0..3] valori aggiornati
```

Chapter 67

iperf TCP Client/Server

67.1 Example 44 — iperf TCP client/server

67.1.1 Introduction

Example of TCP throughput measurement on NUCLEO-H753ZI (STM32H753ZI) using the caOS iperf service.

The board obtains an IP address via DHCP and provides two operational modes selectable from CLI:

- **client**: the board opens a TCP connection to the PC and transmits data in bulk for the specified duration;
- **server**: the board accepts an incoming TCP connection and measures the throughput of received data.

Feature	Notes
DHCP client	DORA + IP update at `ca_iperf_update_local_ip`
ARP service	GARP on bind, gateway MAC resolution
TCP service	connection management, RTO timers
iperf service	TX/RX loop, measure bytes/ms/bps
Interactive CLI	`iperf client <ip> [port] [dur_s]`, `iperf server [port] [idle_s]`
Pool diagnostics	`tcp buf` — free, held, leak pool
ICMP echo reply	ping from board during test

67.1.2 Hardware

Board: NUCLEO-H753ZI (STM32H753ZI, Cortex-M7 @ 480 MHz)
PHY: LAN8742A (RMII, phy_addr=0)

Pin	Function
PB0	Red LED — ETH link up/down
PB14	Blue LED — heartbeat stats
PA1, PA2, PA7, PC1, PC4, PC5, PG11, PB13, PG13	ETH RMII (AF11)

67.1.3 os_config.h Configuration

```
#define EN_ETH              1
#define EN_NET              1
#define EN_ARP_SERVICE      1
#define EN_DHCP_SERVICE     1
#define EN_NET_DHCP         1
#define EN_TCP_SERVICE      1
#define EN_IPERF_SERVICE    1
#define TCP_RX_RING_DEPTH   16U
```

`NET_BUF_COUNT` **is not here**: it is passed by CMake, in `examples/<fam>/<board>/CMakeLists.txt`, and it is a per-part value — 64 on H753, F7xx and H563, 32 on U575, 16 on F4xx, 0 on F103 (which has no MAC). On the H753 there are 64 × 2 KB = 128 KB in NET_SRAM1.

67.1.4 Architecture

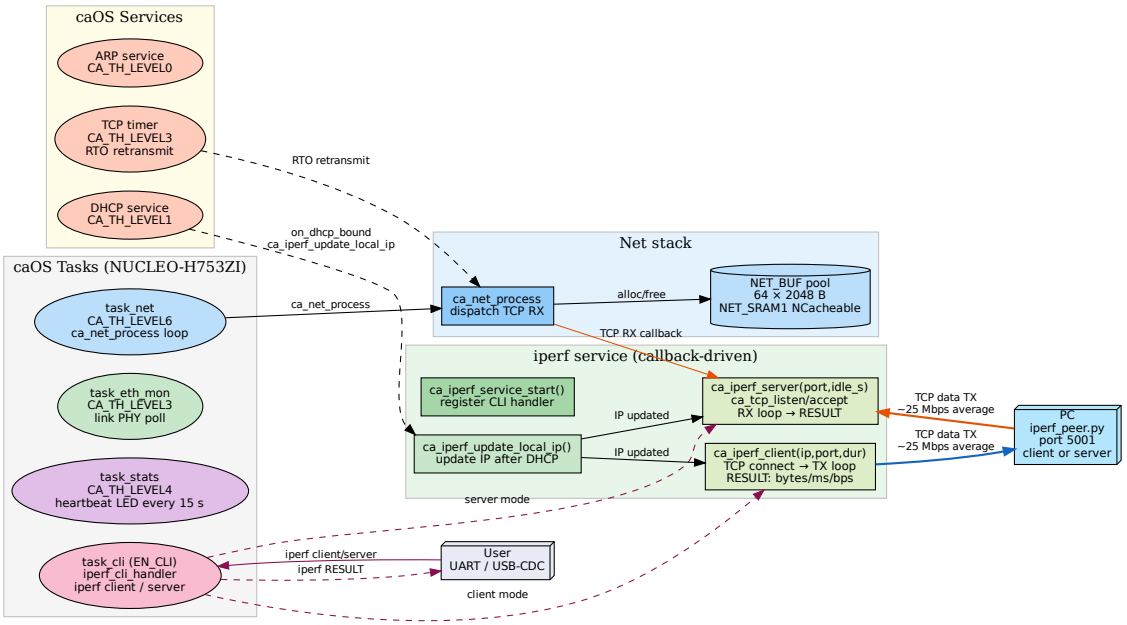

Figure 67.1: Example architecture 44

The system starts 3 application tasks; the iperf service is executed in the context of the task that invokes the CLI command.

Task	Priority	Function
`task_net`	LEVEL6	RX loop: `ca_sem_wait` + `ca_net_process`
`task_eth_mon`	LEVEL3	ETH link polling every 500 ms
`task_stats`	LEVEL4	LED heartbeat toggle every 15 s
`task_cli` (EN_CLI_IPERF)	LEVEL5	iperf client / server on-demand

67.1.5 iperf client and server flow

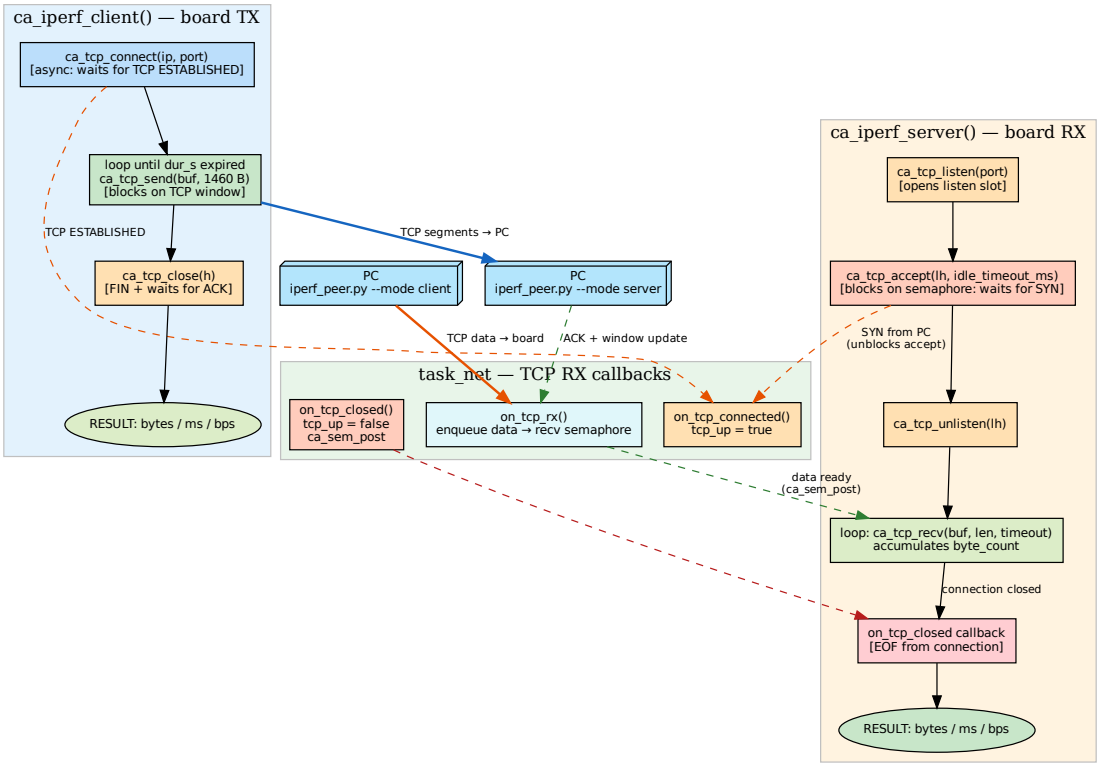

Figure 67.2: iperf flow

Client Mode (board → PC)

```
ca_iperf_client(ip, port=5001, dur_s=10)
      ca_tcp_connect(ip, port)          # TCP SYN
      loop dur_s secondi:
      ca_tcp_send(buf, 1460)          # MSS segments, blocking on window
      ca_tcp_close(h)                   # FIN
      stampa RESULT: bytes / ms / bps
```

Server Mode (PC → board)

```
ca_iperf_server(port=5001, idle_s=30)
      ca_tcp_listen(port)               # opens a listen slot
      ca_tcp_accept(lh, idle_timeout_ms)# attende SYN (bloccante)
      ca_tcp_unlisten(lh)
      loop:
      ca_tcp_recv(buf, len, timeout)  # accumula byte_count
      [on_tcp_closed     EOF]
      stampa RESULT: bytes / ms / bps
```

67.1.6 Interactive CLI

With `EN_CLI_IPERF 1` and `ENABLE_CLI 1` the service automatically registers `iperf_cli_handler`.

Command	Description
`iperf help`	list sub-commands
`iperf client <ip> [port] [dur_s]`	start TX bulk towards PC
`iperf server [port] [idle_s]`	listen, measure RX
`tcp buf`	free pool / held / leak

Example session — client

```
> iperf client 192.168.10.1 5001 10
  iperf RESULT: 39906910 bytes  10036 ms  31925528 bps

> tcp buf
  pool=40/64  held=24  leak=0
```

Example session — server

```
> iperf server 5001 30
  iperf RESULT: 38675400 bytes  10000 ms  30940320 bps

> tcp buf
  pool=40/64  held=24  leak=0
```

67.1.7 Test PC — iperf_peer.py

The Python peer in the example directory acts as the opposite role to the board.

```
# board as client, PC as server
python3 examples/example_44/iperf_peer.py --mode server [--port 5001]

# board as server, PC as client
python3 examples/example_44/iperf_peer.py --mode client --ip <board_ip> \
        [--port 5001] [--dur 10]
```

Alternatively with netcat:

```
# PC as server
nc -l 5001 | pv > /dev/null

# PC as client
dd if=/dev/zero bs=64k | nc <board_ip> 5001
```

67.1.8 Expected UART Output

```
=== EX44: iperf TCP client/server ===
MAC  02:00:00:00:00:44
DHCP: avvio DORA...
ETH LINK UP
DHCP BOUND  IP=192.168.10.150

```

```
> iperf client 192.168.10.1 5001 10
  iperf RESULT: 39906910 bytes  10036 ms  31925528 bps

> iperf server 5001 30
  iperf RESULT: 38675400 bytes  10000 ms  30940320 bps
```

67.1.9 Measured Performance

Tests on direct board–PC link (Ethernet 100BASE-TX, cat.5e cable):

Mode	Average Throughput	Peak Throughput
Client (board TX → PC RX)	~25 Mbps	~32 Mbps
Server (PC TX → board RX)	~25 Mbps	~39 Mbps

The average throughput of 25 Mbps on a 100 Mbps link reflects:

- **Cortex-M7 overhead**: CPU copy of payloads between DMA buffers and application buffers — the lack of scatter-gather DMA at L4 level forces two memcpy operations per TCP segment;
- **caOS scheduling**: the SysTick at ~104 µs introduces wakeup latency in the task_net; the presence of `__WFI()` in the idle task is essential to immediately yield the CPU to the ETH interrupt without burning cycles.

What is NOT the bottleneck

Not the TCP window. The assumption is natural, and with an example using `TCP_RX_RING_DEPTH=4` the math even works out too well ($4 \times \text{MSS} = 5840$ bytes, which at 32 Mbps implies an RTT of 1.45 ms). But it is false: the cost is **per packet**, and a wider window only queues more packets that cost the same. Here the ring is already **16** and the throughput is the same as ex79, which had 4 — which settles the matter by itself.

Not the driver. On the same silicon, example 84 — L2 echo, with the transport layer removed — achieves **78 Mbps with 5000 frames out of 5000** and a 1.00 transmission-to-reception ratio. Here the ratio is 1.86.

The meaningful comparison is in **events per second**, not bits: a 1500-byte frame and a 60-byte ACK cost almost the same, so Mbps can be misleading.

	Mbps	events/s
ex84, L2 echo (RX **and** TX per frame)	62.3	~10 200
ex44, iperf (RX + 1 ACK every 2)	23–32	~3 000–4 100

Where the traffic really goes

A run of iperf on the H563, captured with `eth dump`:

```
rx frames=156484   tx calls=290841   rbu=648
```

34.8 MB divided by the MSS make **23,866 data frames** out of 156,484 received: the **15.3%**. The other 132,618 are ACKs and retransmissions, and the board transmits 1.86 for each one it receives. `rbu=648` says the receive ring runs dry: frames are lost, the PC retransmits, the load increases, the ring runs dry again.

It's a self-sustaining cycle, and there's much more margin here than in any TCP parameter.

67.1.10 Memory

Region	Address	Size	Content
NET_SRAM1	0x30000000	128 KB	pool 64 × 2 KB (MPU NCacheable)
USB_SRAM	0x30020000	128 KB	reserved for future USB DMA
ETH_SRAM3	0x30040000	32 KB	ETH DMA descriptors + ring buf

`held=24` under load: 8 RX DMA slots + 16 TX DMA slots occupied by the ETH H7xx driver.

67.1.11 Technical Notes

NCacheable Pool and DMA Coherency

The pool `.net_pool` is mapped in D2 SRAM1 and the MPU region 3 is configured as Normal NCacheable. CPU and ETH DMA share the buffers without explicit cache invalidation.

> **The D-cache is disabled on this part**, as on all M7 in caOS (the I-cache remains enabled). The NCacheable region is therefore not what makes CPU and DMA coherent — it would be if the cache were active, and it remains the correct configuration if the cache is ever re-enabled. With the cache disabled **no cache maintenance is performed**: `clean`/`invalidate` on a disabled D-cache are not a harmless redundancy.
>
> Barriers are another matter: `__DSB()`/`__DMB()` in the ETH driver order bus accesses and are also needed with a disabled cache, because Normal Non-cacheable memory is not Strongly-ordered and the DMA writes the same memory as an independent master.

Importance of `__WFI()` in the idle task

Removing `__WFI()` from the idle task causes an increase from 31% to 57% of CPU idle time with 286,000 context switches/s: the idle task competing actively with task_net degrades throughput. With `__WFI()` the CPU stops until the ETH interrupt and restarts immediately, minimizing receive latency.

TCP CLI Commands during testing

```
tcp list            1  ESTABLISHED  <sport>  5001  192.168.10.1
tcp info 1          snd_wnd=65535  inflight=N/4
tcp buf             pool=40/64  held=24  leak=0
```

Chapter 68

HTTP Server with CLI over HTTP

68.1 Example 45 — HTTP and HTTPS Server with CLI via HTTP

68.1.1 Introduction

Example of an HTTP server on NUCLEO-H753ZI (STM32H753ZI) that exposes the entire caOS CLI via browser or `curl`.

The board obtains an IP address via DHCP and starts an HTTP server on port 80 and, with `EN_HTTPS_SERVICE`, an HTTPS server (TLS 1.3) on port 443 with the same routes. From any browser on the network, it is possible to execute CLI commands and view their output in text format.

Feature	Notes
DHCP client	DORA + IP update on bind
ARP service	GARP on bind, MAC resolution
TCP service	connection management
HTTP service	GET/POST/HEAD/OPTIONS, route table
HTTPS service	same routes on TLS 1.3, port 443 (HTTPS and TLS 1.3)
CLI capture	`ca_cli_exec_capture` — redirect stdout to HTTP buffer
ICMP echo reply	ping from the board
Packet tracer	`trace on/off/filter` — dump RX/TX frames on UART

68.1.2 Hardware

Board: NUCLEO-H753ZI (STM32H753ZI, Cortex-M7 @ 480 MHz)
PHY: LAN8742A (RMII, phy_addr=0)

Pin	Function
PB0	Red LED — ETH link up/down
PE1	Green LED — heartbeat
PA1, PA2, PA7, PC1, PC4, PC5, PG11, PB13, PG13	ETH RMII (AF11)

68.1.3 os_config.h configuration

```
#define EN_ETH              1
#define EN_NET              1
#define EN_ARP_SERVICE      1
#define EN_DHCP_SERVICE     1
#define EN_NET_DHCP         1
#define EN_TCP_SERVICE      1
#define EN_HTTP_SERVICE     1
#define EN_CLI_CAPTURE      1
#define EN_PACKET_TRACER    0    /* opzionale: CLI trace on/off/filter */
#define EN_CLI_TRACE        0    /* accendere entrambi per usare 'trace' */
#define NET_BUF_COUNT       64U

/* Dimensioni buffer HTTP     critiche per browser reali */
#define HTTP_REQ_BUF_SIZE   2048U   /* Chrome invia ~610 byte di headers POST */
#define HTTP_RESP_BUF_SIZE  4096U   /* copre output CLI lunghi: top, help, ecc.
    */

/* HTTPS (23/10/2026) */
#define EN_HTTPS_SERVICE    1
#define EN_TLS              1
#define EN_ECDSA_P256       1    /* firma del certificato */
#define EN_X25519           1    /* scambio chiavi */
#define EN_AES              1    /* AES-128-GCM del record layer */
#define EN_SHA256           1
#define EN_RNG              1
#define EN_KEYS_STORE       1    /* la chiave privata sta nel keys_store */
#define EN_CLI_HTTPS        1    /* comando 'https info' */
```

Flags are set using `caos_config.py --on ...`, never manually.

> **Warning**: values smaller than `2048U` and `4096U` (the current defaults in `http_service.h`) are insufficient for real browsers. Chrome sends POST headers of ~610 bytes (User-Agent, Accept, Referer, Origin, Accept-Language, etc.); with a 512-byte buffer, the body falls into the headers → 400 Bad Request. Always set `HTTP_REQ_BUF_SIZE 2048` in `os_config.h`.

68.1.4 Architecture

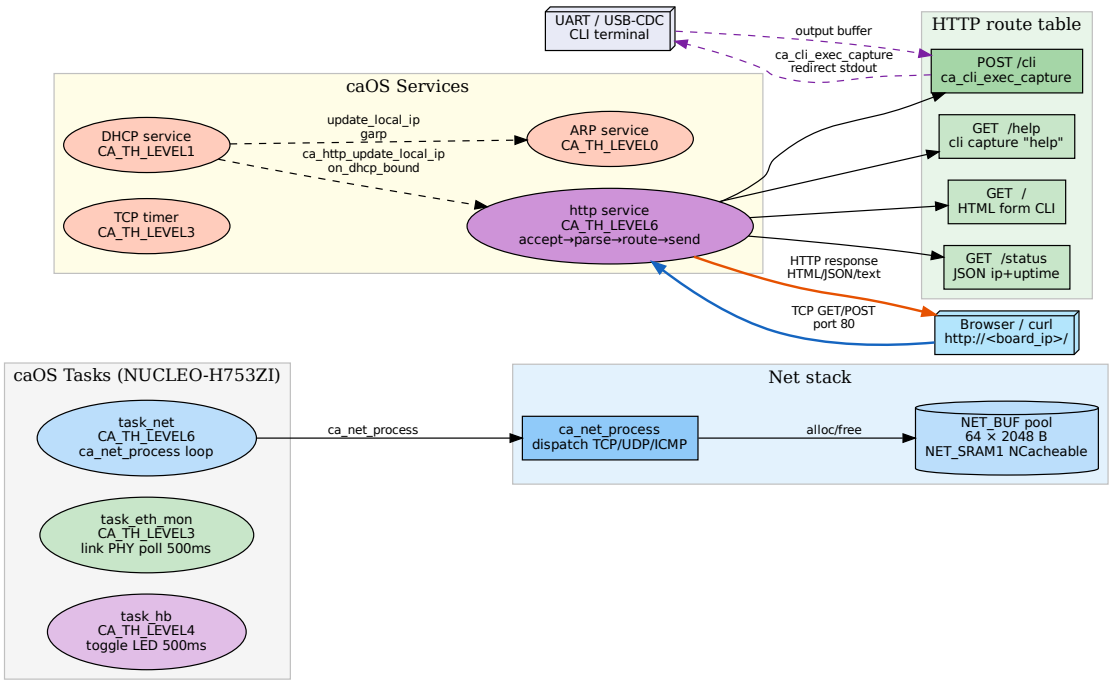

Figure 68.1: Task and service architecture

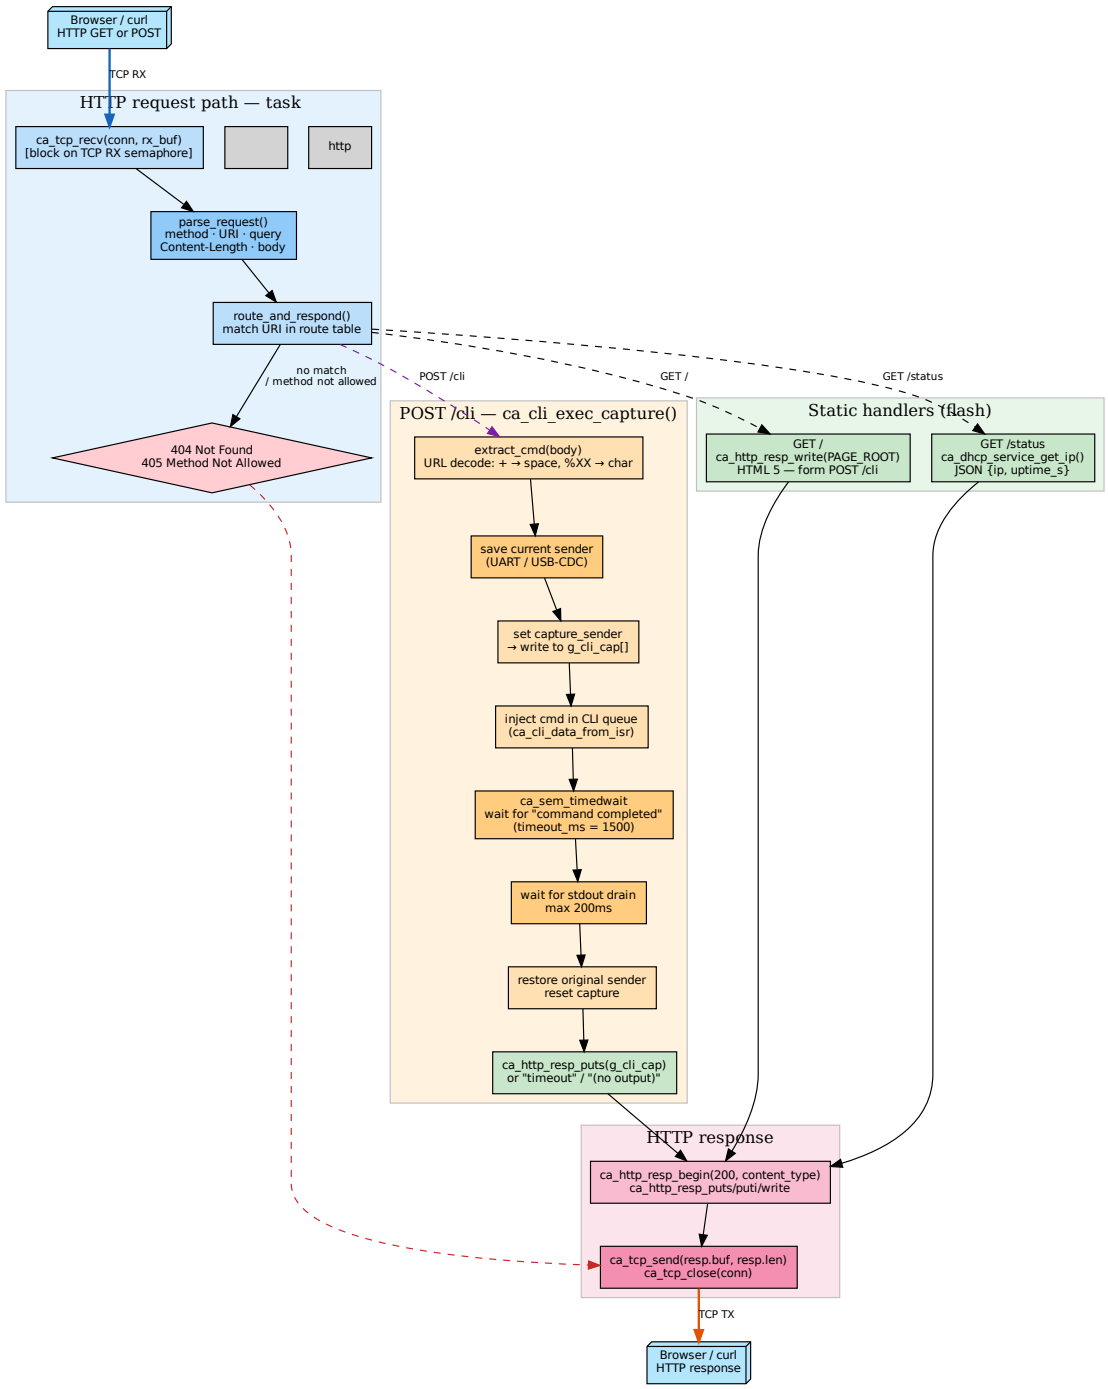

Figure 68.2: HTTP request flow — parse, route, CLI capture

Task	Priority	Function
`task_net`	LEVEL6	RX loop: `ca_sem_wait` + `ca_net_process`
`task_eth_mon`	LEVEL3	ETH link polling every 500 ms

Task	Priority	Function
`task_hb`	LEVEL4	heartbeat LED toggle every 500 ms
`http` (internal)	LEVEL6	accept → parse → route → response → close
`https` (internal)	LEVEL6	accept → TLS handshake → same path as `http` → close_notify → close
`ptrace` (internal)	LEVEL3	drain tracer ring, filter, print to sender

---

68.1.5 Route Table

URI	Methods	Description
`/`	GET, HEAD, OPTIONS	HTML page with command form
`/status`	GET, HEAD, OPTIONS	JSON: `{"ip":"...","uptime_s":N}`
`/cli`	POST, OPTIONS	Executes CLI command, responds with text
`/help`	GET, HEAD, OPTIONS	Output of `help` from the CLI

68.1.6 PC Tests

Browser

Open `http://<board_ip>/` — a text form with a command field appears. Type `top`, `free`, `eth`, `arp`, `dhcp info`, `tcp list`, etc.

curl

```
# IP assegnato da DHCP
curl http://192.168.10.150/status
#     {"ip":"192.168.10.150","uptime_s":42}

curl -X POST http://192.168.10.150/cli -d "cmd=top"
#     output del comando "top" dalla CLI caOS

curl -X POST http://192.168.10.150/cli -d "cmd=free"
#     blocchi memoria liberi

curl http://192.168.10.150/help
#     lista comandi CLI disponibili
```

HTTPS

The server identity (P-256 key and self-signed certificate for `caos.local`) is in `examples/example_45/tls_identity.h`, generated with:

```
python3 tools/gen_tls_identity.py examples/example_45
```

The certificate carries a name and not the IP, because the IP comes from DHCP:

```
curl --cacert examples/example_45/tls_identity_cert.pem \
     --resolve caos.local:443:192.168.10.84 https://caos.local/status
#     {"ip":"192.168.10.84","uptime_s":53}

curl --cacert examples/example_45/tls_identity_cert.pem \
     --resolve caos.local:443:192.168.10.84 -X POST https://caos.local/cli -d "
    cmd=free"
```

Browser: add `192.168.10.84 caos.local` to `/etc/hosts` and open `https://caos.local/`. The page opens with an "insecure" warning, which is normal for a self-signed certificate (verified on H563 on 10/23/2026).

Python script (automated test)

```
# Con DHCP automatico (richiede root per dnsmasq)
sudo python3 examples/example_45/http_test.py --iface enp7s0 --pc-ip
    192.168.10.1

# Senza DHCP, IP noto
python3 examples/example_45/http_test.py --no-dhcp --board-ip 192.168.10.158

# Singolo comando CLI, no browser
python3 examples/example_45/http_test.py --no-dhcp --board-ip 192.168.10.158 --
    cmd "top"
```

68.1.7 Parsing HTTP POST — "from the bottom" body

The body of a POST (`cmd=top`, `cmd=free`, etc.) is the last `Content-Length` bytes of the TCP payload. `parse_request` finds it with a direct O(1) calculation:

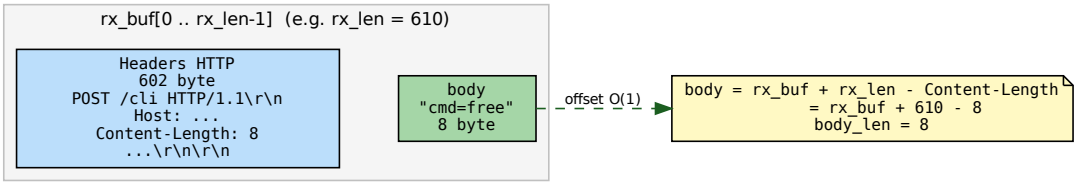

Figure 68.3: POST buffer layout — body offset

```
/* parse_request()      caos/net/src/http_service.c */
req->body     = buf + buf_len - content_length;   /* puntatore diretto */
req->body_len = (u16)content_length;              /* nessun loop */
```

The approach works because HTTP guarantees that the body is exactly the last `Content-Length` bytes of the received payload.

Multi-segment reception

If Chrome splits the request into multiple TCP segments (headers > 512 bytes in one segment, body in the next), `ca_http_serve_connection` accumulates the data:

```
/* Loop recv finch  \r\n\r\n non    nel buffer (header completo) */
for (;;) {
    body_off = cerca_rnrn(rx_buf, rx_len);
    if (body_off > 0 || rx_len >= HTTP_REQ_BUF_SIZE) break;
    more = io_read(io, rx_buf + rx_len, ...);   /* segmento successivo */
    if (more == 0) break;
    rx_len += more;
}
/* Il body si aspetta solo se Content-Length > 0, fino a riceverlo tutto */
want = header_content_length(rx_buf, body_off);
while (want > 0 && rx_len - body_off < want && rx_len < HTTP_REQ_BUF_SIZE) {
    more = io_read(io, rx_buf + rx_len, ...);
    if (more == 0) break;
    rx_len += more;
}
```

Before 10/23/2026, the body always expected: every GET paid a 1.5 s timeout (`HTTP_RECV_TIMEOUT_MS`). Now a GET responds in less than a millisecond.

68.1.8 `ca_cli_exec_capture` flow

The detailed flow is shown in diagram `ex45_http_flow` (section “POST /cli — ca_cli_exec_capture()”):

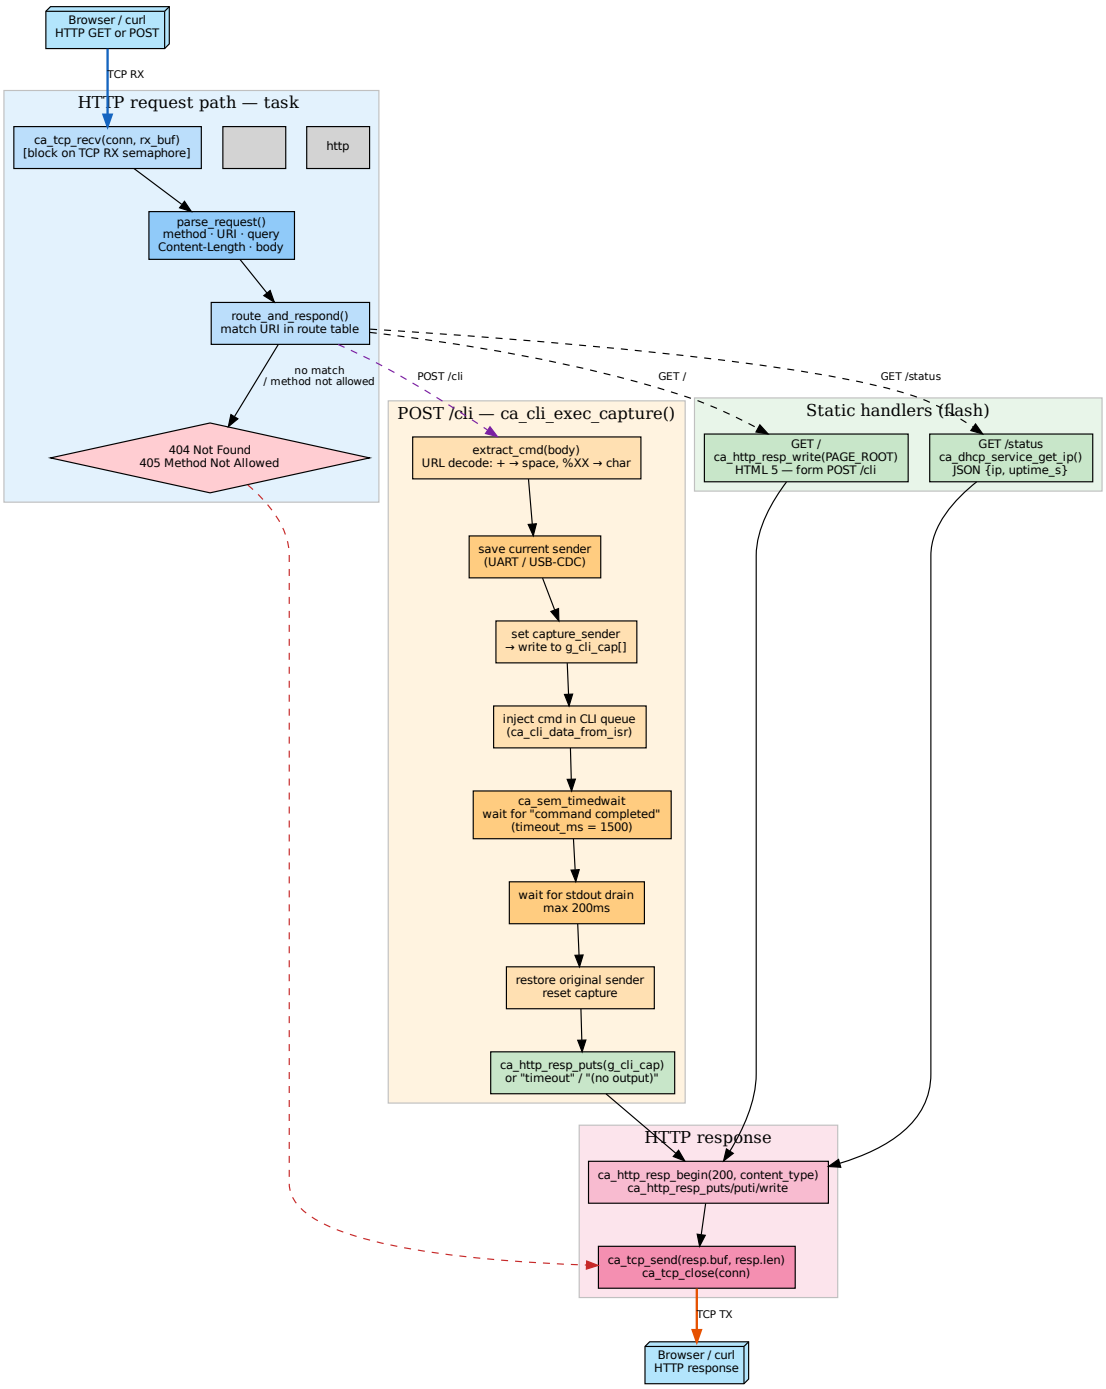

Figure 68.4: CLI capture flow

The mechanism uses a semaphore internal to the CLI thread to synchronize the HTTP caller with the completion of the asynchronous command.

68.1.9 Content-Length in the HTTP response

`ca_http_resp_begin` writes a 10-space placeholder for `Content-Length` and records its position in the buffer. Upon completion of the body construction, `ca_http_serve_connection` patches the actual value in place:

```
/* placeholder in ca_http_resp_begin() */
resp_append(r, "Content-Length: ", 16U);
r->cl_pos = r->len;
resp_append(r, "          ", 10U);   /* 10 spazi     patchati dopo */
r->hdr_end = r->len + 4U;           /* inizio body (dopo \r\n\r\n) */

/* patch in ca_http_serve_connection() dopo route_and_respond() */
u16 body_len = rp->len - rp->hdr_end;
ca_memcpy(resp.buf + resp.cl_pos, itoa10(body_len), 10U);
```

This avoids the double-pass on the response and is compatible with `HEAD` (body not written, `Content-Length` = 0 patched correctly).

68.1.10 Packet Tracer

The packet tracer is enabled by `ca_pktrace_start()` in `ca_os_main()` with sender set to `STDOUT`. At startup it is **disabled** — zero overhead until it is activated via CLI.

Terminal usage

```
c.a.O.S. > trace on
trace: on
[RX] ARP  192.168.10.1 -> 192.168.10.158 len=60

[TX] TCP  192.168.10.158:80 -> 192.168.10.1:48282 len=58
[RX] TCP  192.168.10.1:48282 -> 192.168.10.158:80 len=531
[TX] TCP  192.168.10.158:80 -> 192.168.10.1:48282 len=1059

c.a.O.S. > trace filter src 192.168.10.1
src filter: 192.168.10.1

c.a.O.S. > trace off
trace: off
```

> **Note**: `trace filter` is used via serial terminal, **not** via HTTP POST `/cli`. The tracer uses an independent sender (not stdout); calling it during an HTTP capture session is safe because the two channels do not overlap.

68.1.11 Expected UART output

```
=== EX45: HTTP server + CLI via HTTP ===
MAC  02:00:00:01:02:45
DHCP: avvio DORA...
ETH LINK UP
DHCP BOUND  IP=192.168.10.158  GW=192.168.10.1
HTTP  http://192.168.10.158/
HTTPS https://192.168.10.158/
```

68.1.12 Technical notes

HTTP buffer — critical sizing

Parameter	Recommended value	Notes
`HTTP_REQ_BUF_SIZE`	2048	Chrome POST: ~610 byte headers + body
`HTTP_RESP_BUF_SIZE`	4096	output `top`/`help` can exceed 1 kB
`CLI_CAP_SIZE`	2048	capture CLI output in the handler

The old 512/1024 defaults were only sufficient for curl with minimal headers; now `http_service.h` uses 2048/4096. Real browsers send User-Agent, Accept, Accept-Language, Accept-Encoding, Referer, Origin, Cache-Control → ~610 bytes of headers alone.

Browser: simultaneous connections

Modern browsers (Chrome, Firefox) open **2–3 simultaneous TCP connections** for each loaded page (e.g., GET + prefetch favicon). The caOS TCP service uses a **FIFO queue** (`hq[]`) in the `accept_sem` to correctly handle multiple incoming connections without losing any.

Fix details in `tcp_service.c`: - `accept_sem` initialized with `max = TCP_MAX_CONN` (not 1) - `hq[TCP_MAX_CONN]` in every listen slot with head/tail → FIFO - `rx_sem` re-initialized upon PCB reuse (SEM OVERFLOW fix) - `pcb_close` uses `ca_sem_post_capped` to unblock pending recv without overflow

CLI capture serialization

`ca_cli_exec_capture` is not reentrant. With a single HTTP task (current configuration) this is not an issue. In a future multi-task version, use a protection mutex on `g_cli_cap`.

URL decode in POST body

The browser sends the body as `cmd=top` or `cmd=dhcp+info` (spaces → `+`). `extract_cmd` handles: - `+` → space - `%XX` → corresponding hex character - Terminator: `&` or end of buffer

```
/* extract_cmd     ricerca "cmd=" nel body con flag found */
bool found = false;
while (p + 4U <= end) {
    if (p[0]=='c' && p[1]=='m' && p[2]=='d' && p[3]=='=') {
        p += 4U; found = true; break;
    }
    p++;
}
if (!found || p >= end) return 0U;  /*     400 Bad Request */
```

68.1.13 Bench verification

The `test_ex45` class (10 phases) also tests HTTPS: `/status` and `POST /cli` over TLS 1.3 with the certificate verified by curl (`--cacert`, never `-k`), the rejection of a TLS 1.2-only client, and the `https info` counters. Passed on 10/23/2026 on H563, H753, and F767. On boards without Ethernet (U575, F446), the example declares itself unsupported.

Chapter 69

AES Channel Service: Encrypted Ping-Pong

69.1 Example 46 — Secure pipe: encrypted ping-pong between two tasks

69.1.1 Introduction

Example of **synchronous** encrypted communication between two tasks on NUCLEO-H753ZI. The two tasks exchange messages through a **secure pipe** (`ca_secure_pipe_t`, in `secure_pipe_service.h`): a `aes_channel_service` channel based on **AES-256-GCM** with integrated authentication, plus a queue for direction. Encryption, transport and buffer wipe are all handled by the service.

The objective is to verify end-to-end the entire crypto chain:

```
keys_store (MPU)     secure pipe (aes_channel + code)     encrypt/decrypt GCM
       verifica
```

Item	Value
Algorithm	AES-256-GCM (encryption + authenticity)
Wire format	`[nonce:12B][orig_len:2B][ciphertext_padded: ceil(N,16)B][tag:16B]`
Fixed overhead	30 bytes (`AES_CH_OVERHEAD`)
Key	32 bytes in `keys_store` (MPU-protected area)
IV/nonce	Generated by HW RNG (`ca_rng_fill`) for each message
Heap	internal buffers within the service, always freed with wipe
Communication	`ca_secure_pipe_t` — peers `CA_SECURE_PIPE_A` (Alice) and `_B` (Bob), depth 4
Iterations	100 ping-pong (`PING_COUNT`) with 1 s interval
HW Result	**100/100 ping OK**

69.1.2 Hardware

Board: NUCLEO-H753ZI (STM32H753ZI, Cortex-M7 @ 480 MHz)

Pin	Function
PB7	Green LED — heartbeat (toggle every 500 ms)

69.1.3 os_config.h Configuration

```
#define EN_AES                    1   /* H7xx CRYP peripheral */
#define EN_RNG                    1   /* TRNG for IV generation */
#define EN_KEYS_STORE             1   /* MPU-protected area for keys */
#define EN_AES_CHANNEL_SERVICE    1   /*  r e d black  encrypted pipe */
```

69.1.4 Architecture

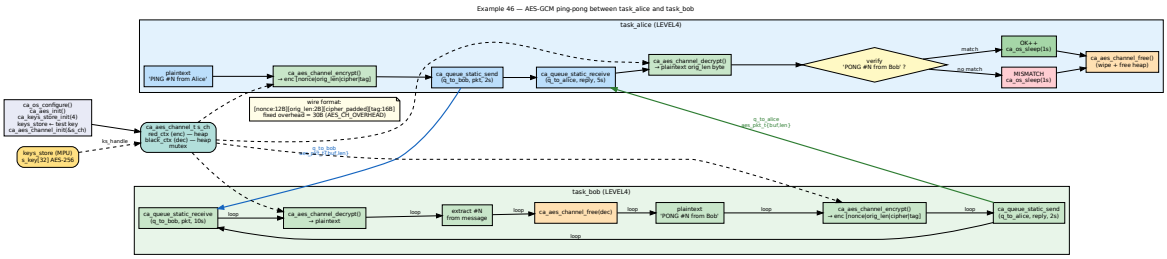

Figure 69.1: Ping-pong AES-GCM flow — task_alice, task_bob, keys_store, wire format

The pipe

```
static ca_secure_pipe_t s_pipe;

/* ca_os_configure() */
ca_secure_pipe_init(&s_pipe, CA_AES_MODE_GCM, CA_AES_KEY_256, s_key_ptr, 4);
```

Inside the pipe, only pointers to the ciphertext (8 bytes per item) travel: the encrypted buffer is allocated on the heap by the channel and transferred without copying; `recv` decrypts it, **copies** the plaintext into the task's buffer and clears both internal buffers. Before the service, this code (two code paths, the packet struct, who frees what) was manually written in ex46 and ex47.

69.1.5 Wire format GCM

Every encrypted message has the form (also visible as node `WF` in the architecture diagram):

Field	Size	Notes
`nonce`	12 byte	random from `ca_rng_fill()` for each encrypt

Field	Size	Notes
`orig_len`	2 byte	original plaintext length, big-endian
`ciphertext`	`ceil(plain_len, 16)` byte	always multiple of 16 (padding with zeros)
`GCM tag`	16 byte	authenticity — verified during decrypt

Fixed overhead = `AES_CH_OVERHEAD` = **30 byte** (nonce + orig_len + tag).

- **nonce**: 12 random bytes from `ca_rng_fill()` for each call to `ca_aes_channel_encrypt()`
- **orig_len**: original plaintext length in big-endian 2-byte format
- **ciphertext**: always multiple of 16 bytes (padding with zeros to plaintext before encryption)
- **tag**: 16 byte GCM — authenticity verification in `ca_aes_channel_decrypt()`; if incorrect, the function returns `-1` and the buffer is not delivered

The plaintext is always padded to a multiple of 16 before encryption (→ HW CRYP Notes section).

The GCM IV passed to the CRYP H7 peripheral is `[nonce:12][0x00000002:4]` — the initial counter required by the hardware for the GCM Init phase.

enc_len calculation

Plaintext	ceil(N,16)	enc_len = 30 + ceil(N,16)
“PING #0 from Alice” = 18 B	32	**62**
“PONG #0 from Bob” = 16 B	16	**46**
“PONG #99 from Bob” = 17 B	32	**62**
17 B	32	62

69.1.6 Keys Store — MPU protection

The AES key resides in a memory area protected by MPU via `keys_store`:

```
/* ca_os_configure() */
ca_keys_store_init(4);                                  /* max 4 keys */
s_key_ptr = ca_keys_store_allocate(32);                 /* 32 byte = AES-256 */

ca_keys_store_temp_enable_access(s_key_ptr, CA_KEYS_STORE_READ_WRITE);
ca_keys_store_copy(s_key_ptr, s_test_key, 32);          /* copy the key into the
    protected area */
ca_keys_store_lock_completely(s_key_ptr);               /* no CPU access */
```

During each encrypt/decrypt operation, `aes_channel_service` temporarily opens the region in read-only mode, copies the key to a local buffer on the stack, closes the protection, uses the key and clears it:

```
ca_keys_store_temp_enable_access(ks_handle, CA_KEYS_STORE_READ_ONLY);
ca_memcpy(key_buf, ks_handle, key_bytes);
ca_keys_store_lock_completely(ks_handle);
/* ... usa key_buf ... */
ca_memzero(key_buf, sizeof(key_buf));     /*     wipe the stack after use */
```

69.1.7 Heap management — mandatory wipe

The `ca_aes_channel_encrypt/decrypt` buffers are allocated on the heap and must be freed with `ca_aes_channel_free` (`ca_memory_free(p, NULL, true)`: zero before returning to the pool). With the pipe, the service does it in every branch: send failure, wrong tag, message too large, `deinit` with messages still in queue. The task only sees its own clear buffer.

69.1.8 Task_alice flow (100 iterations)

```
per ping = 0..99:
  1. formato plaintext: "PING #N from Alice"
  2. ca_secure_pipe_send(A)      cifra e accoda verso B   (timeout 2 s)
  3. ca_secure_pipe_recv(A)      decrypts the reply       (timeout 5 s)
  4. verifica: "PONG #N from Bob" ?
  5. sleep 1 s
stampa contatore OK/PING_COUNT
```

69.1.9 Task_bob flow (infinite loop)

```
loop:
  1. ca_secure_pipe_recv(B)      decrypts the ping        (timeout 10 s)
  2. extracts the ping number from the message (#N)
  3. formato pong: "PONG #N from Bob"
  4. ca_secure_pipe_send(B)      cifra e accoda verso A   (timeout 2 s)
```

69.1.10 Output UART

```
=== EX46: AES-GCM ping-pong (secure pipe) ===
Alice TX: 'PING #0 from Alice'
Bob RX: 'PING #0 from Alice'
Bob TX: 'PONG #0 from Bob'
Alice RX: 'PONG #0 from Bob' - OK
...
Alice: 100/100 ping OK
Alice: test done.
```

The encrypted length is no longer printed: it remains inside the pipe (see the table "Calcolo enc_len" above). The order between `Bob TX` and `Alice RX` can be inverted, because Bob prints after having appended.

69.1.11 Task and priority

Task	Priority	Stack	Function
`alice`	LEVEL4	STACK_MEDIUM	initiator — encrypt/send/receive/decrypt
`bob`	LEVEL4	STACK_MEDIUM	responder — receive/decrypt/encrypt/send
`hb`	LEVEL3	STACK_SMALL	toggle LED every 500 ms

Alice and Bob have the same priority — the scheduler alternates them for time-slicing. The queues block the task waiting without busy-wait.

69.1.12 Tamper detection GCM

If a byte of the ciphertext in transit is corrupted (attack or transmission error), `ca_aes_gcm_decrypt` recognizes the mismatch of the tag and returns `false`. The service frees the buffer with wipe and returns `-1` to the caller:

```
ciphertext corrotto     ca_aes_gcm_decrypt     tag mismatch     -1

                                              ca_memory_free(buf, NULL, true)
                                              (buffer plaintext azzerato)
```

The ping continues with the next one without crashing.

69.1.13 Implementation notes — CRYP H7 and partial blocks GCM

The **STM32H7 CRYP peripheral** has an asymmetry in GHASH calculation for partial blocks in GCM mode:

- In **encrypt**: GHASH covers the OUTPUT (ciphertext), including the keystream bytes produced by the padding bits — non-zero bytes.
- In **decrypt**: GHASH covers the INPUT (ciphertext), padded with zeros.

If a message is not a multiple of 16 bytes, the two GHASH values diverge → **tag mismatch**.

The `NPBLB` field of the CR register (bits [23:20]) should correct this behavior, but it has proven unreliable on the CRYP H753 in the caOS context.

Solution adopted: the plaintext is always padded to a multiple of 16 in `ca_aes_channel_encrypt` before being passed to the driver. The hardware CRYP sees only complete blocks — no partial blocks, no NPBLB. The original length is stored in the wire at offset 12 (2 byte big-endian) and used in decrypt to return exactly `orig_len` bytes.

Chapter 70

Keystore Service: makekey + Encrypted Ping-Pong

70.1 Example 47 — Keystore service: makekey + ping-pong encrypted

70.1.1 Introduction

Example of key lifecycle management through `keystore_service` of caOS, combined with encrypted communication of `aes_channel_service`.

The flow is divided into two distinct phases, both controlled by CLI:

1. **makekey** — generates a block of 16 random AES-256 keys, encrypts it with a key derived from two passwords, and writes it to flash (sector 6, bank1).
2. **start** — decrypts the block in flash using only `pwd2`, loads the chosen key into `keys_store` (MPU-protected area), and starts the encrypted ping-pong between two tasks.

Element	Value
Block encryption algorithm	AES-256-GCM
KDF	`SHA256^N(IV || pad16(pwd))[:16]` — N configurable evolutions
Number of keys in the block	16 (`NUM_KEYS`)
Flash sector	6 bank1 — `0x080C0000`
Ping-pong wire format	`[nonce:12B][orig_len:2B][ciphertext_padded][tag:16B]`
Fixed overhead	30 bytes (`AES_CH_OVERHEAD`)
Ping-pong iterations	20 (`PING_COUNT`)
HW result	**20/20 ping OK**

70.1.2 Hardware

Board: NUCLEO-H753ZI (STM32H753ZI, Cortex-M7 @ 480 MHz)

Pin	Function
PB7	Green LED — heartbeat (toggle every 500 ms)

70.1.3 os_config.h Configuration

```
#define EN_AES                  1   /* H7xx CRYP peripheral */
#define EN_RNG                  1   /* TRNG for IV and key generation */
#define EN_HASH                 1   /* SHA256 per KDF */
#define EN_FLASH                1   /* key block write */
#define EN_KEYS_STORE           1   /* MPU-protected area for keys */
#define EN_AES_CHANNEL_SERVICE  1   /*  r e d black  encrypted pipe */
#define EN_KEYSTORE_SERVICE     1   /* management of the key block in flash */
```

70.1.4 Architecture

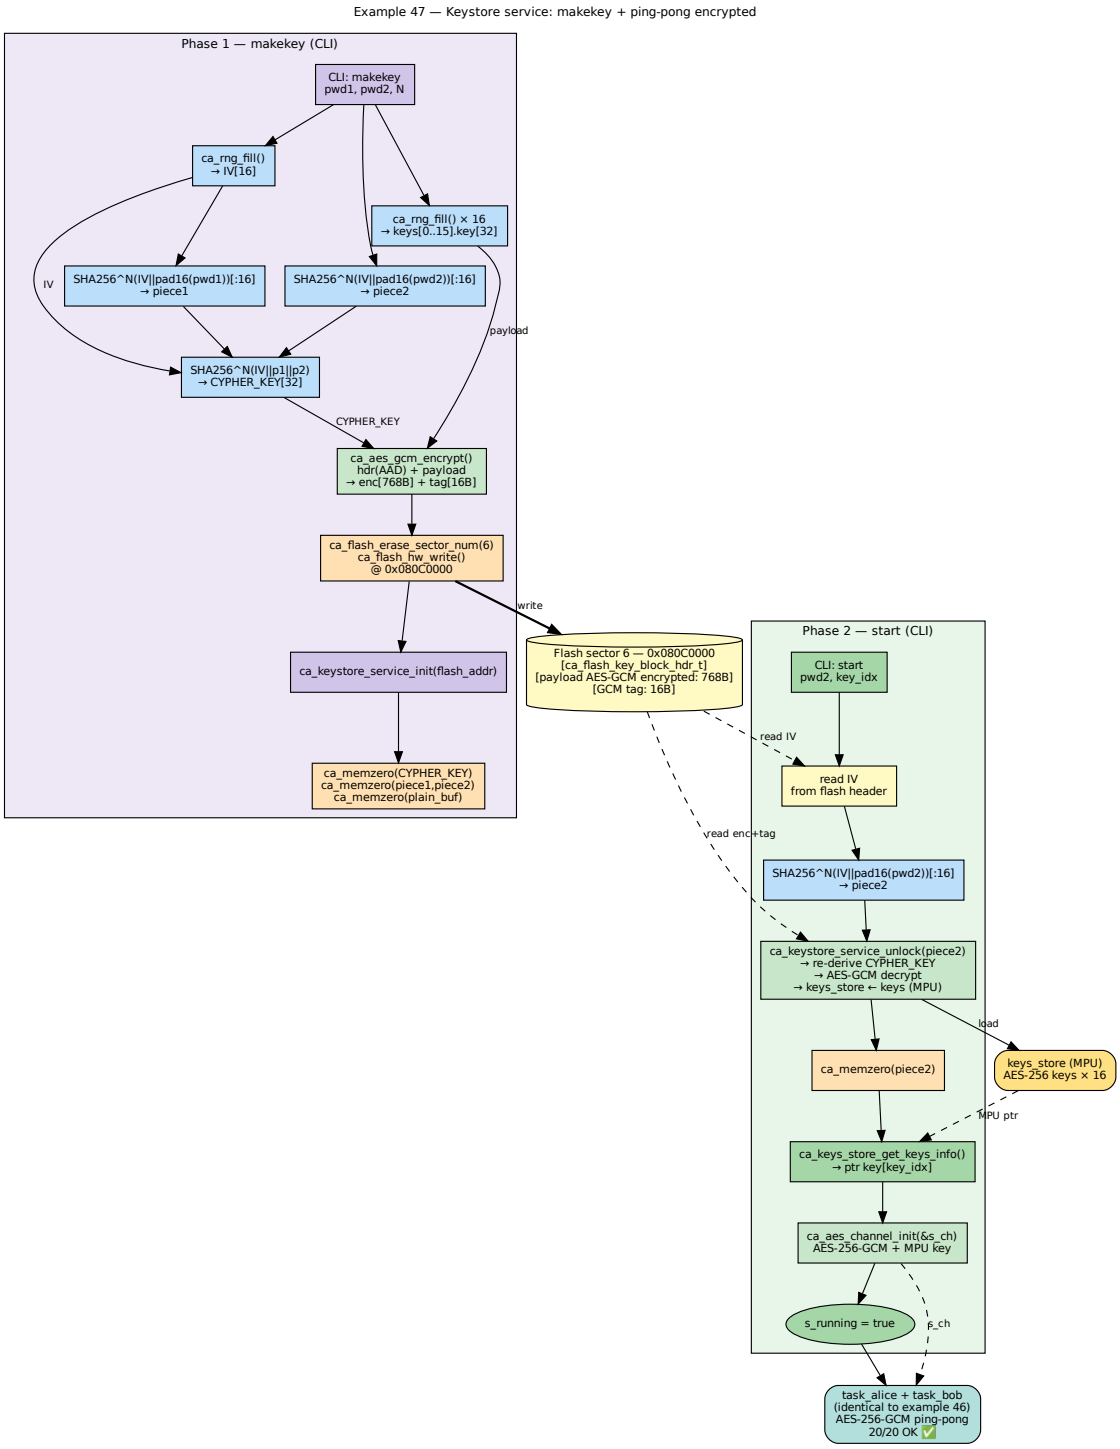

Figure 70.1: makekey + start + ping-pong flow — keystore service

70.1.5 Phase 1 — makekey

KDF (Key Derivation Function)

```
piece1 = SHA256^N(IV || pad16(pwd1))[:16]
piece2 = SHA256^N(IV || pad16(pwd2))[:16]

CYPHER_KEY = SHA256^N(IV || piece1 || piece2)   [32 byte]
```

- `IV` = 16 random bytes from `ca_rng_fill()`
- `pad16(pwd)` = password truncated/padded to 16 bytes with zeros
- `N` = number of hash iterations (1..16), configurable via CLI

Separating `pwd1` and `pwd2` allows distributing the two passwords to different entities (e.g. provisioner and operator): to decrypt the block only `pwd2` is needed, but to recreate it both are required.

Flash block structure

```
typedef struct {
    u32 size;           /* dimensione totale blocco in byte */
    u8  IV[16];         /* random IV     needed to derive piece2 in do_start()
    */
    u32 n_evolve;       /* number of SHA256 rounds */
    u8  p1[16];         /* piece1 salvato in chiaro nell'header */
    u16 n_key;          /* number of keys (16) */
    u8  gcm_nonce[12];  /* AES-GCM nonce for the payload */
} ca_flash_key_block_hdr_t;
```

The encrypted payload contains an array of `ca_flash_key_entry_t` (16×48 bytes $= 768$ bytes), each with `key_id`, `label`, `key[32]`, `start`, `stop`.

Operation sequence

```
1. RNG     IV[16]
2. derive_piece(IV, pwd1, N)     piece1[16]
3. derive_piece(IV, pwd2, N)     piece2[16]
4. RNG     keys[0..15].key[32]   (16 random AES-256 keys)
5. KDF     CYPHER_KEY[32]
6. RNG     gcm_nonce[12]
7. costruisce header (IV, n_evolve, p1, n_key, gcm_nonce)
8. AES-GCM encrypt(CYPHER_KEY, gcm_nonce, header_AAD, payload)     enc + tag
9. ca_flash_erase_sector_num(6)
10. ca_flash_hw_write(addr, [hdr | enc | tag], len)
11. ca_keystore_service_init(flash_addr)
```

70.1.6 Phase 2 — start

```
1. ca_keystore_service_init(flash_addr)   if not already active
2. legge IV dall'header in flash
3. derive_piece(IV, pwd2, n_evolve)     piece2
4. ca_keystore_service_unlock(piece2)
       re-derives CYPHER_KEY = SHA256^N(IV || p1_dal_hdr || piece2)
       AES-GCM decrypt payload
       loads the keys into keys_store (MPU-protected area)
5. ca_memzero(piece2)
6. ca_keys_store_get_keys_info()     reads the ptr to key[key_idx]
7. ca_secure_pipe_init(&s_pipe, CA_AES_MODE_GCM, CA_AES_KEY_256, key_ptr, 4)
8. s_running = true     sblocca task_alice e task_bob
```

The password `pwd1` is never needed after `makekey`. Only `pwd2` + IV in flash allows to reconstruct `piece2` and decrypt the block.

70.1.7 Encrypted ping-pong (same as example 46)

Once started (`s_running = true`), the tasks `alice` and `bob` execute the same encrypted ping-pong of example 46 through the secure pipe `ca_secure_pipe_t s_pipe`.

The pipe is recreated at every `start` (the key changes with index N), therefore it must also be closed: at the end of the loop Alice raises `s_done`, and **Bob** closes it — the only task that can still be inside `ca_secure_pipe_recv` — `deinit` must be called on a closed pipe. Until Bob closes it, `start` responds "already running".

Task	Priority	Stack	Role
`alice`	LEVEL4	STACK_MEDIUM	initiator — encrypt/send/receive/decrypt
`bob`	LEVEL4	STACK_MEDIUM	responder — receive/decrypt/encrypt/send
`hb`	LEVEL3	STACK_SMALL	heartbeat LED

For details on the GCM wire format and heap management see Example 46.

70.1.8 CLI — state machine

The CLI uses a state hook to collect parameters in sequence:

```
makekey:
  prompt: password1     password2     n_evoluzioni     esegue do_makekey()

start:
  prompt: password2     key index (0..15)     runs do_start()
```

Both reset the passwords from RAM with `ca_memzero` after use.

70.1.9 UART Output

```
makekey: password1:
> admin
makekey: password2:
> operator
makekey: n_evoluzioni (1..16):
> 3
[makekey] IV: 9a f3 12 ...
[piece1] SHA256 iter 1: ...
[piece1] piece[:16]: 5c 2b ...
[piece2] piece[:16]: a1 d7 ...
[makekey] CYPHER_KEY iter 3: 44 8e ...
[makekey] write 880 byte @ 0x080C0000
makekey: OK     852 bytes on flash @ 0x080C0000, 16 keys

start: password2:
> operator
start: key index (0..15):
> 0
[start] IV da flash: 9a f3 12 ...
```

```
[start/p2] piece[:16]: a1 d7 ...
start: OK     key[0] loaded, starting ping-pong
=== EX47: AES-GCM ping-pong (keystore, secure pipe) ===
Alice TX: 'PING #0 from Alice'
Bob RX: 'PING #0 from Alice'
Bob TX: 'PONG #0 from Bob'
Alice RX: 'PONG #0 from Bob'     OK
...
Alice: 20/20 ping OK
Alice: test completato.
```

70.1.10 Security — notes

Aspect	Solution
Keys in RAM	`keys_store` with MPU — CPU access blocked except during use
Password in RAM	`ca_memzero` immediately after derivation
Encryption key block	calculated on-the-fly, zeroed (`ca_memzero`) after encrypt
GCM nonce reuse	impossible — new random nonce for each session `makekey`
Block reconstruction	requires `pwd1` + `pwd2` + new `makekey`
Block decryption	requires only `pwd2` + `IV` saved in flash header

---

Previous chapter: Example 46 — AES channel service See also: Encryption in caOS

Chapter 71

IP Defrag Service: DHCP + UDP Server + Fragments

71.1 Example 48 — IP defrag service: DHCP + UDP server + fragment reassembly

71.1.1 Introduction

This example demonstrates the IP fragment reassembly service (`ip_defrag_service`) of caOS, according to RFC 791.

The system receives UDP datagrams that the sender transmits split into multiple IP fragments. The `defrag task` collects the fragments, reassembles them in order, and injects the reconstructed packet into the normal IP dispatch chain, making the reassembly completely transparent to the UDP application.

Element	Value
Parallel sessions	`IP_DEFRAG_MAX_SESSIONS` (default 4)
Session timeout	`IP_DEFRAG_TIMEOUT_MS` (default 15 000 ms)
Maximum payload	`IP_DEFRAG_MAX_PAYLOAD` (default 1480 bytes)
Allocated heap	`IP_DEFRAG_MAX_SESSIONS IP_DEFRAG_MAX_PAYLOAD`
Session identification	`(src_ip, dst_ip, proto, ip_id)`
Buffer pool release	immediately upon fragment arrival
HW Test	**NUCLEO-H753ZI — tested OK**

71.1.2 Hardware

Board: NUCLEO-H753ZI (STM32H753ZI, Cortex-M7 @ 480 MHz)

Pin	Function
PB0	Green LED — ETH link (on = link UP)
PB14	Red LED — heartbeat (toggle every 500 ms)
PHY LAN8742A	RMII, addr 0 — Ethernet connection

71.1.3 os_config.h Configuration

```
#define EN_ETH                1   /* driver Ethernet H7xx */
#define EN_NET                1   /* caOS network stack */
#define EN_NET_DHCP           1   /* parser DHCP in net_proto */
#define EN_ARP_SERVICE        1   /* cache ARP + GARP */
#define EN_DHCP_SERVICE       1   /* DHCP client DORA + renew */
#define EN_UDP_SERVER         1   /* multi-client UDP server */
#define EN_IP_DEFRAG          1   /* IP fragment reassembly */
#define EN_CRC                1   /* HW CRC (optional     used by the tests) */

/* Defrag parameters (default values) */
#define IP_DEFRAG_MAX_SESSIONS   4U
#define IP_DEFRAG_TIMEOUT_MS     15000U
#define IP_DEFRAG_MAX_PAYLOAD    1480U
```

71.1.4 Architecture

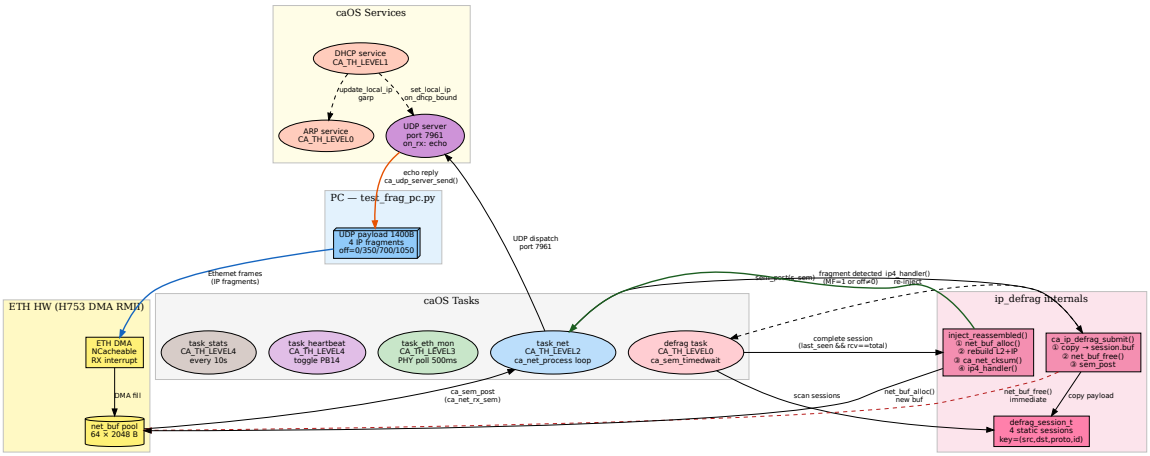

Figure 71.1: IP defrag flow — fragments, submit, defrag task, inject, UDP server

---

71.1.5 ip_defrag_service API

Initialization

```
bool ca_ip_defrag_init(u32 max_payload_size);
```

Allocate `IP_DEFRAG_MAX_SESSIONS` `max_payload_size` bytes from caOS heap. Initialize semaphore `s_sem` and mutex `s_mtx`. To be called in `ca_os_configure()`.

Parameter	Description
`max_payload_size`	Maximum IP payload size (without header). Typically 1480 (MTU 1500 20 IP hdr).
Return	`true` if allocation successful, `false` if heap exhausted or parameter out of range.

Task startup

```
void ca_ip_defrag_service_start(void);
```

Create task `defrag` with priority `CA_TH_LEVEL0`. To be called in `ca_os_main()`.

Submit fragment (internal use)

```
void ca_ip_defrag_submit(u16 buf_idx);
```

Automatically called by `ca_net_proto_ip4_handler()` when a fragmented packet is detected (`MF=1` or `fragment offset  0`).

71.1.6 Internal structure — session

```
typedef struct {
    bool     active;
    u32      src_ip, dst_ip;
    u8       proto;
    u16      ip_id;           /* identification key */
    u8       src_mac[6], dst_mac[6];
    u32      expires_ms;      /* ca_os_tick_ms() + IP_DEFRAG_TIMEOUT_MS */
    u32      total_payload;   /* set when the last fragment arrives */
    u32      received;        /* byte accumulati */
    bool     last_seen;       /* true when MF=0 received */
    u8      *buf;             /* slice of s_mem: reassembled payload */
} defrag_session_t;
```

The session is identified by the quadruple `(src_ip, dst_ip, proto, ip_id)`. Each session has a fixed-size `s_max_payload` pre-allocated buffer. The net_buf are freed **immediately** after copying, avoiding pool starvation.

71.1.7 Tasks and priorities

Task	Priority	Stack	Function
`net`	CA_TH_LEVEL2	STACK_SMALL	rx loop + dispatch
`defrag`	CA_TH_LEVEL0	STACK_SMALL	reassembly + inject
`eth_mon`	CA_TH_LEVEL3	STACK_SMALL	poll PHY every 500 ms
`stats`	CA_TH_LEVEL4	STACK_SMALL	statistics every 10 s
`heartbeat`	CA_TH_LEVEL4	STACK_SMALL	toggle LED PB14

71.1.8 PC Tests

```
sudo python3 examples/example_48/test_frag_pc.py --ip <ip_board> --port 7961
```

The script sends a 1400-byte UDP datagram (incremental fill `i % 256`) split into 4 IP fragments of 350 bytes each, with offset multiples of 8. It waits for the echo and verifies that `len` and `checksum` match those sent.

Expected output on board:

```
=== EX48: DHCP + UDP server + IP defrag ===
MAC  02:00:00:00:00:48
defrag: sessions=4 timeout=15000ms payload_max=1480B
DHCP: avvio DORA...
DHCP BOUND  IP=192.168.1.42  mask=255.255.255.0
            GW=192.168.1.1  DNS=192.168.1.1
DEFRAG init OK: sessions=4 max_payload=1480 heap=5920 B
DEFRAG frag: off=0   len=350 MF=1 rcv=350
DEFRAG frag: off=350 len=350 MF=1 rcv=700
DEFRAG frag: off=700 len=350 MF=1 rcv=1050
DEFRAG frag: off=1050 len=350 MF=0 rcv=1400 [LAST]
DEFRAG COMPLETE: id=0x1234 total=1400 B     inject
UDP[7961] cid=0  rx=1400 B  sum=0x0006DC00  from 192.168.1.10:12345
```

71.1.9 Implementation notes

Reconstructed IP checksum: `inject_reassembled` clears `ip4->cksum`, then calls `ca_htons(ca_net_cksum(...))` to recalculate the correct checksum. Without this fix the packet would be dropped by `ca_net_proto_ip4`.

Fragment order: the service supports out-of-order fragments — each fragment is written to `buf` at the correct `byte_off` position before `last_seen` becomes true.

Pool starvation: net_bufs are freed in `ca_ip_defrag_submit()`, not in the defrag task. This ensures that under burst of fragments the pool does not get exhausted before the task can process them.

Chapter 72

TFTP Client: GET and PUT over UDP (RFC 1350)

72.1 Example 49 — TFTP Client (RFC 1350)

72.1.1 Description

Example 49 demonstrates the **TFTP client** of caOS: a UDP-based file transfer service conforming to RFC 1350, with support for GET (download from server) and PUT (upload to server).

Main use case: **OTA firmware update** — the board downloads a binary image from a PC TFTP server and writes it to flash.

Example features: 1. **DHCP** — obtains IP address automatically 2. **ARP** — resolves server MAC address 3. **ICMP echo reply** — responds to ping requests 4. **CLI** — `tftp get <ip> <file>`, `tftp put <ip> <file> [size]`, `tftp info` 5. **TFTP client** — blocking GET and PUT with retry

Hardware: NUCLEO-H753ZI (STM32H753ZI), PHY LAN8742A RMII.

> **HW test status (H753, 2026-06-04):** GET and PUT verified on NUCLEO-H753ZI. The network stack has no regressions after introduction of the `ca_net_iface_t` abstraction (NCM): ARP/ICMP (ex33) and DHCP+TFTP (ex49) OK.

72.1.2 TFTP Protocol (RFC 1350)

TFTP uses UDP port 69 for the initial request; the server replies from its own TID (Transfer ID = ephemeral port). PDU types are:

Opcode	Name	Description
1	RRQ	Read Request (GET)
2	WRQ	Write Request (PUT)
3	DATA	Data block (max 512 bytes)
4	ACK	Acknowledgement (block number)
5	ERROR	Error (code + message)

GET flow:

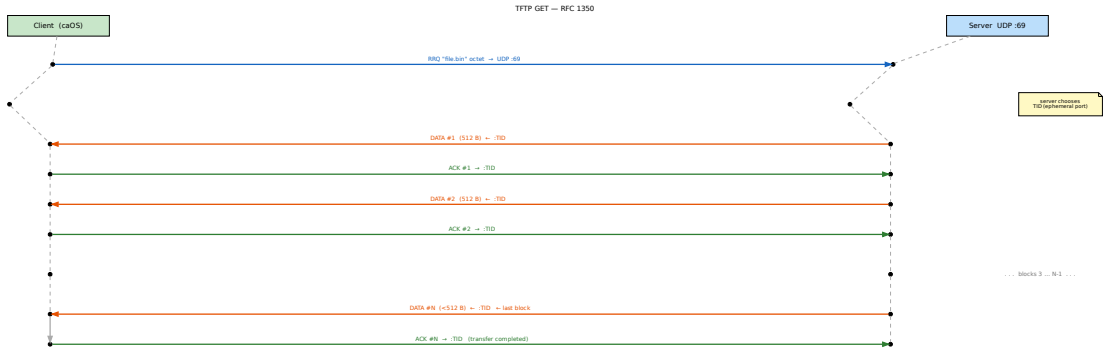

Figure 72.1: TFTP GET sequence — RFC 1350

PUT flow and PDU table:

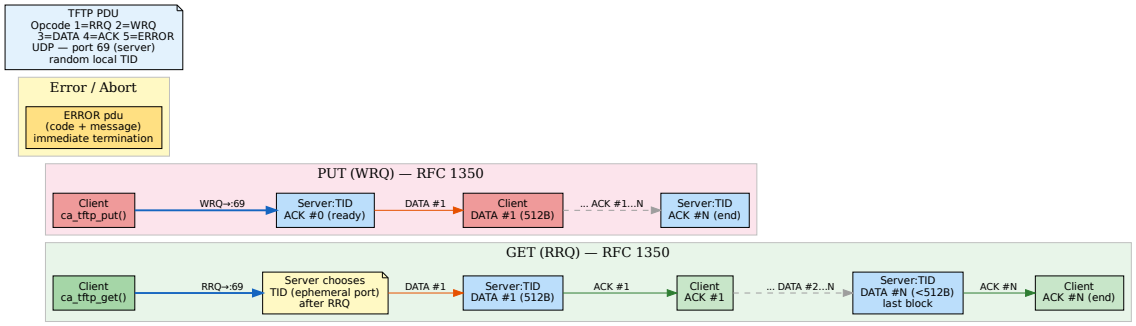

Figure 72.2: TFTP PUT sequence / PDU table — RFC 1350

72.1.3 Architecture `tftp_service`

```
Caller task (LEVEL3+)
  ca_tftp_get(cfg, on_block, arg)
            ca_net_resolve_mac()            ARP bloccante
            ca_net_proto_bind_udp()         porta TID locale
            tftp_send_pkt(port=69)          RRQ
            loop:
          ca_sem_timedwait(rx_sem)
          on_block(blk, data, len, arg)
          tftp_send_pkt(server_tid)       ACK

Net task (LEVEL2)
  tftp_rx_handler(buf_idx)
            verifica server_ip + TID
            ring_push(buf_idx)
            ca_sem_post(rx_sem)
```

72.1.4 API

ca_tftp_get

```
bool ca_tftp_get(const ca_tftp_cfg_t *cfg,
                 ca_tftp_rx_block_t on_block,
                 void *arg);
```

Download a file from the TFTP server. Call `on_block` for each received block (max 512 byte); the last block has `len < 512`. Returns `true` if the transfer is completed successfully.

Callback:

```
typedef bool (*ca_tftp_rx_block_t)(u16 block_num,
                                   const u8 *data, u16 len,
                                   void *arg);
```

Returning `false` from the abort callback aborts the transfer (the service sends an ERROR PDU to the server).

ca_tftp_put

```
bool ca_tftp_put(const ca_tftp_cfg_t *cfg,
                 const u8 *data, u32 total_len);
```

Load a memory buffer on the TFTP server as a remote file. Returns `true` if all blocks have been ACK-ed.

> **EOF (RFC 1350):** if `total_len` is a multiple of 512, the client sends a final DATA block of **0 bytes** to signal end of transfer. Without this block the server would remain waiting (timeout).

ca_tftp_service_init

```
void ca_tftp_service_init(ca_mac_t local_mac);
```

Initialize the service and register the CLI. Call from `ca_os_configure()`.

72.1.5 ca_tftp_cfg_t Configuration

```
typedef struct {
    ca_ipv4_t      server_ip;
    const char *filename;
    ca_mac_t       local_mac;
    ca_ipv4_t      local_ip;
    u16         local_port;         /* 0 = auto (TFTP_LOCAL_PORT_BASE) */
    u32         arp_timeout_ms;     /* 0 = 2000 ms */
    u32         block_timeout_ms;   /* 0 = TFTP_BLOCK_TIMEOUT_MS */
    u8          retry_n;            /* 0 = TFTP_RETRY_N */
} ca_tftp_cfg_t;
```

72.1.6 Parameters os_config.h

Define	Default	Description
`EN_TFTP_SERVICE`	1	Enable TFTP service
`TFTP_BLOCK_TIMEOUT_MS`	5000	Block timeout (ms)
`TFTP_RETRY_N`	3	Retries per block before fail
`EN_CLI_TFTP`	1	Enable CLI `tftp`

72.1.7 CLI Commands

Command	Description
`tftp get <ip> <file>`	Download `<file>` from `<ip>` server (PC→board download)
`tftp put <ip> <file> [size]`	Upload a pattern buffer of `size` bytes (default 1024, max 64 KB) as `<file>` to the server (board→PC upload)
`tftp info`	Show port, timeout, retries, block size

The command `put` allocates the buffer in RAM with `ca_memory_allocate(size)`, fills it with a known pattern (`0x00..0xFF` cyclic) and frees it with `ca_memory_free()` at the end.

72.1.8 PC Testing

The script `test_tftp_pc.py` runs **DHCP server + TFTP server** in one single command. With `--iface` it configures the interface (IP `192.168.10.1/24` + dnsmasq, pool `.100 .200`) as in example 35. Then TFTP is served. Requires root (port 69 + network setup) and automatic cleanup on exit.

```
# DHCP + TFTP server in one go (replace enp7s0 with your own interface)
sudo python3 examples/example_49/test_tftp_pc.py --iface enp7s0 \
    --file firmware.bin --size 16384

# TFTP only (board with an IP already assigned): legacy behaviour
sudo python3 examples/example_49/test_tftp_pc.py --bind 0.0.0.0 \
    --file firmware.bin --size 16384
```

The board, having obtained the IP via DHCP, prints `DHCP BOUND IP=192.168.10.1xx`.

GET (download from PC):

```
> tftp get 192.168.10.1 firmware.bin
TFTP GET firmware.bin from 192.168.10.1 ...
TFTP GET OK: 32 blocks, 16384 bytes
```

PUT (upload to PC — requires `--put` on server side, saves to `<file>_recv.bin`):

```
> tftp put 192.168.10.1 up.bin 4096
TFTP PUT up.bin (4096 B) to 192.168.10.1 ...
TFTP PUT OK: 4096 bytes
```

```
sudo python3 examples/example_49/test_tftp_pc.py --iface enp7s0 --put --file up.
    bin
# ... [OK] received 4096B     up.bin_recv.bin
```

72.1.9 Application flow (example 49)

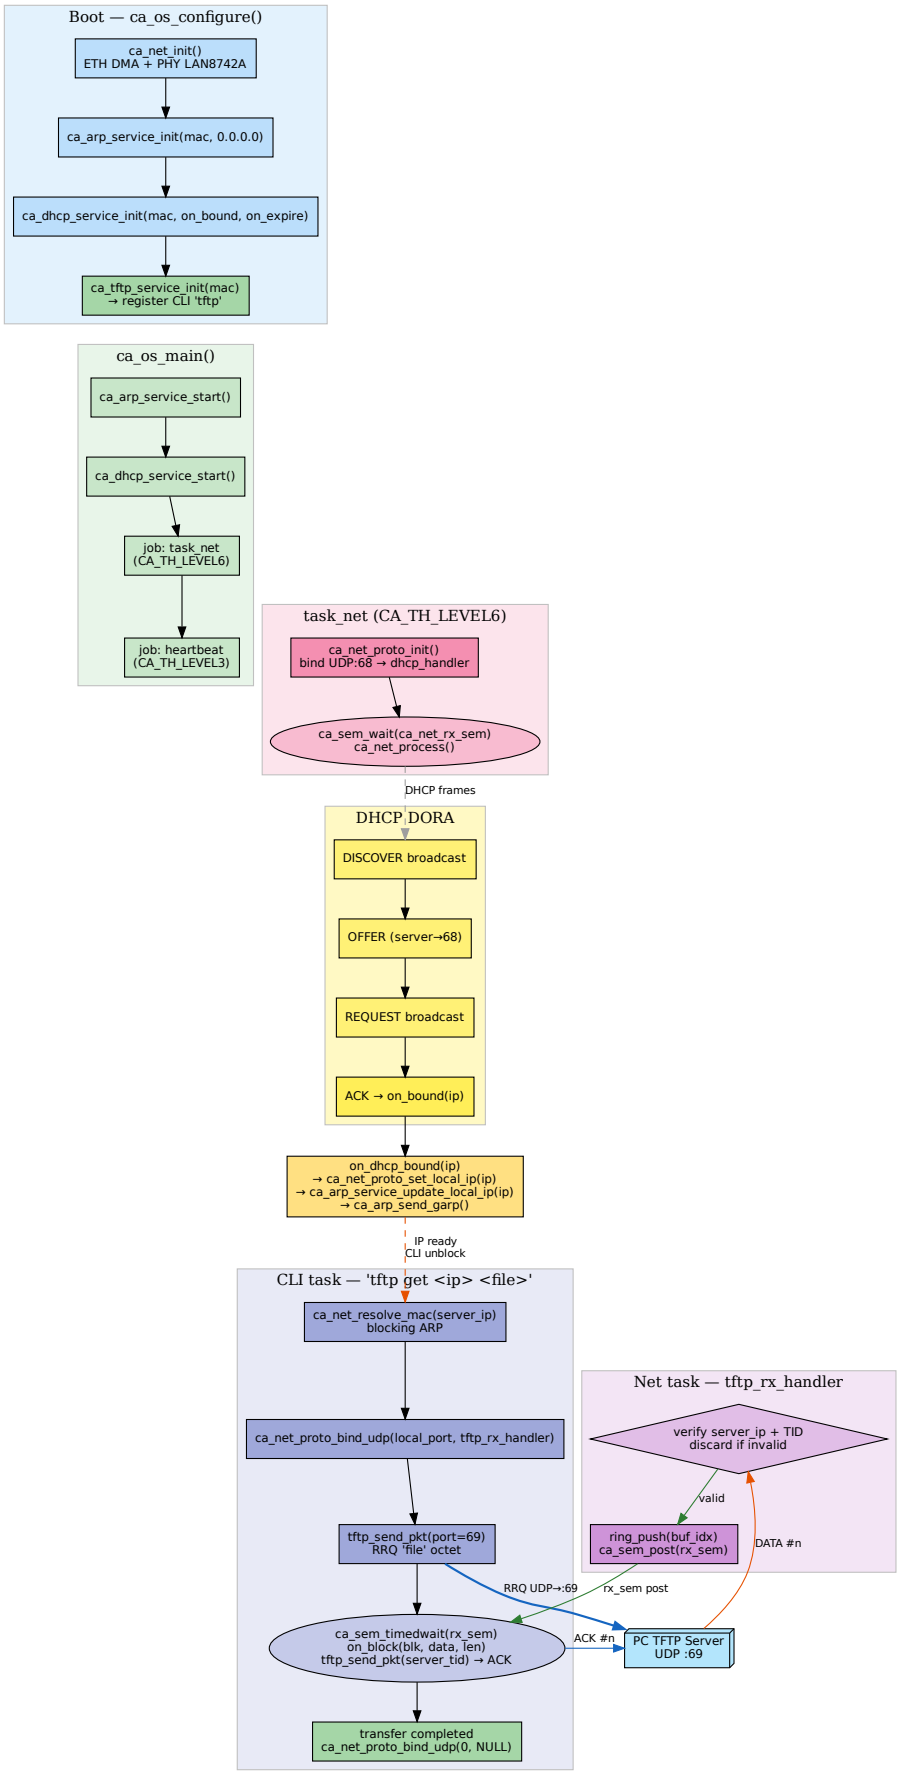

Figure 72.3: Complete DHCP → TFTP GET flow — example 49

```
ca_os_configure()
         ca_arp_service_init()
         ca_dhcp_service_init()
         ca_tftp_service_init(mac)        registra CLI

ca_os_main()
         ca_arp_service_start()
         ca_dhcp_service_start()
         jobs: net / eth_mon / heartbeat

task_net:
  ca_net_proto_init()
  ca_net_proto_bind_udp(68, dhcp_handler)
  ca_dhcp_service_net_ready()
  loop: ca_net_process()

CLI (after DHCP):
  tftp get <ip> <file>
           ca_tftp_get()     blocking in the CLI task
```

72.1.10 File Structure

File	Description
`caos/net/inc/tftp_service.h`	Public API
`caos/net/src/tftp_service.c`	Implementation + CLI
`examples/example_49/ca_os_ex49.c`	DHCP + TFTP CLI Example
`examples/example_49/test_tftp_pc.py`	TFTP server Python for testing

Chapter 73

USB Vendor Class: Multi-EP Bulk Loopback

73.1 Example 50 — USB Vendor-Class Bulk Loopback

73.1.1 Description

Example 50 demonstrates the **bare-metal USB driver** of caOS (DWC2 core) used directly, without a class stack: the board enumerates as a **vendor-class** device and exposes N pairs of bulk IN/OUT endpoints that perform **loopback** (every byte received on OUT is sent back on the corresponding IN).

It is the test bench for the low-level driver and the **per-EP queue** mechanism: each bulk endpoint has a dedicated loopback task, so all EPs run in parallel (composite device).

Example features: 1. **Enumeration** as a vendor device (VID `0xCA01`, PID `0x0001`) 2. **EP0 control**: `GET_DESCRIPTOR`, `SET_ADDRESS`, `SET_CONFIGURATION`, `CLEAR/SET_FEATURE(ENDPOINT_HALT)`, `GET_STATUS` 3. **EP1..EPn bulk IN/OUT**: loopback, one task per EP 4. **CLI** `usb`: status, halt/resume, ep, open/close/stall/unstall, errs

Supported hardware:

Board	OTG	`USB_NUM`	MPS	Data EP
NUCLEO-H753ZI	FS CN14 (or HS ULPI)	1 (or 0)	64 (512 HS)	6
NUCLEO-U575ZI-Q	Internal FS	0	64	5
STM32F4VE (black board)	Internal FS	0	64	3

Measured HW throughput: **H753 6 EP @ 0.491 MB/s**, **U575 5 EP @ 0.466 MB/s**, **F407 3 EP @ 0.548 MB/s** (aggregated across parallel EPs).

> The low-level USB driver (API, DMA vs slave mode, per-EP queues) is documented in `S02_11_00_usb_driver.md`. This chapter only describes the application usage in example 50.

73.1.2 Example Architecture

```
ISR DWC2 (driver)
  on_reset       s_dev_state=ATTACHED, notify task_usb
  on_setup       copia SETUP 8B, notify task_usb (NOTIFY_SETUP)
  on_rx(epN)     notify task_loop[N] (NOTIFY_BULK_RX)
  on_tx_done     applica SET_ADDRESS deferred su EP0
```

```
6
7  task_usb (LEVEL6)     controllo
8    handle_setup()       EP0: descriptor, address, config, feature, status
9    handle_status()      logs the state change
10
11 task_loop[1..N] (LEVEL5)     one per bulk EP
12   loop_drain(ep): ca_usb_ep_read(OUT)     ca_usb_ep_write(IN)
13
14 task_hb (LEVEL4)     heartbeat LED 500 ms
```

Each bulk EP has a **per-EP driver queue + dedicated task** → no contention, fair round-robin between endpoints with equal priority.

73.1.3 Descriptors

Minimal vendor-specific device:

- **Device**: class/subclass/protocol = `0xFF`, `bMaxPacketSize0 = 64`, 1 configuration.
- **Config**: 1 vendor interface with `NUM_DATA_EP * 2` bulk endpoints (`wTotalLength = 9 + 9 + NUM_DATA_EP*2*7`).
- **String**: LANGID US-EN, “caOS”, “USB Vendor Test”.

`NUM_DATA_EP` = 6 (H7/F4) or 5 (U5, for `USB_EP_MAX=6`). The cap stems from the `XFRSIZ` limit of EP0: the config descriptor (18 + N*14 bytes) must fit in 127 B to avoid requiring data-stage chunking across all families.

73.1.4 SETUP handler (EP0)

`handle_setup()` runs in task context (woken by `on_setup`) and implements the standard subset required for enumeration:

bmRequest	bRequest	Action
`0x80`	`GET_DESCRIPTOR`	send device/config/string
`0x00`	`SET_ADDRESS`	`ca_usb_set_address` immediately + ZLP status
`0x00`	`SET_CONFIGURATION`	open EP1..N IN+OUT, ZLP status
`0x02/0x82`	`CLEAR/SET_FEATURE(HALT)`	`ep_clear_stall`/`ep_stall` + ZLP
`0x82`	`GET_STATUS` (endpoint)	return HALT bit from `ep_is_stalled`
`0x80/0x81`	`GET_STATUS` (dev/iface)	return `0x0000` (bus-powered)
other	—	STALL EP0 + log in debug ring

`CLEAR/SET_FEATURE(ENDPOINT_HALT)` and `GET_STATUS` are **necessary**: pyusb and the Linux kernel issue them at `set_configuration`. Without a handler, the device STALLs and the host reacts with a bus reset → infinite enumeration loop (bug encountered on U575).

73.1.5 CLI `usb`

```
usb status                  # state, speed, rx/tx/err counters
usb ep                      # list EPs and their state (open/closed/STALL)
usb halt | resume           # soft disconnect / reconnection (re-enumerates)
usb open|close   <ep>       # apre/chiude EP a runtime (Patch 1)
usb stall|unstall <ep>      # forces/clears STALL on an EP (Patch 1)
usb errs                    # ring of the last 16 SETUPs that went to STALL
usb dbg | dbg reset         # H753 only: ISR latencies via the DWT cycle counter
```

`usb open/close/stall/unstall` exercise the API endpoint at runtime while the device is configured — useful for testing flow-control and host-side STALL recovery.

`usb errs` decodes the ring of unhandled SETUPs (`bmRequestType / bRequest / wValue / wIndex / wLength`). These commands are the debug template to be replicated in the next USB examples (51–56).

73.1.6 Parameters (per-MCU, in `ca_os_ex50.c`)

Define	H753	U575	F407
`USB_NUM`	1	0	0
`EP_BULK_MPS`	64	64	64
`NUM_DATA_EP`	6	5	3
LED heartbeat	PB7	PC7	PA6

F407 (STM32F4VE black board): `OTG_FS` has only 4 total endpoints (`USB_EP_MAX=4`), so data EP = EP1..3 = 3 bulk pairs. The LED is **PA6** (D2, user on the black board) — not PD12 as on NUCLEO F4 boards. Measured throughput: **0.548 MB/s** aggregated over 3 EPs. The EP3 ring queue was increased from 16 to 64 slots to eliminate drops that caused RX sequence misalignment during loopback.

`os_config.h` requirements: `EN_USB = 1`; all standard classes at 0 (`EN_USB_CDC`, `EN_USB_MSC`, `EN_USB_NCM`, `EN_USB_CUSTOM`): the example builds its own vendor-class descriptors directly in the source code. The USB stack is the native caOS one: TinyUSB has been removed from the project.

73.1.7 Test from PC

Verify enumeration:

```
lsusb                       # VID=0xCA01 PID=0x0001  "USB Vendor Test"
```

Perform a loopback on all EPs (the number is auto-detected from the config descriptor — H753=6, U575=5):

```
sudo python3 examples/example_50/test_usb_loopback.py --ep 6
```

Expected output (H753, 6 EP):

```
EP pairs detected from config descriptor: 6
loopback EP1..EP6  500 frames each ...
OK: 3000/3000 frames  @ 0.491 MB/s aggregate
```

The `count_device_ep_pairs()` script reads the config descriptor and auto-detects the number of EPs, so there are no magic numbers on the test side.

73.1.8 File structure

File	Description
caos/drivers/inc/usb.h	USB driver API (see S02_11)
caos/drivers/src/usb.c	generic wrapper
hw/h7xx/drivers/usb_h7xx.c	DWC2 DMA (H753)
hw/u5xx/drivers/usb_u5xx.c	DWC2 slave + per-EP code (U575)
hw/f4xx/drivers/usb_f4xx.c	DWC2 slave FIFO (F407/F429/F446, no DMA)
examples/example_50/ca_os_ex50.c	vendor loopback example + CLI
examples/example_50/test_usb_loopback.py	PC loopback test (auto-EP)

73.1.9 F407 Notes — slave mode driver

The DWC2 OTG_FS of the STM32F407 (RM0090 §34.3.2) **does not have DMA**: the DMAEN bit in GAHBCFG is *hardwired* to 0. The usb_f4xx.c driver is therefore written in **slave mode** (CPU push/pop on FIFOs), identical in structure to usb_u5xx.c. Hardware differences compared to the U575:

Aspect	F407 OTG_FS	U575 OTG_FS
DMA	no (DMAEN=0)	no (slave Phase 1b)
Total EPs	4 (EP0..3)	6 (EP0..5)
Bulk data EPs	3 (EP1..3)	5 (EP1..5)
Total FIFO	320 words (1280 B)	320 words (1280 B)
VBUS sensing	GCCFG.NOVBUSSENS	GOTGCTL.BVALOEN
Clock	PLLQ = 48 MHz	HSI48
GPIO	PA11=DM, PA12=DP AF10	PA11=DM, PA12=DP AF10
IRQ	OTG_FS_IRQn (single)	OTG_FS_IRQn (single)

GCCFG.NOVBUSSENS is necessary on F407 because the DWC2 GUID is < 0x2000 (F2/F4 generation): it does not expose GOTGCTL.BVALOEN/BVALOVAL used by the U575 to force VBUS sensing on the software side.

Chapter 74

USB Management Stack: Custom Class

74.1 Example 51 — USB Management Stack: custom class

74.1.1 Description

Example 51 demonstrates the **high-level USB stack** of caOS (`caos/usb/usb_mgmt`) using the `ca_usb_custom` service as reference implementation of `ca_usb_class_ops_t`.

Unlike example 50 — where descriptors and EP0 were entirely in the application — here the app **does not touch** EP0 nor the descriptors: the management builds composite device/config descriptors and dispatches standard SETUP; the custom service provides only the interface descriptor, opens its EP on `SET_CONFIGURATION` and does fan-out of `on_rx`/`on_tx_done`.

Three calls are enough to bring up the device:

```
ca_usb_dev_mng_init(CA_USB_SPEED_FS, USB_NUM);          /* registers the mgmt driver callbacks */
ca_usb_dev_mng_add(&s_custom.header);   /* registers the custom class */
ca_usb_dev_mng_start();                /* build descriptors + connect enumerates */
```

Features: 1. **Enumeration** as device vendor (VID `0xCA01`, PID `0x0001`) — descriptors generated by mgmt, not hard-coded in app 2. **1 bulk IN/OUT EP** (EP1) with loopback in task context 3. **CLI** `usb`: status, start/stop, add/remove (runtime lifecycle)

Supported hardware: NUCLEO-H753ZI (`USB_NUM=1`), NUCLEO-U575ZI-Q (`USB_NUM=0`), NUCLEO-F407ZG (`USB_NUM=0`), all OTG_FS, MPS 64.

> The `ca_usb_dev_mng` stack is documented in the `doc/usb_stack_workplan.md` plan (decisions D1–D20). The low-level driver is in `S02_11_00_usb_driver.md`.

74.1.2 Hardware

All boards operate in OTG_FS. No external wiring: connect the device USB connector (OTG_FS, not ST-LINK).

Board	MCU	`USB_NUM`	USB Connector	Heartbeat LEI
NUCLEO-H753ZI	STM32H753ZI	1	OTG_FS (CN14, “USB user”)	PB7 (LD2 gre
NUCLEO-U575ZI-Q	STM32U575ZI	0	Internal OTG_FS	PC7 (LD1 gre
STM32F4VE (black board)	STM32F407VET6	0	Internal OTG_FS (PA11/PA12)	PA6 (D2)

F407 (Chinese black board): the LED is PA6; user USB connector on-board micro-USB connected to PA11/PA12. Tested HW: 10000/10000 EP1 loopback OK.

74.1.3 os_config.h Configuration

```
#define EN_USB        1     /* driver USB DWC2 + stack mgmt */
#define EN_USB_CUSTOM 1     /* enables the custom class (reference class_ops) */
/* Test isolato: le altre classi a 0 */
#define EN_USB_CDC    0
#define EN_USB_MSC    0
#define EN_USB_NCM    0
```

`ca_usb_custom` is the **reference implementation** of `ca_usb_class_ops_t`: the minimal model to copy when writing a new USB class.

74.1.4 Architecture

```
ca_usb_dev_mng_init(CA_USB_SPEED_FS, USB_NUM)
         ca_usb_init(USB_NUM, &s_mgmt_cb)       mgmt registra i SUOI callback
    driver

ISR DWC2     callback mgmt     fan-out via ops ai servizi attivi:
  mng_on_setup     dispatch_standard (EP0: descriptor/address/config/...)
                  dispatch_class    (SETUP class-level     ops->on_setup)
  mng_on_rx        ops->on_rx          custom_on_rx     cfg->on_rx (app)
  mng_on_tx_done     ops->on_tx_done     custom_on_tx_done     cfg->on_tx_done (
    app)

ca_usb_custom_ops (in caos/usb/usb_custom.c):
  build_iface_desc     interface vendor 0xFF + 2 EP bulk (23B)
  on_configure         ca_usb_ep_open EP1 IN+OUT
  on_rx / on_tx_done     fan-out a cfg->on_rx / cfg->on_tx_done

App (example_51):
  custom_rx(ep,len)      da ISR     notify task_loop
  task_loop: loop_drain()     ca_usb_ep_read(OUT)     ca_usb_ep_write(IN)
```

The management does not switch on `type`: it iterates the registered services and invokes their `ops`. Adding a class (CDC/MSC/NCM) means only registering a new `cfg` with its `ops` table — the core remains unchanged.

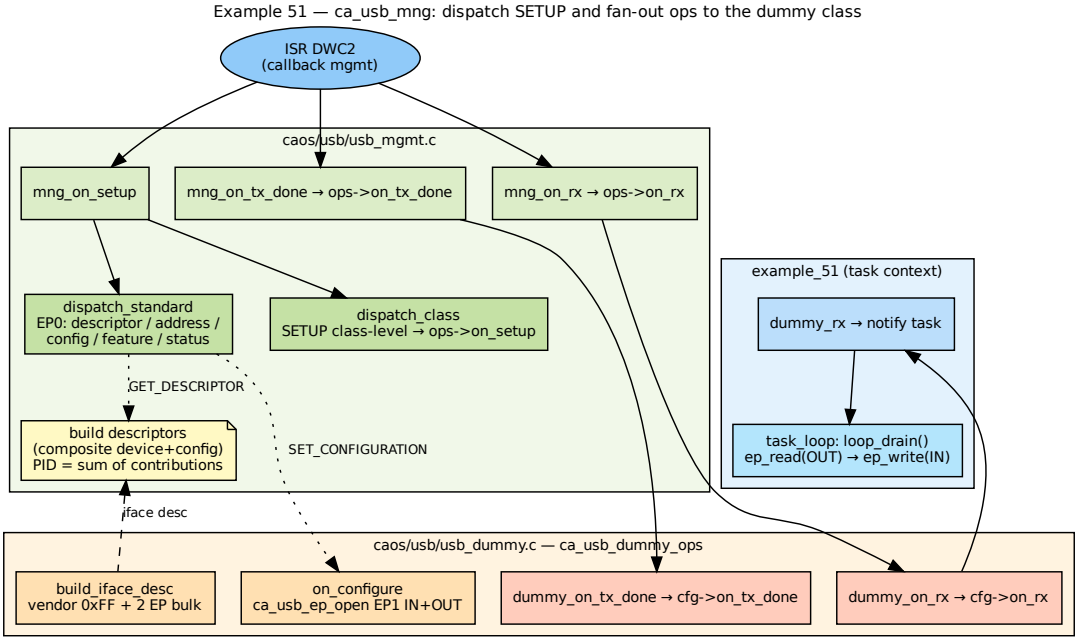

Figure 74.1: Dispatch SETUP and fan-out ops (ex51)

Source: `doc/diagrams/ex51_mgmt_dispatch.dot` *(regenerated from* `make diagrams`*).*

Task	Priority	Function
`lp1`	LEVEL5	loopback bulk: woken by `custom_rx`, `ep_read(OUT)` → `ep_write(IN)`
`usb`	LEVEL6	init stack + polling mount/unmount (print state changes)
`hb`	LEVEL4	toggle LED heartbeat every 500 ms

The task `lp1` is created **before** `usb` so `s_loop_task_id` is valid when the first `on_rx` arrive (the ISR notifications point to an already existing task).

74.1.5 Class config (D20: persistent lifetime)

```
static const ca_usb_custom_cfg_t s_custom = {
    .header     = { CA_USB_TYPE_CUSTOM, &ca_usb_custom_ops },
    .ep_data    = 1,                /* EP1 IN + EP1 OUT */
    .mps        = 64,
    .on_rx      = custom_rx,
    .on_tx_done = custom_tx_done,
};
```

The cfg **must** be `static` (ideally `static const`): the management preserves the pointer without copying it. The first field `header` (tag + ops) must remain at the head of the struct (D19).

`PID = USB_PID_BASE_CUSTOM + ep_data = 0 + 1 = 0x0001` — the management sums the PID contributions of all active services (composite PID, D14).

74.1.6 CLI `usb`

```
usb status                    # mount state + rx/tx counters
usb start | stop              # connect / disconnect (the host re-enumerates)
usb add | remove              # registra/rimuove la classe custom a runtime
```

The `remove stop add start` loop allows to check the re-attach: `ca_usb_dev_mng_start` reconstructs the descriptors based on the currently registered services.

74.1.7 Mount/unmount state

The custom cfg exposes `on_mounted`/`on_unmounted` (fan-out from ops via `ca_usb_dev_mng`). The example uses them to report state changes on the console:

- **mount** → `on_mounted` on `ENUMDNE` (host has enumerated the device)
- **unmount** → `on_unmounted` on `USBSUSP` (cable unplugged / host suspended)

The task polls a volatile state and prints `host enumerated (mounted)` / `host disconnected (unmounted)` on changes; `usb status` shows the current state.

74.1.8 Parameters

Define	H753	U575	F407
`USB_NUM`	1	0	0
`EP_BULK_MPS`	64	64	64
`CUSTOM_EP_DATA`	1	1	1
LED heartbeat	PB7	PC7	PA6

`os_config.h` requirements: `EN_USB = 1`, `EN_USB_CUSTOM = 1`.

74.1.9 Expected UART output

```
[USB] mng init...
[USB] D+ pull-up on     plug cable (custom vendor loopback EP1)
[USB] host enumerated device (mounted)
```

At cable disconnection (or host suspension):

```
[USB] host disconnected (unmounted)
```

74.1.10 Test from PC

```
lsusb                                       # VID=0xCA01 PID=0x0001
sudo python3 examples/example_51/test_usb_custom.py
```

The script prints the descriptors generated by mgmt and then performs loopback on EP1:

```
Descriptors (generati da ca_usb_dev_mng):
  idVendor=0xca01 idProduct=0x0001
  bInterfaceClass=0xff bNumEndpoints=2
    EP 0x81 IN  type=2 mps=64
    EP 0x01 OUT type=2 mps=64
Loopback EP1 x 10000 packets x 64 bytes ...
EP1: 10000/10000 OK  0 err
```

Chapter 75

USB CDC-ACM: Virtual Serial Port

75.1 Example 52 — USB CDC-ACM: virtual serial port

75.1.1 Description

Example 52 demonstrates the **CDC-ACM** class (`ca_usb_cdc`): a virtual USB serial port. The device enumerates with IAD + comm-interface + data-interface; the PC mounts it as `/dev/ttyACM0` (Linux) or COM port (Windows).

It is the first "real" USB class above `ca_usb_dev_mng`: unlike the custom (vendor), it uses **SETUP class-level** (`SET/GET_LINE_CODING`, `SET_CONTROL_LINE_STATE`), **mixed endpoints** (interrupt NOTIF + bulk DATA) and an **IAD** to group the two interfaces.

Behavior: 1. on terminal opening (DTR asserted) sends a welcome banner 2. does **echo** of every received byte (serial loopback)

```
ca_usb_dev_mng_init(CA_USB_SPEED_FS, USB_NUM);
ca_usb_dev_mng_add(&s_cdc.header);
ca_usb_dev_mng_start();
```

Hardware: H753 (`USB_NUM=1`), U575 (`USB_NUM=0`), F407 (`USB_NUM=0`).

> The `ca_usb_cdc` service and `ca_usb_dev_mng` stack are described in `doc/usb_stack_workplan.md` and `S02_11_00_usb_driver.md` (low-level drivers).

75.1.2 Hardware

Board	MCU	`USB_NUM`	USB Connector	LED heartbeat
NUCLEO-H753ZI	STM32H753ZI	1	OTG_FS (CN14, "USB user")	PB7 (LD2 gree
NUCLEO-U575ZI-Q	STM32U575ZI	0	Internal OTG_FS	PC7 (LD1 gree
STM32F4VE (black board)	STM32F407VET6	0	Internal OTG_FS (PA11/PA12)	PA6 (D2)

No external wiring: connect the device USB connector (OTG_FS, not ST-LINK).

> **F407**: HW tested (black board STM32F4VE, OTG_FS slave mode). Echo 100/100 OK on `/dev/ttyACM0`. The LED is PA6 instead of PD12 (black board, not NUCLEO F4).

75.1.3 os_config.h Configuration

```
#define EN_USB        1     /* driver USB DWC2 + stack mgmt */
#define EN_USB_CDC    1     /* enables the CDC-ACM class */
/* Test isolato: le altre classi a 0 */
#define EN_USB_MSC    0
#define EN_USB_NCM    0
#define EN_USB_CUSTOM 0
```

Optional overrides for endpoints (the defaults do not collide with other classes):

```
#define USB_CDC_EP_NOTIF  2U     /* EP2: interrupt IN, notifiche (8 byte) */
#define USB_CDC_EP_DATA   3U     /* EP3: bulk IN+OUT, serial data */
/* PID = USB_PID_BASE_CDC + USB_CDC_EP_DATA = 0x0010 + 3 = 0x0013 */
```

75.1.4 CDC ACM Structure

The descriptor (66 bytes, TinyUSB `TUD_CDC_DESCRIPTOR` layout) is generated by `cdc_build_iface_desc` and contains:

Block	Bytes	Notes
IAD	8	groups the 2 interfaces (CDC class)
Comm interface	9	class 0x02, subclass ACM 0x02
Functional Header	5	bcdCDC 1.20
Functional Call Mgmt	5	data iface = comm+1
Functional ACM	4	bmCapabilities 0x06 (line coding + line state)
Functional Union	5	master=comm, slave=data
EP NOTIF	7	interrupt IN, 8B, bInterval 16
Data interface	9	class 0x0A (CDC-DATA)
EP OUT + EP IN	14	bulk, MPS

Endpoint numbers (override in `os_config.h`): `USB_CDC_EP_NOTIF=2` (interrupt IN), `USB_CDC_EP_DATA =3` (bulk IN+OUT). PID = `USB_PID_BASE_CDC + USB_CDC_EP_DATA` = `0x0010 + 3 = 0x0013`.

75.1.5 SETUP class-level

`cdc_on_setup` (invoked by `mng_dispatch_class`) handles:

bmRequestType	bRequest	Action
`0x21`	`SET_LINE_CODING` (0x20)	data-stage OUT 7B → applies baud/parity/stop
`0xA1`	`GET_LINE_CODING` (0x21)	returns current line coding (7B)
`0x21`	`SET_CONTROL_LINE_STATE` (0x22)	wValue bit0=DTR bit1=RTS → `on_line`

> `SET_LINE_CODING` is a **control OUT**: SETUP → data OUT (7B) → status IN. The service does not write the status in SETUP; it receives the 7 bytes via `on_rx(0)` and only then emits the ZLP IN (proper data-stage EP0 handling).

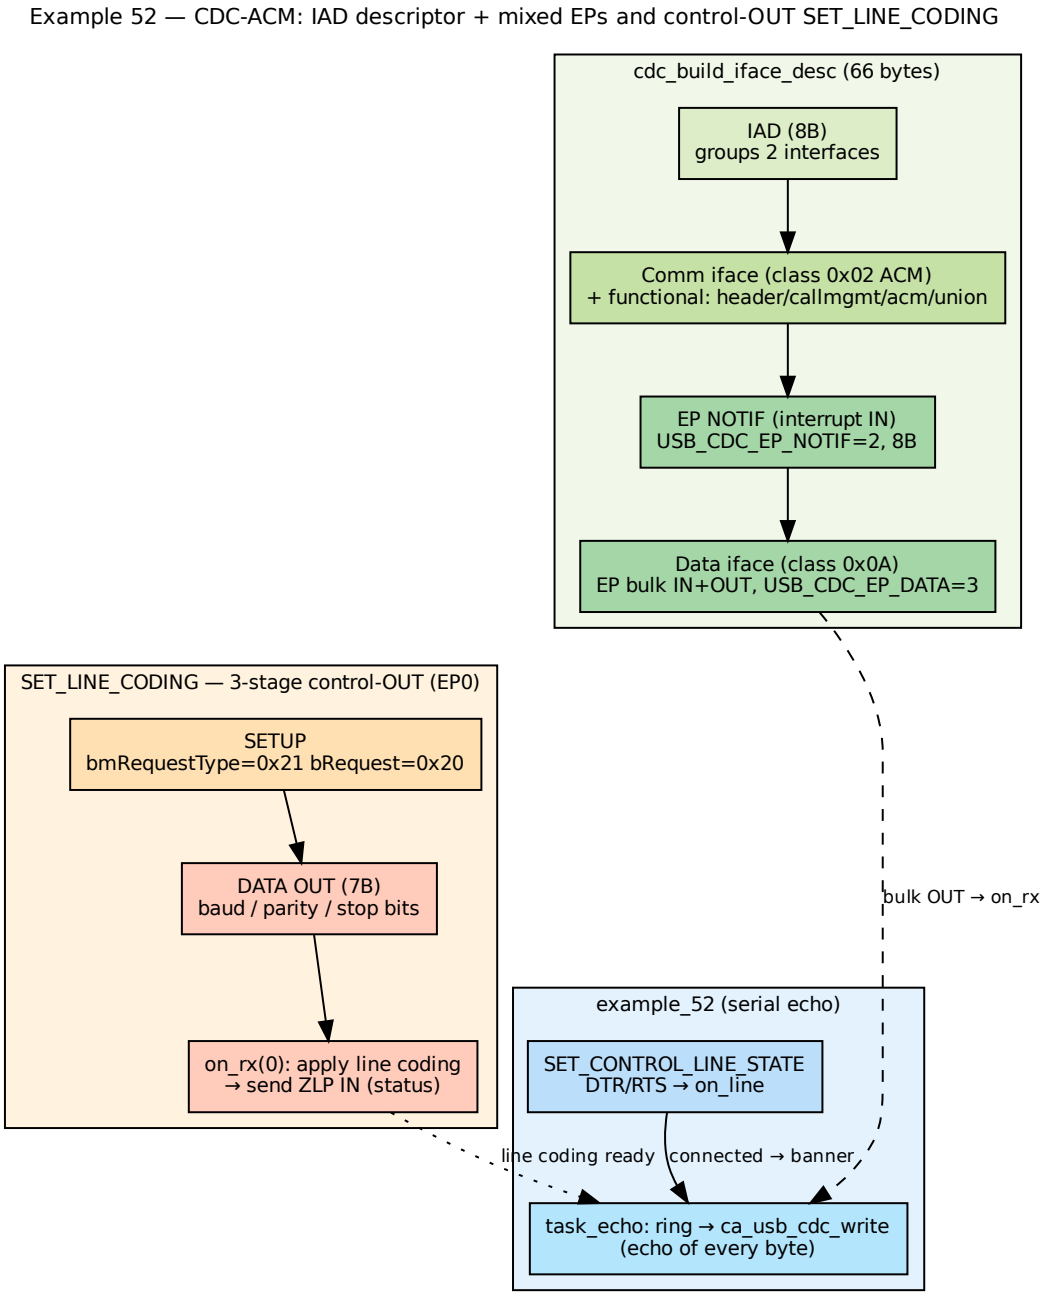

Figure 75.1: CDC descriptor and control-OUT SET_LINE_CODING (ex52)

Source: `doc/diagrams/ex52_cdc_setup.dot` *(regenerated from* `make diagrams`*).*

75.1.6 Architecture

Task	Priority	Function
`echo`	LEVEL5	drains the RX ring (filled by ISR) → echoes bytes to host
`usb`	LEVEL6	init stack + polling DTR status (prints terminal open/close)
`hb`	LEVEL4	toggle LED heartbeat every 500 ms

The CDC callbacks (`on_rx`, `on_line`) are called **from ISR**: `cdc_rx` accumulates bytes in a ring and wakes up `task_echo` with `ca_notify_send_isr`. Echo never occurs in ISR — only in the task, never blocking the interrupt.

75.1.7 Application API

```
bool ca_usb_cdc_write(const u8 *buf, u16 len);   /* send to the host */
bool ca_usb_cdc_connected(void);                 /* true if DTR asserted */
const ca_usb_cdc_line_t *ca_usb_cdc_get_line(void);  /* current baud/parity */
```

The callbacks in cfg (`on_rx`, `on_line`) are called **from ISR**: the example accumulates received bytes in a ring and echoes them from a dedicated task (`task_echo`), never blocking in ISR.

75.1.8 Parameters

Define	H753	U575	F407
`USB_NUM`	1	0	0
`CDC_MPS`	64	64	64
LED heartbeat	PB7	PC7	PA6

`os_config.h` requirements: `EN_USB=1`, `EN_USB_CDC=1`.

75.1.9 Expected UART output

```
[USB] CDC init...
[USB] D+ pull-up on     waiting host (plug cable)
```

At serial terminal open and close from PC:

```
[USB] host opened CDC terminal (DTR on)
[USB] host closed CDC terminal (DTR off)
```

75.1.10 Test from PC

Verify enumeration (must show IAD + CDC Communications + CDC Data):

```
lsusb -v -d ca01: | grep -A2 -iE "interface association|CDC"
```

Interactive echo:

```
sudo screen /dev/ttyACM0 115200      # type: it is echoed back
```

Automatic test (requires pyserial):

```
python3 examples/example_52/test_usb_cdc.py --lines 100
```

Expected output:

```
Porta: /dev/ttyACM0
Echo: 100/100 OK  0 err
```

75.1.11 File Structure

File	Description
`caos/usb/inc/usb_cdc.h`	cfg `ca_usb_cdc_cfg_t` + API write/connected/line

Chapter 76

USB MSC: Mass Storage Device (Ramdisk)

76.1 Example 53 — USB MSC: Mass Storage Device (ramdisk)

76.1.1 Introduction

This example demonstrates the **MSC** (Mass Storage Class) of caOS: once the board is connected to the PC, the device appears as a **removable disk** — exactly like a USB flash drive. The host operating system recognizes it, assigns it a drive letter (`/dev/sdX` on Linux, a letter on Windows), and can create a filesystem on it.

An important point to understand: **caOS does not have a filesystem**. The device exposes only a **block device** — an array of 512-byte blocks, addressed by LBA (Logical Block Address). The filesystem (FAT, exFAT, ext4...) is created and managed **by the host**, not the board. The board simply acts as "block memory": it reads and writes 512-byte blocks upon request from the host. This is the standard model of all real USB flash drives.

The storage backend in this example is a **ramdisk on heap**: 128 KB allocated with `ca_memory_allocate`. The three calls that bring up the device are the same as in every example above the `ca_usb_dev_mng` stack:

```
1 ca_usb_dev_mng_init(CA_USB_SPEED_FS, USB_NUM);        /* registers the
    management driver callbacks */
2 ca_usb_dev_mng_add(&s_msc.header);   /* registers the MSC class with ramdisk
    read/write */
3 ca_usb_dev_mng_start();              /* builds the descriptors and connects (
    enumerates) */
```

Feature	Notes
MSC Enumeration	removable disk device, BOT (Bulk-Only Transport)
SCSI Subset	INQUIRY, READ_CAPACITY10, READ10, WRITE10, ...
Block device	512 B blocks, 256 blocks → 128 KB
Back-end ramdisk	`ca_memcpy` from/to heap array
Class SETUP	`GET_MAX_LUN` (1 LUN) + BOT `RESET`

The service `ca_usb_msc` (CBW/CSW state machine + SCSI subset) is in `caos/usb/src/usb_msc.c`; the management stack `ca_usb_dev_mng` is described in `S02_11` and in the plan `doc/usb_stack_workplan.md`.

76.1.2 Hardware

The example runs on three NUCLEO boards, all in OTG_FS mode (Full-Speed, 12 Mbit/s). No external wiring is required: just the USB cable to the board's device connector.

Board	MCU	USB_NUM	USB Connector	Heartbeat LEI
NUCLEO-H753ZI	STM32H753ZI	1	OTG_FS (CN14, "USB user")	PB7 (green LI
NUCLEO-U575ZI-Q	STM32U575ZI	0	Internal OTG_FS	PC7 (green LI
STM32F4VE (black board)	STM32F407VET6	0	Internal OTG_FS (PA11/PA12)	PA6 (D2)

F407 (black board): HW tested. The ramdisk is reduced to **64 KB** (`BLK_COUNT =128`) because the STM32F407VET6 has 192 KB of SRAM; 128 KB remain for the OS and stacks. 64 KB is the minimum for a valid FAT12. LED is PA6 (not PD12).

Attention to the connector: on NUCLEO boards, the "ST-LINK" connector is for flashing/debugging and is **not** the application's USB device connector. To make the disk appear, you must connect the OTG_FS connector (the second micro-USB / USB-C "USER" on the board).

76.1.3 os_config.h Configuration

```
#define EN_USB        1     /* enables the USB DWC2 driver + stack mgmt */
#define EN_USB_MSC    1     /* enables the Mass Storage class */
/* For the isolated test, leave the other classes at 0: */
#define EN_USB_CDC    0
#define EN_USB_NCM    0
#define EN_USB_CUSTOM 0
```

EP number and PID are optional overrides (defaults work):

```
#define USB_MSC_EP_DATA  4U      /* EP4: bulk IN + bulk OUT with the same number
    */
/* PID = USB_PID_BASE_MSC + USB_MSC_EP_DATA = 0x0020 + 4 = 0x0024 */
```

Note on EP allocation: MSC uses **a single endpoint number** for two directions (EP4 IN for responses, EP4 OUT for commands and write data). This is normal in USB: IN and OUT with the same number are distinct endpoints.

76.1.4 Architecture

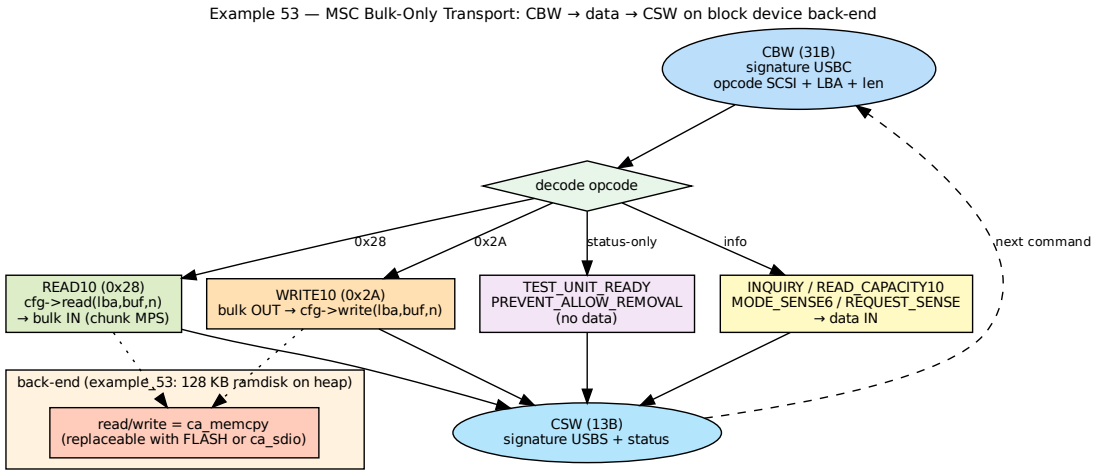

Figure 76.1: State machine BOT CBW → data → CSW (ex53)

Source: `doc/diagrams/ex53_msc_bot.dot` (regenerated from `make diagrams`).

Task	Priority	Function
`usb`	LEVEL6	`ca_usb_dev_mng_init/add/start` then idle (the service runs from ISR)
`hb`	LEVEL4	toggle LED heartbeat every 500 ms (system life)

Unlike the CDC/NCM examples, here **there is no application task** that drains the data: the MSC service is entirely driven by the host. Each SCSI command arrives as a bulk transfer, the BOT state machine processes it in the ISR/callback context and calls `read`/`write` of the ramdisk. The task `usb` only serves to initialize and then sleep.

76.1.5 Back-end block device

The MSC service is **storage agnostic**: the cfg provides two callbacks, one for reading and one for writing blocks. By changing only these two functions the same service works on FLASH, on SD card (`ca_sdio_*`) or on any other medium.

```
typedef struct {
    ca_usb_device_type_t header;       /* { tag, ops }     must stay first */
    u16  mps;                          /* max packet size bulk (64 in FS) */
    u32  block_size;                   /* 512 */
    u32  block_count;                  /* 256     128 KB */
    bool (*read) (u32 lba, u8 *buf, u32 count);        /* reads count blocks */
    bool (*write)(u32 lba, const u8 *buf, u32 count);  /* writes count blocks */
} ca_usb_msc_cfg_t;
```

The ramdisk implementation is trivial — `ca_memcpy` with boundary checking:

```c
static u8 *s_disk;   /* 128 KB allocati in ca_os_configure */

static bool ramdisk_read(u32 lba, u8 *buf, u32 count)
{
    if (s_disk == NULL || (lba + count) > BLK_COUNT) return false;  /* out of
    range */
    ca_memcpy(buf, &s_disk[lba * BLK_SIZE], count * BLK_SIZE);
    return true;
}

static bool ramdisk_write(u32 lba, const u8 *buf, u32 count)
{
    if (s_disk == NULL || (lba + count) > BLK_COUNT) return false;
    ca_memcpy(&s_disk[lba * BLK_SIZE], buf, count * BLK_SIZE);
    return true;
}
```

> The control `(lba + count) > BLK_COUNT` is a **security guard**: the host might (due to bugs or attack) request an LBA outside the declared capacity. Returning `false` causes the service to respond with a SCSI error status instead of writing outside the buffer.

76.1.6 Bulk-Only Transport + SCSI

`ca_usb_msc` implements the **BOT** (`CBW` `data` `CSW`) state machine and the minimal SCSI subset required for enumeration and I/O. The BOT protocol encapsulates each command in three phases:

1. **CBW** (Command Block Wrapper, 31 bytes) — the host sends the SCSI command
2. **data** — data transfer (read or write, optional)
3. **CSW** (Command Status Wrapper, 13 bytes) — the device reports the result

SCSI Command	Opcode	Usage
INQUIRY	0x12	device identity (vendor / product / revision)
TEST_UNIT_READY	0x00	is the media ready?
READ_CAPACITY10	0x25	capacity: last LBA + block size
REQUEST_SENSE	0x03	details of the last error
MODE_SENSE6	0x1A	parameters (here: not write-protected)
READ10	0x28	read N blocks starting from LBA
WRITE10	0x2A	write N blocks starting from LBA
PREVENT_ALLOW_REMOVAL	0x1E	lock/unlock ejection

At the **class SETUP** level (control transfer on EP0), the service handles `GET_MAX_LUN` (responds with 1 LUN, the number of "logical disks") and the **BOT RESET** (reset of the state machine after an error). Data travels on **1 bulk IN EP + 1 bulk OUT EP** with the same number (`USB_MSC_EP_DATA`).

76.1.7 Parameters

Define	H753 / U575	F407	Meaning
`BLK_SIZE`	512	512	block size (SCSI standard)
`BLK_COUNT`	256	128	blocks → 128 KB (H7/U5) / 64 KB (F407)
`DISK_BYTES`	131072	65536	total ramdisk capacity
`USB_MSC_EP_DATA`	4	4	bulk endpoint for data
PID	`0x0024`	`0x0024`	`USB_PID_BASE_MSC (0x20) + 4`

Reduced ramdisk on F407: 64 KB is the minimum for FAT12 with 1 primary partition (`mkfs.fat -F 12`). The STM32F407VET6 has only 192 KB of total SRAM; 128 KB remain for the OS, stacks, and code.

76.1.8 Expected UART Output

On the serial console (STDOUT) at startup:

```
[USB] MSC init...
[USB] ramdisk 128 KB ready     plug cable (mkfs.fat)
```

From this point on, the heartbeat LED blinks at 1 Hz and the device is ready: by connecting the OTG_FS cable, the host enumerates the disk.

76.1.9 Test from PC

The script `examples/example_53/test_fat.sh` automates the entire cycle (auto-detection of the device for VID caOS `0xCA01`, partitioning, `mkfs.fat`, mount, file copy, verification of persistence at remount):

```
sudo ./examples/example_53/test_fat.sh             # auto-detect the device
sudo ./examples/example_53/test_fat.sh /dev/sdb    # forced device
```

The script is destructive on the selected device: it asks for confirmation and uses `lsblk` to identify the correct unit (~128 KB) before formatting.

Equivalent manual procedure (`sdX` = letter assigned by the host):

```
lsblk                                  # find the device (capacity ~128 KB)

# 1) Partitioning: DOS table + 1 primary FAT partition     /dev/sdX1
sudo fdisk /dev/sdX <<'EOF'
o                                      # new DOS partition table
n                                      # new partition
p                                      # primary
1                                      # partizione #1
                                       # first sector: default (enter)
                                       # last sector: default = whole disk (enter)
t                                      # change partition type
b                                      # b = W95 FAT32 (LBA)
w                                      # write and quit
EOF
sudo partprobe /dev/sdX                # reread the partition table (creates /dev/
    sdX1)

# 2) Filesystem on the partition (NOT on the whole device)
sudo mkfs.fat -F 12 /dev/sdX1          # FAT12 (small capacity     FAT12)
```

```
sudo mount /dev/sdX1 /mnt
echo "ciao caOS" | sudo tee /mnt/test.txt
sync; sudo umount /mnt

# 3) Check persistence: remount and read back
sudo mount /dev/sdX1 /mnt && cat /mnt/test.txt && sudo umount /mnt
```

`/dev/sdX` **vs** `/dev/sdX1`: partitioning (`fdisk`) operates on the **entire device** (`/dev/sdX`); the filesystem (`mkfs.fat`, `mount`) operates on the **partition** (`/dev/sdX1`). Confusing them is the most common mistake: formatting `/dev/sdX` creates a "superfloppy" without a partition table, which some systems fail to mount. The script `test_fat.sh` uses the same flow with the partition.

The ramdisk is **volatile**: its contents persist as long as the board is powered, but are lost on reset. The tested persistence above is only between successive mounts, not between board resets.

76.1.10 Technical Notes

Transfer Chunking with respect to MPS

A SCSI read/write operation can involve many blocks (e.g., `READ10` of 8 blocks = 4096 bytes), but each USB Full-Speed bulk packet carries at most **64 bytes** (MPS). The MSC service automatically splits the data transfer into multiple packets of MPS size. This is transparent to the back-end: `read`/`write` always see the complete block count, and chunking occurs in the driver.

Single LUN

`GET_MAX_LUN` responds with 0 (meaning "1 LUN", numbered from 0). caOS exposes a single logical disk. For multi-LUN support, the cfg would need to be extended with an array of back-ends.

Reusing the back-end with real storage

To use an SD card instead of the ramdisk, simply replace the two callbacks:

```
static bool sd_read(u32 lba, u8 *buf, u32 count)  { return ca_sdio_read(lba, buf
    , count); }
static bool sd_write(u32 lba, const u8 *buf, u32 count) { return ca_sdio_write(
    lba, buf, count); }
```

The MSC service and descriptors remain identical: the block-device abstraction completely isolates the USB transport from the physical storage.

76.1.11 File structure

File	Description
`caos/usb/inc/usb_msc.h`	cfg block-device `ca_usb_msc_cfg_t` + ops

Chapter 77

USB NCM: USB Ethernet (L2 Loopback)

77.1 Example 54 — USB NCM: USB Ethernet (L2 loopback)

77.1.1 Introduction

This example demonstrates the **NCM** (CDC-NCM 1.0, *Network Control Model*) class of caOS: connecting the board to the PC, the device appears as a **USB network card** — `usb0` (or `enxXXXXXX`) on Linux, "USB Ethernet" / "Remote NDIS" on Windows. This is the same mechanism used by 4G USB modems and many devices that "provide internet" through the USB cable.

The transport is **Layer 2 Ethernet**: the device receives and transmits complete Ethernet frames (destination MAC, source MAC, ethertype, payload), encapsulated in **NTB** (NCM Transfer Block) — the wire format of the CDC-NCM specification.

This example deliberately stops at the **Layer 2** level and performs **loopback**: for every frame received from the host, it swaps source MAC destination MAC and sends it back. There is no IP stack on the device. The purpose is to validate in isolation the most sensitive part — the encode/decode of the wire NTB and the integration of the service into the `ca_usb_dev_mng` stack. The next example (55) adds the IP stack for actual ping.

```
ca_usb_dev_mng_init(CA_USB_SPEED_FS, USB_NUM);
ca_usb_dev_mng_add(&s_ncm.header);   /* cfg con MAC + callback on_rx */
ca_usb_dev_mng_start();
```

Feature	Notes
NCM Enumeration	device "USB Ethernet" (CDC-NCM 1.0)
Wire NTB	1 datagram per block (NTH16 + NDP16 + payload)
L2 Loopback	swap SADA, re-inject the frame
Link Control	`SET_INTERFACE` alt0=down / alt1=up
Notifications	`NETWORK_CONNECTION` + `CONNECTION_SPEED_CHANGE`
String descriptor	`iMACAddress` (MAC exposed to host)

The service `ca_usb_ncm` (CDC-NCM descriptors, NTB, SET_INTERFACE alt0/1, MAC string) is in `caos/usb/src/usb_ncm.c`; the stack `ca_usb_dev_mng` is in `S02_11`.

77.1.2 PC Prerequisite: Remove the interface from NetworkManager

When the board enumerates, a new network interface appears on the PC (`enx02ca0500xx` — the name udev derives from the MAC). NetworkManager sees it as any other newly connected card and **assigns it an address of its own**: it has been observed `172.21.10.100/24`. The board is on `192.168.10.0/24`, so the two end up on different subnets and the board is unreachable.

The symptom is misleading, because the interface **exists and is UP**: `ip link` shows it, and even `ping -I <iface>` responds — that flag bypasses the routing table. What doesn't work is everything else (`socat`, `nc`, the PC scripts from the examples), which follow the routing table.

The rule is versioned in the repository:

```
sudo cp tools/99-caos-ncm.conf /etc/NetworkManager/conf.d/
sudo systemctl reload NetworkManager
nmcli -t -f DEVICE,STATE dev status | grep enx    # it must say: unmanaged
```

> **The glob goes to `interface-name`, not to `mac:`.** The form `mac:02:ca:05:00:00:*` seems equivalent but it is not: it requires a full MAC and fails **silently** with a wildcard character — no error, and the interface remains managed.

The address of the bank does not set this rule: it is set by `sudo ./tools/bench_net.sh usb` or the example PC script.

77.1.3 Hardware

Board	MCU	`USB_NUM`	USB Connector	LED heartbeat
NUCLEO-H753ZI	STM32H753ZI	1	OTG_FS (CN14, "USB user")	PB7 (green LD
NUCLEO-U575ZI-Q	STM32U575ZI	0	internal OTG_FS	PC7 (green LD
STM32F4VE (black board)	STM32F407VET6	0	internal OTG_FS (PA11/PA12)	PA6 (D2)

No external wiring: the "network cable" is the USB cable itself. Connect the OTG_FS connector (not the ST-LINK one).

> **F407**: HW tested (black board STM32F4VE). Loopback L2 5/5 OK (`test_ncm.sh`). LED PA6.

77.1.4 os_config.h Configuration

```
#define EN_USB         1     /* driver USB DWC2 + stack mgmt */
#define EN_USB_NCM     1     /* enables the CDC-NCM class */
/* Test isolato: le altre classi a 0 */
#define EN_USB_CDC     0
#define EN_USB_MSC     0
#define EN_USB_CUSTOM  0
```

Optional overrides for endpoints (the defaults do not collide with other classes):

```
#define USB_NCM_EP_DATA   1U     /* EP1: bulk IN+OUT, trasporto NTB */
#define USB_NCM_EP_NOTIF  5U     /* EP5: interrupt IN, notifiche link */
/* PID = USB_PID_BASE_NCM + USB_NCM_EP_DATA */
```

77.1.5 Architecture

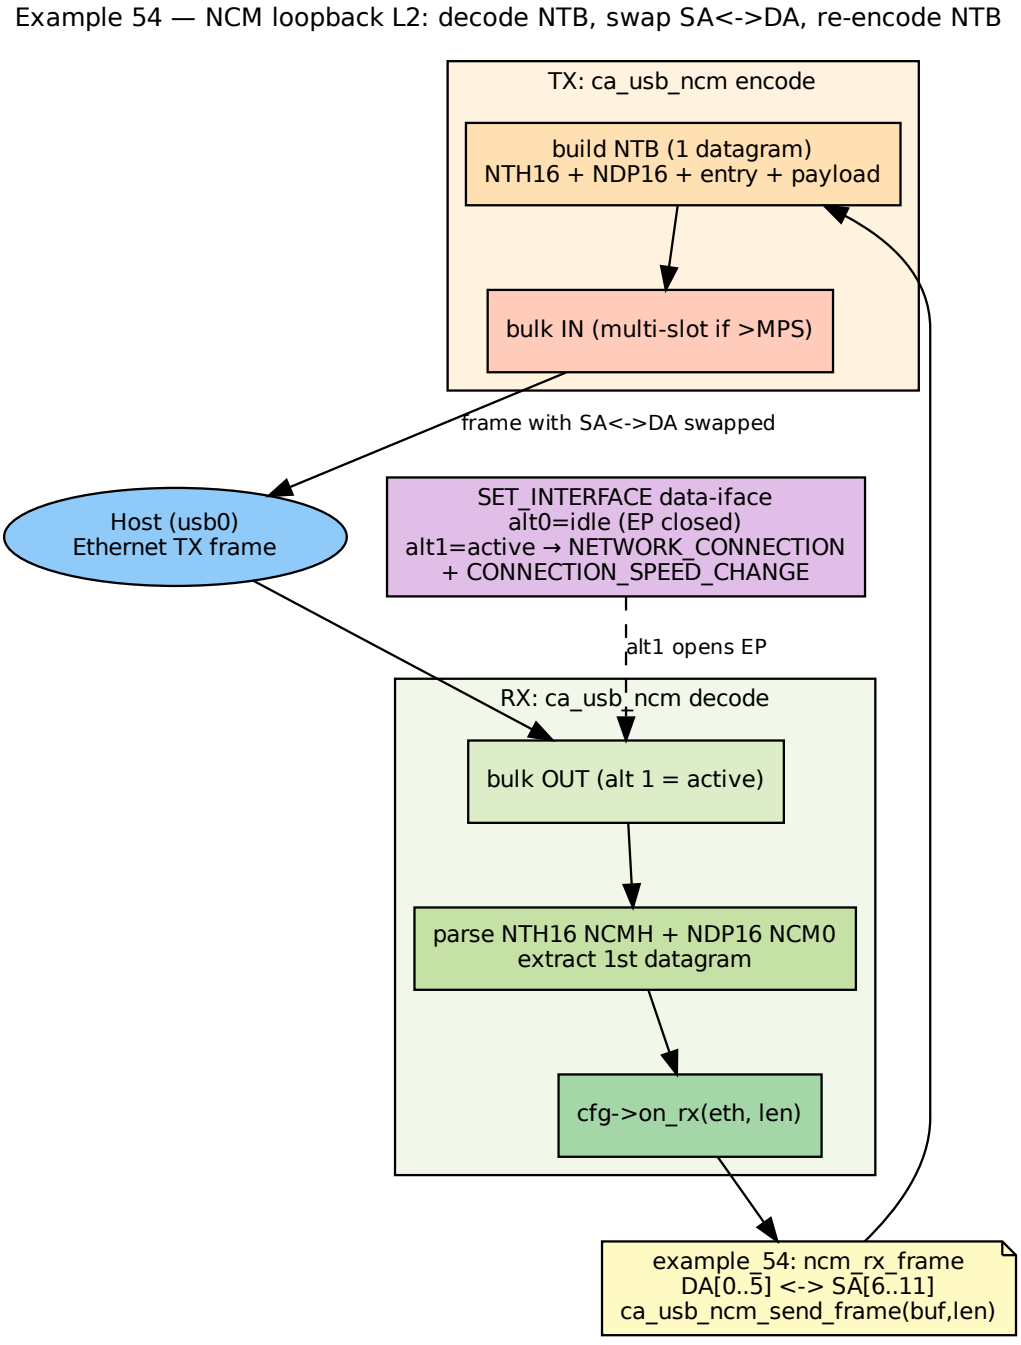

Figure 77.1: Loopback L2: decode NTB, swap SADA, re-encode (ex54)

Source: `doc/diagrams/ex54_ncm_loopback.dot` *(regenerated from* `make diagrams`*).*

Task	Priority	Function
`usb`	LEVEL6	init stack + polling link up/down (print status change)
`hb`	LEVEL4	toggle LED heartbeat every 500 ms

Frame reception **does not** go through a task: the NCM service delivers each decoded datagram directly to the `on_rx` callback, called in ISR context. The example performs the work (swap + retransmission) inside the callback because it is a short operation; in a real case with heavy processing, the frame would be queued and processed in a task (this is what example 55 does with the net core).

77.1.6 Loopback L2 with SADA swap

The NCM service is a **neutral L2 transport**: it delivers each received Ethernet frame to the `on_rx(eth, len)` callback, where `eth` points to the complete frame starting from the destination MAC address. The example swaps the first 12 bytes (DA[0..5] SA[6..11]) and reinjects the frame:

```
static void ncm_rx_frame(const u8 *eth, u16 len)
{
    if (len < 14U) return;                  /* at least the Ethernet header is
    needed */
    s_rx_count++;

    static u8 buf[USB_NCM_MAX_FRAME] __attribute__((aligned(4)));
    if (len > sizeof(buf)) return;
    ca_memcpy(buf, eth, len);
    for (u32 i = 0U; i < 6U; i++) {          /* DA <-> SA: scambia i 6+6 byte */
        u8 t = buf[i]; buf[i] = buf[i + 6U]; buf[i + 6U] = t;
    }
    if (ca_usb_ncm_send_frame(buf, len)) s_tx_count++;
}
```

By swapping SADA, the host sees a frame returning with **DA = its own MAC** (thus accepting it) and **SA = the device's MAC**. Without the swap, the host would discard the frame because it is addressed to itself (DA = own MAC, already in the outgoing frame is the case of a frame that the device echoes identically — the host ignores it).

> Copying to a local buffer is necessary: `eth` points to service memory that may be reused after the return of `on_rx`. `ca_usb_ncm_send_frame` copies to its own NTB, therefore `buf` (static) is reusable in the next iteration.

77.1.7 Wire NTB (1 datagram per block)

Each Ethernet frame is encapsulated in an **NTB** (NCM Transfer Block) containing a single datagram. The block structure:

```
NTH16 (12B) : signature "NCMH", wHeaderLength, wSequence, wBlockLength,
    wNdpIndex
NDP16  (8B) : signature "NCM0", wLength, wNextNdpIndex
entries     : (wDatagramIndex, wDatagramLength) + terminatore (0, 0)
payload     : full Ethernet frame (from DA up to the payload)
```

The NTH16 header declares the total length of the block and points to the NDP16 descriptor; the latter lists the entries (offset + length of each datagram) terminated by a (0,0) pair. With a single datagram per block, the logic remains simple; the support for aggregated multi-datagram is a future extension (`wNtbOutMaxDatagrams=1` for now).

Link Control via SET_INTERFACE

The NCM data-interface has two **alternate settings** that act as link switches:

- **alt 0** = idle → bulk endpoints closed, no traffic (`ca_usb_ncm_is_up()` returns `false`)
- **alt 1** = active → bulk endpoints open, the service sends the notifications `NETWORK_CONNECTION` + `CONNECTION_SPEED_CHANGE` (link up) on the interrupt EP

It is the host that decides when to bring up the link (`ip link set usb0 up` → sends `SET_INTERFACE alt 1`). As long as it remains at alt 0, the device does not transmit.

77.1.8 Parameters

Define	Value	Meaning
`USB_NCM_EP_DATA`	1	Bulk EP for NTB transport
`USB_NCM_EP_NOTIF`	5	Interrupt EP for link notifications
`mps`	64	max packet size bulk (Full-Speed)
Device MAC	`02:CA:05:00:00:01`	MAC of the device (locally administered)

77.1.9 Expected UART Output

```
[USB] NCM init...
[USB] NCM ready     bring up usb0 on host (loopback L2)
```

When the host asserts the interface (`ip link set usb0 up`):

```
[USB] link UP
```

And at shutdown or disconnection:

```
[USB] link DOWN
```

Diagnostic CLI — the `ncm` command reports the status:

```
c.a.O.S. > ncm
ncm: link=up rx=42 tx=42
```

77.1.10 Test from PC

```
ip link                                  # find the interface (usb0 / enxXX)
sudo ip addr add 192.168.7.1/24 dev usb0
sudo ip link set usb0 up                 #     SET_INTERFACE alt1     link UP on
    the device
sudo tcpdump -i usb0 -e                  # watch incoming/outgoing frames
arping -I usb0 192.168.7.2               # requests bounce back with  S A DA
    swapped
```

> **Success criterion**: (1) `usb0` correctly enumerated, (2) TX frames bounce back in RX with SADA swapped, visible in `tcpdump -e`. Without IP stack on the device, `ping` **does not** receive ICMP reply — expected: loopback is purely L2. Integration with `caos/net` (push via `ca_net_iface_t`) is example 55.

Tested HW on U575: 5/5 frame `arping` bounced correctly (`test_ncm.sh`).

77.1.11 Technical notes

Why loopback and not ping immediately?

Separating validation of the wire NTB from the net stack is a debug choice: if the ping of example 55 does not work, example 54 tells whether the problem is in the encode/decode NTB (low level) or in the integration with the net core (high level). The L2 loopback only exercises the first.

MAC locally administered

The MAC `02:CA:05:00:00:01` has bit 1 of the first byte set to 1 (`0x02`): it is a *locally administered* address, not assigned by IEEE. This is the correct practice for devices that do not have a registered OUI — avoids collisions with real hardware on the network.

Buffer alignment

`buf` is declared `__attribute__((aligned(4)))`: word alignment speeds up `ca_memcpy` and the swap, and is required by some driver implementations that access the buffer at 32 bit.

77.1.12 File structure

File	Description
`caos/usb/inc/usb_ncm.h`	cfg `ca_usb_ncm_cfg_t` + API `ca_usb_ncm_send_frame/is_up`
`caos/usb/src/usb_ncm.c`	`ca_usb_ncm_ops` (CDC-NCM descriptors + wire NTB)
`hw/f4xx/drivers/usb_f4xx.c`	DWC2 slave FIFO (F407/F429/F446)
`examples/example_54/ca_os_ex54.c`	L2 loopback + CLI `ncm`
`examples/example_54/test_ncm.sh`	automated test (arping + swap verification)

Chapter 78

Net Stack over USB-NCM: Real Ping

78.1 Example 55 — caOS Net Stack on USB-NCM (real ping)

78.1.1 Introduction

This example is the **USB variant of example 33** (net stack on Ethernet). The same caOS net core — ARP for address resolution, ICMP for ping — runs here on a **USB network adapter** (CDC-NCM) instead of wired Ethernet. The concrete result: after bringing up `usb0`, from the PC you can do `ping` to the board and receive a response.

The central pedagogical point is the `ca_net_iface_t` abstraction: the net core does not know and does not care whether frames arrive from the integrated Ethernet MAC or the USB port. It only sees a "network interface" — a struct of function pointers. By changing only the argument of `ca_net_init`, the exact same IP stack works on both transports. It's the same principle as the Linux/BSD driver model, scaled down for embedded use.

Unlike example 54 (pure L2 loopback), here the device has the **active IP stack** and therefore responds to a real ping:

```
ca_usb_dev_mng_init(CA_USB_SPEED_FS, USB_NUM);
ca_usb_dev_mng_add(&s_ncm.header);
ca_usb_dev_mng_start();
ca_net_init(ca_ncm_iface_get(&s_ncm));   /* registers NCM as a PUSH iface */
ca_net_proto_init(&net_cfg);             /* enables ARP + ICMP echo reply  */
```

Feature	Notes
USB Ethernet (NCM)	device `usb0` via CDC-NCM
`ca_net_iface_t` abstraction	same net core on ETH or NCM
RX push model	`ca_net_rx_push` (NCM delivery, no DMA pull)
ARP service	MAC IP resolution
ICMP echo reply	replies to `ping` from host
CLI `ping` / `ip`	reverse ping device → host (with `EN_CLI_NET`)

78.1.2 PC Prerequisite: Remove the interface from NetworkManager

When the board enumerates, a new network interface appears on the PC (`enx02ca0500xx` — the name that udev derives from the MAC). NetworkManager sees it as any other attached card

and **assigns it an address of its own**: it has been observed `172.21.10.100/24`. The board is on `192.168.10.0/24`, so the two end up on different subnets and the board becomes unreachable.

The symptom is misleading, because the interface **exists and is UP**: `ip link` shows it, and even `ping -I <iface>` responds — that flag bypasses the routing table. What fails is everything else (`socat`, `nc`, the PC scripts from the examples), which follow the routing table.

The rule is versioned in the repository:

```
sudo cp tools/99-caos-ncm.conf /etc/NetworkManager/conf.d/
sudo systemctl reload NetworkManager
nmcli -t -f DEVICE,STATE dev status | grep enx    # it must say: unmanaged
```

> **The glob goes on `interface-name`, not on `mac:`.** The form `mac:02:ca:05:00:00:*` seems equivalent but it is not: it requires a full MAC and fails **silently** with a wildcard character — no error, and the interface remains managed.

The bank address does not set this rule: it is set by `sudo ./tools/bench_net.sh usb` or the example PC script.

78.1.3 Hardware

Board	MCU	`USB_NUM`	USB Connector	LED heartbea
NUCLEO-U575ZI-Q	STM32U575ZI	0	Internal OTG_FS	PC7 (green LI
NUCLEO-H753ZI	STM32H753ZI	1	OTG_FS (CN14, “USB user”)	PB7 (green LI
STM32F4VE (black board)	STM32F407VET6	0	Internal OTG_FS (PA11/PA12)	PA6 (D2)

> **F407**: HW tested. PING 5/5 OK from PC → device; CLI `ping` reverse OK. LED PA6. `NET_BUF_COUNT=8` (reduced to leave RAM for ramdisk in ex56).

Device network identity (defined in the example):

Parameter	Value
IP device	192.168.10.55
MAC device (caOS side)	02:CA:05:00:00:55
MAC host (exposed by NCM)	00:CA:05:00:00:A5

78.1.4 os_config.h Configuration

```
#define EN_NET       1     /* net core: pool buffer, ARP, ICMP,     */
#define EN_USB       1     /* driver USB DWC2 + stack mgmt */
#define EN_USB_NCM   1     /* CDC-NCM class (the network transport) */
#define EN_CLI_NET   1     /* optional: CLI commands 'ping' / 'ip' */
/* Test isolato: altre classi USB a 0 */
#define EN_USB_CDC    0
#define EN_USB_MSC    0
#define EN_USB_CUSTOM 0

#define NET_BUF_COUNT  32U   /* number of net_buf in the RX/TX pool */
```

> **Note**: `EN_NET` enables the full net core. `ca_net_proto_init` automatically registers the CLI command `ping`/`ip` if `EN_CLI_NET=1`.

78.1.5 Architecture

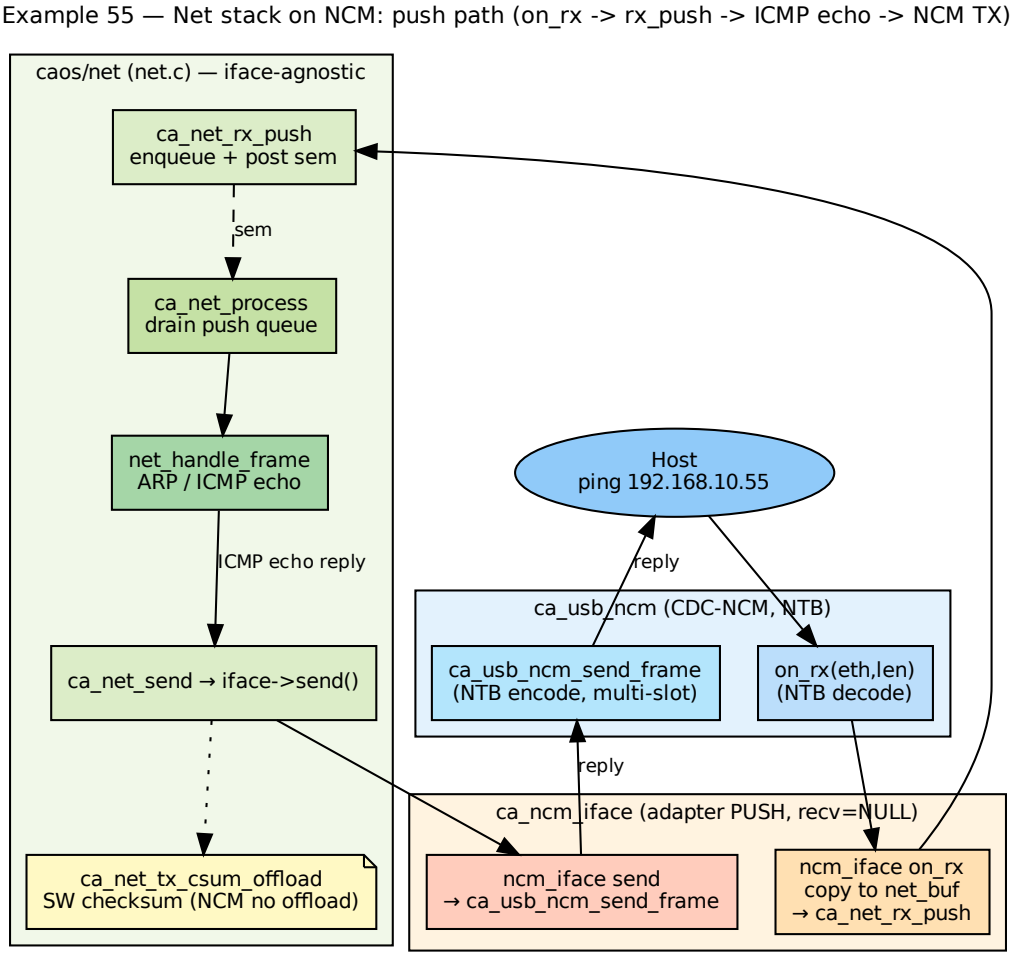

Figure 78.1: Path push: on_rx → rx_push → ICMP echo → NCM TX (ex55)

Source: `doc/diagrams/ex55_ncm_netstack.dot` *(regenerated from* `make diagrams`*).*

Task	Priority	Function
`net`	LEVEL1	init USB+NCM+net core, then loop: `ca_sem_wait(&ca_net_rx_sem)` → `ca_net_process`
`net_stats`	LEVEL4	print network counters every 5 s (pool, rx, tx, drop)
`heartbeat`	LEVEL4	toggle LED heartbeat every 500 ms

The task `net` has high priority (LEVEL1): it must drain incoming frames with low latency

to avoid saturating the `net_buf` pool. It blocks on `ca_net_rx_sem` and wakes up when the NCM adapter has queued a frame.

78.1.6 Interface Abstraction: ETH vs NCM

The net core (`net.c`) **never calls the driver directly**: it uses a `ca_net_iface_t`, a function pointer struct. Two adapters provide it, with different receive models:

Adapter	RX Model	TX
`ca_eth_iface_get(&eth_cfg)`	**pull** zero-copy (DMA, `ops.recv`)	`ca_eth_send`
`ca_ncm_iface_get(&ncm_cfg)`	**push** (`ca_net_rx_push`, `ops.recv=NULL`)	copy to NTB

Pull (ETH): the ETH driver has frames already in RAM via DMA; the net core "pulls" them when ready, without copies. **Push (NCM)**: the USB service delivers each datagram to the adapter's callback, which copies it into an `net_buf` and calls `ca_net_rx_push()` (queues + posts the semaphore that wakes up the net task). NCM TX copies the `net_buf` into an NTB and sends it with `ca_usb_ncm_send_frame()`.

The notable thing is that `ca_net_init` is **identical** to the one in example 33 — only the argument changes:

```
/* ex33 (Ethernet):  */ ca_net_init(ca_eth_iface_get(&eth_cfg));
/* ex55 (USB-NCM):   */ ca_net_init(ca_ncm_iface_get(&s_ncm));
```

All the rest (ARP, ICMP, the loop `ca_net_process`, the counters) is the same code.

78.1.7 Expected UART Output

```
=== EX55: caOS net stack su USB-NCM ===
MAC  02:CA:05:00:00:55
IP   192.168.10.55
Net task ready     bring up usb0 then ping 192.168.10.55
CLI: 'ping <ip> [count=N] [time=T]' to ping the host from here
```

Periodic statistics (every 5 s) from task `net_stats`:

```
STATS link=up pool_free=32/32 rx=5 drop_pool=0 no_handler=0 tx=5 tx_fail=0 proc
   =5
```

78.1.8 Test from PC

```
ip link                                    # find usb0 / enxNN
sudo ip addr add 192.168.10.1/24 dev usb0
sudo ip link set usb0 up
ping -c 5 192.168.10.55                     # ICMP echo reply from the device
arping -c 3 -I usb0 192.168.10.55           # ARP reply from the device
```

Success criterion: `ping` receives reply from device — entire path push works: NCM `on_rx` → adapter `ca_net_rx_push` → net task `ca_net_process` → ARP/ICMP → ICMP echo reply → NCM TX. Tested HW on U575: **ping 5/5 ~0.8 ms**.

Reverse ping (device → host) from serial CLI

`ca_net_proto_init()` automatically registers CLI commands `ping`/`ip` (requires `EN_CLI_NET=1`). From device's serial console:

```
ping 192.168.10.1 [count=N] [time=T]    # the device pings the host
ip info | set <ip> | flush | link up|down | mtu <N>
```

The command resolves the host's MAC via ARP, sends echo requests over the NCM interface and measures the RTT with DWT — **the exact same code** used on Ethernet, a tangible proof that the stack is interface-agnostic.

78.1.9 Technical notes

Push vs pull: why two models

Ethernet has a DMA that writes frames to RAM autonomously: pull zero-copy (no copy, the net core reads directly from the DMA buffer) is preferred. USB does not have this: data arrives "pushed" by a bulk transfer inside an ISR callback, and must be copied into a `net_buf` to decouple it from the volatile service memory. The `ca_net_iface_t` abstraction hides this difference from the net core.

Two MACs, one per side

NCM has **two** MACs: the device's (`...:55`, used by caOS's net core) and the "host side" (`...:A5`) that the device declares to the host via `iMACAddress`. This is the standard CDC-NCM model: the USB link is a point-to-point Ethernet segment with two nodes, each with its own MAC.

Pool sizing

`NET_BUF_COUNT` limits how many frames can be in flight. With the push path, if the net task doesn't drain fast enough, the pool gets exhausted and frames are dropped (`drop_pool` in `STATS`). For higher traffic, increase `NET_BUF_COUNT` or raise the priority of task `net`.

78.1.10 File structure

File	Description
`caos/net/src/net.c`	net core (pool, dispatch, `ca_net_process`)
`caos/net/src/ncm_iface.c`	push adapter `ca_ncm_iface_get` (NCM → net core)
`caos/usb/src/usb_ncm.c`	CDC-NCM service (transport)
`hw/f4xx/drivers/usb_f4xx.c`	DWC2 slave FIFO (F407/F429/F446)
`examples/example_55/ca_os_ex55.c`	net stack on NCM + ping + CLI

Chapter 79

Composite USB: CDC + MSC + NCM

79.1 Example 56 — Composite USB CDC + MSC + NCM

79.1.1 Introduction

This example puts it all together: a **composite USB device** with **three active classes simultaneously** on the same `ca_usb_dev_mng` stack. By connecting a single cable, the PC will see three devices appear at the same time:

- a **virtual serial port** (CDC-ACM) — `/dev/ttyACMx`, with character echo
- a **removable disk** (MSC) — a 128 KB ramdisk on which to create a FAT filesystem
- a **USB network card** (CDC-NCM) — `usb0`, with the caOS net stack on top that responds to real ping requests

The value of this example is to demonstrate that the `ca_usb_dev_mng` stack is truly composable: the application **registers the three classes** with three `ca_usb_dev_mng_add` and the management automatically builds a **single composite config descriptor** (with the necessary IAD for CDC) and sums up the PID contributions of the three classes. There is no special code "for the composite case": it is simply the sum of examples 52, 53 and 55.

```
ca_usb_dev_mng_init(CA_USB_SPEED_FS, USB_NUM);
ca_usb_dev_mng_add(&s_cdc.header);    /* /dev/ttyACMx     serial echo          */
ca_usb_dev_mng_add(&s_msc.header);    /* removable disk     128 KB ramdisk    */
ca_usb_dev_mng_add(&s_ncm.header);    /* usb0     caOS net stack (real ping)  */
ca_usb_dev_mng_start();
ca_net_init(ca_ncm_iface_get(&s_ncm));   /* NCM as a push iface */
ca_net_proto_init(&net_cfg);             /* ARP + ICMP echo     */
```

Feature	Class	Result on PC
Virtual serial port	CDC-ACM	`/dev/ttyACMx`, interactive echo
Removable disk	MSC	`/dev/sdX`, FAT mountable
Network card	CDC-NCM	`usb0`, real ping to the device
Single config descriptor	mgmt	single device, three interfaces
Composite PID	mgmt	sum of the contributions of the 3 classes

79.1.2 PC Prerequisite: Remove the interface from NetworkManager

When the board enumerates, a new network interface appears on the PC (`enx02ca0500xx` — the name that udev derives from the MAC). NetworkManager sees it as any other newly connected card and **assigns it an address of its own**: it has been observed `172.21.10.100/24`. The board is on `192.168.10.0/24`, so the two end up on different subnets and the board is unreachable.

The symptom is misleading, because the interface **exists and is UP**: `ip link` shows it, and even `ping -I <iface>` responds — that flag bypasses the routing table. What doesn't work is everything else (`socat`, `nc`, the PC scripts of the examples), which follow the routing table.

The rule is versioned in the repository:

```
sudo cp tools/99-caos-ncm.conf /etc/NetworkManager/conf.d/
sudo systemctl reload NetworkManager
nmcli -t -f DEVICE,STATE dev status | grep enx    # it must say: unmanaged
```

> **The glob goes to `interface-name`, not to `mac:`.** The form `mac:02:ca:05:00:00:*` seems equivalent but it is not: it requires a full MAC and fails **silently** with a wildcard character — no error, and the interface remains managed.

The bank address does not set this rule: it is set by `sudo ./tools/bench_net.sh usb` or the example PC script.

79.1.3 Hardware

Board	MCU	`USB_NUM`	USB Connector	LED heartbeat	Classes
NUCLEO-U575ZI-Q	STM32U575ZI	0	Internal OTG_FS	PC7 (green LD1)	CDC+MSC+NCM (5 EP)
NUCLEO-H753ZI	STM32H753ZI	1	OTG_FS (CN14, "USB user")	PB7 (green LD2)	CDC+MSC+NCM (5 EP, margin to 6)
STM32F4VE (black board)	STM32F407VET6	0	Internal OTG_FS (PA11/PA12)	PA6 (D2)	**NCM+MSC** (3 EP, no CDC)

> **F407 — bimodal configuration**: the F407's OTG_FS has only **3 data EPs** (EP1..3, `USB_EP_MAX=4`). The composite CDC+MSC+NCM requires 5 EPs → it does not fit. On F407 the example compiles in **NCM+MSC** mode (2 classes, 3 EPs total), controlled by `#define EX56_HAS_CDC 0` (automatically set for `STM32F4`). For U575 and H753 the CDC is included (`EX56_HAS_CDC=1`).

Device network identity (NCM side):

Parameter	Value
IP device	192.168.10.56
MAC device	02:CA:05:00:00:56
MAC host (NCM)	02:CA:05:00:00:A6

> **Endpoint limit**: the three classes together use **5 data endpoints**, which is exactly the maximum of OTG_FS on U575 and F407 (RM0456 §72.2.3: EP0 control + 5 IN + 5 OUT). The H7 has margin (up to 6 data EPs). It is not possible to add a fourth data class without freeing an endpoint.

79.1.4 os_config.h Configuration

```
#define EN_USB        1     /* driver USB DWC2 + stack mgmt */
#define EN_USB_CDC    1     /* virtual serial port (not on F407) */
#define EN_USB_MSC    1     /* removable disk */
#define EN_USB_NCM    1     /* USB network card */
#define EN_NET        1     /* net core for ping over NCM */
```

2-class combinations: to obtain CDC+MSC, MSC+NCM or CDC+NCM, just turn off one of `EN_USB_CDC` / `EN_USB_MSC` / `EN_USB_NCM`. No additional files or examples needed: the EP allocation remains valid (a subset). CDC+MSC = 3 EP, MSC+NCM = 3 EP, CDC+NCM = 4 EP.

F407: keep `EN_USB_CDC=1` in `os_config.h` but the source `ca_os_ex56.c` automatically sets `EX56_HAS_CDC=0` for `STM32F4` → the CDC class is not registered, the composite descriptor is NCM+MSC (3 EP, within the limit). Also reduce `NET_BUF_COUNT` from 16 to 8 to leave space for a 64 KB ramdisk.

```
/* F407 only (ridotto per RAM 192 KB): */
#define NET_BUF_COUNT   8U
```

79.1.5 Endpoint allocation (maximum case)

The three classes together **saturate** the OTG_FS. The default allocation in `os_config.h` is designed to avoid collisions:

EP	Class	Type	Define
EP1	NCM	bulk data (NTB)	`USB_NCM_EP_DATA`
EP2	MSC	bulk data (CBW/CSW)	`USB_MSC_EP_DATA`
EP3	CDC	bulk data (serial)	`USB_CDC_EP_DATA`
EP4	CDC	interrupt notif	`USB_CDC_EP_NOTIF`
EP5	NCM	interrupt notif	`USB_NCM_EP_NOTIF`

The high-bandwidth bulk EPs (NCM, MSC) have a deeper ring queue; the CDC (low bandwidth) has a short queue. A `_Static_assert` (D16 decision) in `usb_mgmt.h` checks at **compile-time** that the EP masks of active classes do not overlap — an allocation error never reaches runtime:

```
USB_POPCOUNT(USB_EPMASK_CDC) + USB_POPCOUNT(USB_EPMASK_MSC) +
USB_POPCOUNT(USB_EPMASK_NCM) == USB_POPCOUNT(USB_EPMASK_ALL)
```

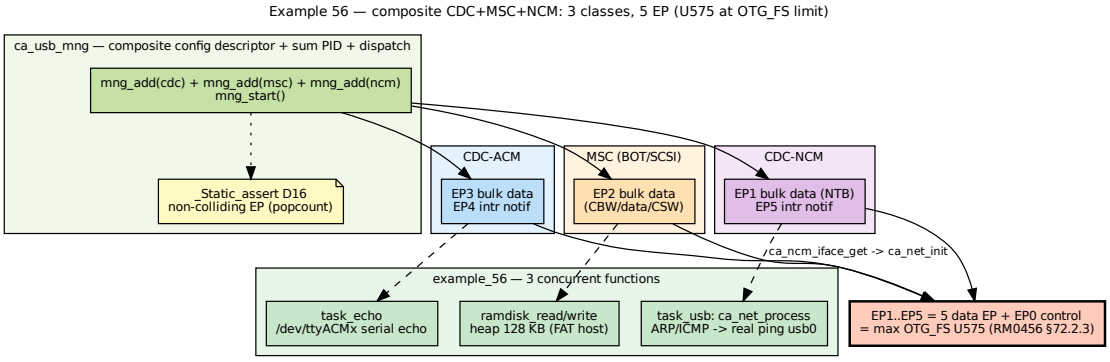

Figure 79.1: Composito CDC+MSC+NCM: 3 classes, 5 EP (ex56)

Source: `doc/diagrams/ex56_composite.dot` *(regenerated from* `make diagrams`*).*

79.1.6 Architecture

Task	Priority	Function
`echo`	LEVEL5	drains the CDC RX ring (filled by ISR) → echo to host
`usb`	LEVEL1	init 3 classes + net core; loop: drains `ca_net_rx_sem` + reports DTR changes
`stats`	LEVEL4	counters (NCM link, DTR, pool, rx/tx) every 5 s
`hb`	LEVEL4	toggle LED heartbeat every 500 ms

The task `usb` provides **dual service** in a non-blocking way: it uses `ca_sem_timedwait(&ca_net_rx_sem, 100ms)` to drain the net core (NCM frames incoming) and, when the timeout expires, checks if the CDC DTR status has changed and reports it to the console. One task, two responsibilities, no indefinite blocking.

```
u8 dtr_prev = 0U;
while (1) {
    if (ca_sem_timedwait(&ca_net_rx_sem, 100U)) {
        ca_net_process();                  /* frame NCM     ARP/ICMP */
    }
    u8 dtr = s_dtr;
    if (dtr != dtr_prev) {                   /* CDC terminal state change */
        ca_stdout_put_n(dtr ? "[USB] CDC terminal opened (DTR on)"
                            : "[USB] CDC terminal closed (DTR off)");
        dtr_prev = dtr;
    }
}
```

79.1.7 The three application functions

Class	Task / context	Behavior
CDC	`task_echo`	ring RX filled by ISR → echo of each byte toward the host
MSC	callback	`ramdisk_read`/`ramdisk_write` on 128 KB heap
NCM	`task_usb`	drains `ca_net_rx_sem` → `ca_net_process` (ARP/ICMP)

The three classes are completely independent: each has its own endpoints, its own callbacks and its own data flow. The management keeps them together only at the descriptor and enumeration level; at runtime each travels on its own EP without interfering.

79.1.8 Expected UART Output

```
=== EX56: USB composito CDC+MSC+NCM ===
[USB] composite up: /dev/ttyACMx + ramdisk 128 KB + usb0
[NET] ping 192.168.10.56 (bring up usb0 first)
```

When opening the CDC terminal from the PC:

```
[USB] CDC terminal opened (DTR on)
```

Periodic statistics (every 5 s):

```
STATS ncm=up cdc_dtr=1 pool=32/32 rx=5 tx=5 tx_fail=0
```

79.1.9 Test from PC

The three interfaces appear together under the same VID `0xCA01`:

```
lsusb -v -d ca01: | grep -iE "interface association|Mass Storage|CDC"
```

CDC — serial echo:

```
sudo screen /dev/ttyACM0 115200      # type     it is echoed back
```

MSC — FAT filesystem (reuses the ex53 script):

```
sudo ./examples/example_53/test_fat.sh    # auto-detect VID 0xCA01
```

NCM — actual ping to the device:

```
sudo ip addr add 192.168.10.1/24 dev usb0
sudo ip link set usb0 up
ping -c 5 192.168.10.56
```

Success criterion (U575/H753 — CDC+MSC+NCM): all three functions respond **simultaneously** without interference (serial echo + FAT + ping active at the same time). Tested HW on U575: NCM ping 5/5 + 3/3 reverse, CDC echo 100/100 on `ttyACM1`, MSC FAT persistence OK.

F407 (black board) — NCM+MSC without CDC:

```
lsusb -v -d ca01: | grep -iE "Mass Storage|NCM"
```

MSC — filesystem FAT (ramdisk 64 KB, minimum FAT12):

```
sudo ./examples/example_53/test_fat.sh
```

NCM — real ping to the device:

```
sudo ip addr add 192.168.10.1/24 dev usb0
sudo ip link set usb0 up
ping -c 5 192.168.10.56
```

Tested HW on F407: NCM ping 5/5 + MSC FAT persistence OK. Without CDC (no `/dev/ttyACMx` appears), the system log is visible only via UART ST-Link.

79.1.10 Technical notes

Composite descriptor over 127 bytes — EP0 multi-round

The config descriptor of the three classes put together is **183 bytes**, exceeding the 127 byte limit manageable in a single EP0 transfer on DWC2 (the `XFRSIZ` field in `DIEPTSIZ0` is 7 bit). The driver splits it into multiple "rounds" of transmission: intermediate rounds are **exactly 64 bytes** (a full packet), only the last round ends with a short packet. A short packet in the middle of the descriptor would terminate the control transfer and the host would timeout — for this reason intermediate rounds must be full. Single-class examples (descriptor 127 bytes) are unaffected. Detail of the fix in `hw/u5xx/drivers/usb_u5xx.c` (and symmetric in `hw/h7xx/drivers/usb_h7xx.c`, DMA mode).

IAD for CDC

The CDC-ACM uses two interfaces (comm + data) that must be grouped for the host with an **IAD** (Interface Association Descriptor). The management inserts it automatically when CDC is among the registered classes. MSC and NCM do not need it (single interface, or group managed differently).

Composite PID

`PID = sum of the contributions of the active classes`. With CDC+MSC+NCM the resulting PID is `0x0066` (`NCM 0x31 + MSC 0x22 + CDC 0x13`). This gives each class combination a distinct PID, useful for host-side udev rules.

79.1.11 File structure

File	Description
`examples/example_56/ca_os_ex56.c`	composite CDC+MSC+NCM (U5/H7) or NCM+MSC (F407)
`caos/usb/src/usb_cdc.c`	CDC-ACM class
`caos/usb/src/usb_msc.c`	MSC class (BOT/SCSI)
`caos/usb/src/usb_ncm.c`	CDC-NCM class
`caos/usb/src/usb_mgmt.c`	composite config descriptor + SETUP dispatch
`hw/f4xx/drivers/usb_f4xx.c`	DWC2 slave FIFO (F407/F429/F446)

Chapter 80

USB DFU: Runtime Mode

80.1 Example 57 — USB Management Stack: DFU runtime

80.1.1 Description

Example 57 demonstrates the `ca_usb_dfu` service (decision **D11** of plan `doc/usb_stack_workplan.md`) over the `caos/usb/usb_mgmt` stack. DFU *runtime* exposes a **DFU interface** (class `0xFE` / subclass `0x01` / protocol `0x01`) **without data endpoints**: all dialog passes through EP0.

In runtime mode the device continues to function normally; the DFU interface serves only to get recognized by the host (e.g. `dfu-util`), which can send `DFU_DETACH` to request switching to **DFU mode** (download/upload of the firmware). caOS notifies the application via `on_detach`: the typical usage is to set a flag in no-init RAM and reset to the system bootloader (ST-ROM or an application bootloader). The actual download is **out of scope** for this service.

Three calls are enough to bring up the device:

```
ca_usb_dev_mng_init(CA_USB_SPEED_FS, USB_NUM);        /* registers the mgmt
    driver callbacks */
ca_usb_dev_mng_add(&s_dfu.header);    /* registra la classe DFU (1 iface, no EP)
    */
ca_usb_dev_mng_start();              /* build descriptors + connect
    enumerates */
```

Features: 1. **Enumeration** as a device with DFU interface (VID `0xCA01`, PID `0x0040`) 2. **DFU runtime**: response to `DFU_DETACH`, `DFU_GETSTATUS`, `DFU_GETSTATE`, `DFU_CLRSTATUS`, `DFU_ABORT` (EP0 only, no data EP) 3. **CLI** `usb`: status, start/stop, add/remove (runtime lifecycle)

Supported hardware: NUCLEO-H753ZI (`USB_NUM=1`), NUCLEO-U575ZI-Q (`USB_NUM=0`), NUCLEO-F407ZG (`USB_NUM=0`), all OTG_FS.

> The `ca_usb_dev_mng` stack is documented in the `doc/usb_stack_workplan.md` plan (decisions D1–D20). The low-level driver is in `S02_11_00_usb_driver.md`.

80.1.2 Hardware

All boards operate in OTG_FS. No external wiring: connect the device USB connector (OTG_FS, not ST-LINK).

Board	MCU	`USB_NUM`	USB Connector	Heartbeat LEI
NUCLEO-H753ZI	STM32H753ZI	1	OTG_FS (CN14, “USB user”)	PB7 (LD2 gre
NUCLEO-U575ZI-Q	STM32U575ZI	0	Internal OTG_FS	PC7 (LD1 gre

Board	MCU	USB_NUM	USB Connector	Heartbeat LEI
STM32F4VE (black board)	STM32F407VET6	0	Internal OTG_FS (PA11/PA12)	PA6 (D2)

F407: HW tested. `dfu-util -l` → `Found Runtime: [ca01:0040]` OK; `dfu-util -e` → `DFU_DETACH` received and `on_detach` callback invoked. LED PA6.

80.1.3 os_config.h Configuration

```
#define EN_USB     1     /* driver USB DWC2 + stack mgmt */
#define EN_USB_DFU 1     /* enables the DFU runtime class */
/* CDC stays compiled but unused: the example does not open it and the console
 * does not go through it (STDOUT_ON_USB_CDC=0, STDIN_ON_USB_CDC=0). */
#define EN_USB_CDC    1
#define EN_USB_MSC    0
#define EN_USB_NCM    0
#define EN_USB_CUSTOM 0
```

DFU runtime uses **only EP0** (control): it does not contribute to the EP collision bitmap management (`USB_EPMASK_*`). It can therefore coexist with any other class without consuming data endpoints.

80.1.4 Architecture

```
ca_usb_dev_mng_init(CA_USB_SPEED_FS, USB_NUM)
         ca_usb_init(USB_NUM, &s_mgmt_cb)       mgmt registra i SUOI callback
    driver

ISR DWC2     callback mgmt     fan-out via ops ai servizi attivi:
  mng_on_setup     dispatch_standard (EP0: descriptor/address/config/...)
                  dispatch_class    (SETUP class-level     ops->on_setup)

ca_usb_dfu_ops (in caos/usb/usb_dfu.c):
  build_iface_desc     interface DFU (0xFE/0x01/0x01) + functional desc (18B)
  on_setup (class)     DFU_DETACH / GETSTATUS / GETSTATE / CLRSTATUS / ABORT
  on_configure         NULL (no data EP to open)

App (example_57):
  dfu_detached()      da on_setup(DFU_DETACH)     set s_detach_req
  task_usb: polling s_detach_req     stampa "DFU_DETACH ricevuto"
```

The DFU service does not open endpoint: `on_configure`, `on_rx`, `on_tx_done` they are `NULL`. The entire protocol lives in `on_setup` (control transfer on EP0).

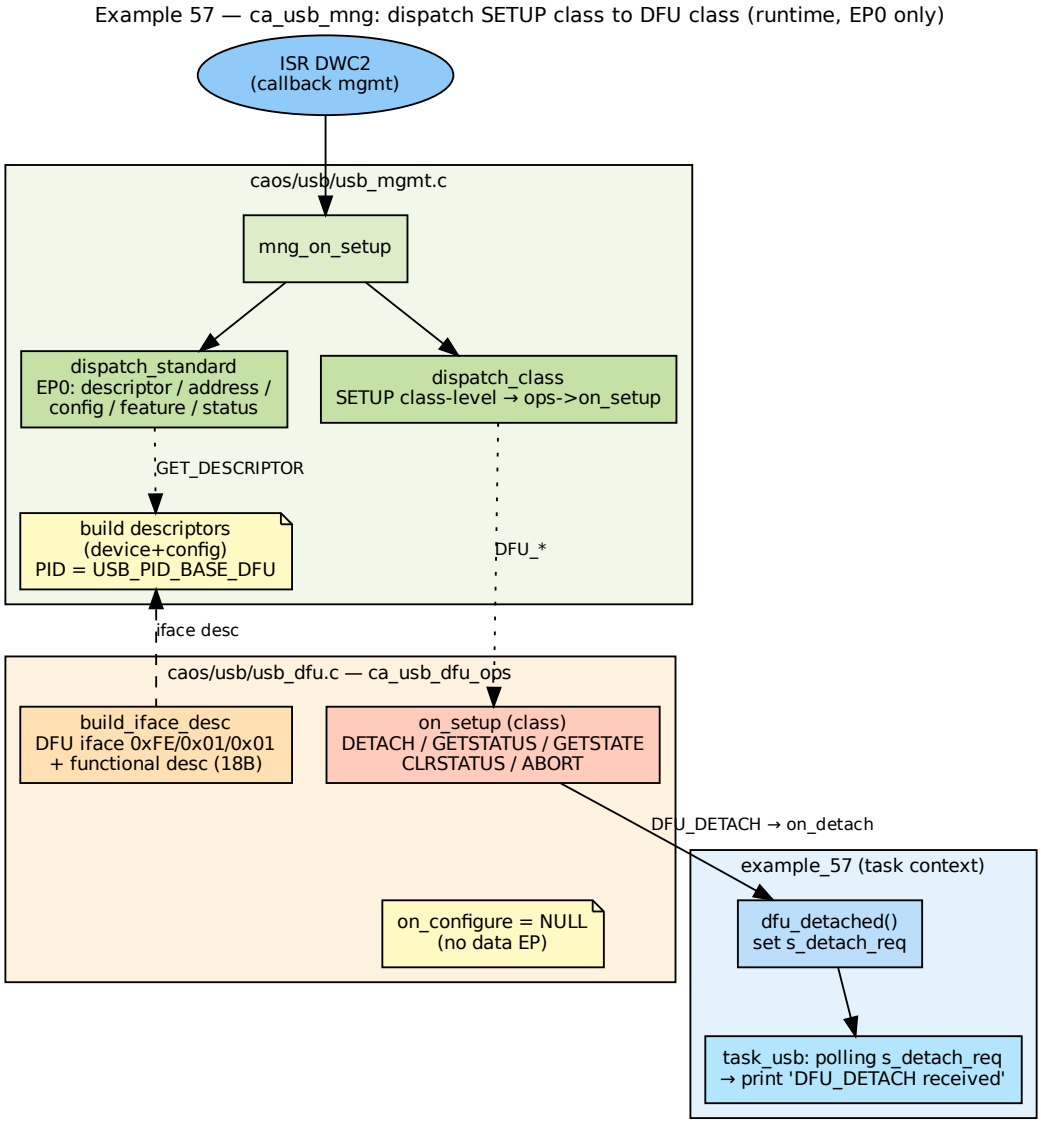

Figure 80.1: Dispatch SETUP class DFU (ex57)

Source: `doc/diagrams/ex57_dfu_runtime.dot` *(regenerated from* `make diagrams`*).*

Task	Priority	Function
`usb`	LEVEL6	init stack + polling `DFU_DETACH` (prints the host request)
`hb`	LEVEL4	toggle LED heartbeat every 500 ms

80.1.5 Class configuration (D20: persistent lifetime)

```
static const ca_usb_dfu_cfg_t s_dfu = {
    .header            = { CA_USB_TYPE_DFU, &ca_usb_dfu_ops },
```

```
    .detach_timeout_ms = 1000,
    .transfer_size     = 1024,
    .attributes        = USB_DFU_ATTR_CAN_DNLOAD | USB_DFU_ATTR_WILL_DETACH,
    .on_detach         = dfu_detached,
};
```

The cfg **must** be `static` (ideally `static const`): the management preserves the pointer without copying it. The first field `header` (tag + ops) must remain at the head of the struct (D19).

`detach_timeout_ms`/`transfer_size`/`attributes` end up in the **DFU functional descriptor** (9B). `PID = USB_PID_BASE_DFU = 0x0040` — the management sums the contributions of all active services (composite PID, D14).

80.1.6 Handled DFU Requests (DFU 1.1)

Request	Code	`bmRequestType`	Action
`DFU_DETACH`	0x00	0x21 (host→dev)	ACK ZLP + `on_detach()`; state → `appDETACH`
`DFU_GETSTATUS`	0x03	0xA1 (dev→host)	6B: `bStatus=OK`, `bwPollTimeout=0`, `bState`
`DFU_GETSTATE`	0x05	0xA1 (dev→host)	1B: `bState`
`DFU_CLRSTATUS`	0x04	0x21 (host→dev)	ACK ZLP; state → `appIDLE`
`DFU_ABORT`	0x06	0x21 (host→dev)	ACK ZLP; state → `appIDLE`

`DFU_DNLOAD`/`DFU_UPLOAD` are not handled at runtime (require switching to DFU mode) → the mgmt stalls on EP0.

80.1.7 CLI `usb`

```
usb status                  # state + detach_req flag
usb start | stop            # connect / disconnect (the host re-enumerates)
usb add | remove            # registra/rimuove la classe DFU a runtime
```

80.1.8 Parameters

Define	H753	U575	F407
`USB_NUM`	1	0	0
LED heartbeat	PB7	PC7	PA6

Requirements `os_config.h`: `EN_USB = 1`, `EN_USB_DFU = 1`.

80.1.9 Expected UART Output

```
[USB] mng init...
[USB] D+ pull-up on     plug cable (DFU runtime, dfu-util -l)
```

When the host sends `DFU_DETACH` (e.g., `dfu-util -e`):

```
[USB] DFU_DETACH received     the app would switch to DFU mode (here: report
    only)
```

80.1.10 Test from PC

First time on a new machine: the udev rule

Without it, udev leaves the device node owned by root and **not writable**:

```
crw-rw-r-- 1 root root 189, 77 /dev/bus/usb/001/078
```

Readable yes, writable no — and that is exactly the trap. `lsusb` reads and that's it, so the device **compares** and seems fine; but `dfu-util` must *open and claim* the interface, and fails one step later:

```
dfu-util: Cannot open DFU device ca01:0040
dfu-util: No DFU capable USB device available
```

The rule is versioned in the repository:

```
sudo cp tools/99-caos-usb.rules /etc/udev/rules.d/
sudo udevadm control --reload-rules && sudo udevadm trigger
```

A board that has already been enumerated retains the old permissions until it re-enumerates: unplug and reattach the cable, or let the next reflash handle it.

The commands

```
lsusb                          # VID=0xCA01 PID=0x0040
dfu-util -l                    # elenca l'interface DFU in runtime:
                               #   Found Runtime: [ca01:0040] ... name="DFU"
dfu-util -e                    # send DFU_DETACH     on_detach on the device
```

Nothing `sudo`: with the udev rule installed the example runs as a normal user, and this is what keeps ex57 in **class C** on the test bench.

`dfu-util -l` recognizes the interface (class 0xFE/sub 0x01); `dfu-util -e` emits `DFU_DETACH`, which on the device triggers `on_detach()` (here only UART signaling; in a real firmware: no-init flag + reset to bootloader).

80.1.11 File structure

File	Description
`caos/usb/inc/usb_mgmt.h`	API management (init/add/remove/start/stop)
`caos/usb/src/usb_mgmt.c`	composite descriptors + SETUP dispatch

Chapter 81

FatFS on SD Card: SDIO Driver with DMA

81.1 Example 58 — FatFS on SD card: SDIO driver with DMA

81.1.1 Description

Example 58 brings a complete FAT32 filesystem on microSD through the `ca_sdio` driver and the **FatFS** library (`external/fatfs`), exposed by an interactive CLI over USB CDC. It is the first example with mass storage managed by a filesystem (in contrast to `sdtest`, which remains available as raw low-level test within the example itself).

CLI commands (prefix `fat`). Volume, file and directory commands come from the **FAT service** of the kernel (`caos/drivers/src/fat_service.c`, `EN_FAT_SERVICE` + `EN_CLI_FAT`), reusable by any application; `blob`, `sdtest`, `test_all` and `log` are test tools and remain in the example:

```
fat fdisk [<MB>]                    partiziona MBR soltanto (default 64MB)
fat mkfs                            formats as FAT32 the partition created by
    fdisk
fat mount                           monta volume, stampa fs_type/size/free
fat umount                          smonta
fat free                            total/free/used space
fat pwd                             current directory
fat cd <dir>                        cambia directory
fat ls [dir]                        lists the current directory or <dir>
fat mkdir <dir>                      crea directory
fat rmdir <dir>                      rimuove directory vuota
fat touch <file>                     creates an empty file (error if it exists)
fat rm <file>                        cancella file
fat cat <file>                       reads into dynamic memory, hexdump, frees
fat blob <file> <n> <B|K|M>          scrive n byte/KB/MB (pattern 0x00..0xFF
    ciclico)
fat sdtest <lba> [<n>]               test raw driver  w r i t e readverify  (
    DISTRUTTIVO)
fat test_all                         sequenza completa non presidiata (DISTRUTTIVA
    )
fat log                              logger counters
inject <Pn> <delay> <hold>           pin to input mid-transfer (C12 = CK)
```

From `mount` onward, **every line printed to stdout is also written to file** on the card (`<uptime>_cmd_log.log`): see "Log of stdout to file". The log is **for the example, not the service**: it hooks into the service events (`ca_fat_service_set_event_cb`: mounted, unmounting, destructive command) and shares its lock (`ca_fat_lock`/`ca_fat_trylock`).

Tested hardware: **STM32F4VE** (F407, SDIO onboard via generic DMA), **Nucleo-H563**, **Nucleo-H753** and **NUCLEO-U575ZI-Q** (SDMMC v2 with IDMA, microSD on Zio CN8 adapter) — 4-bit bus, console on UART, heartbeat LED.

81.1.2 Hardware

Signal	Pin	Notes
SDIO D0	PC8	AF12, pull-up
SDIO D1	PC9	AF12, pull-up
SDIO D2	PC10	AF12, pull-up
SDIO D3	PC11	AF12, pull-up
SDIO CLK	PC12	AF12, no pull
SDIO CMD	PD2	AF12, pull-up
Heartbeat LED	**board-dependent** (see below)	toggle 500 ms
Console	Debug UART	`STDOUT_ON_UART=1`, `STDIN_ON_UART=1`

The SDMMC pins above are for the F4VE. The **heartbeat LED**, however, varies by board, and the example selects it with a `#if MCU_ID` (same mapping as ex18):

Board	LED	Pin
STM32F4VE (F407)	D2 onboard	PA6
NUCLEO-U575ZI-Q	Green LD1	**PC7**
Nucleo-144 (H753, H563, F746, F429, F446, H747)	Green LD1	**PB0**

PA6 is **not an LED** on any Nucleo-144: it's just a Zio pin. While it was hardcoded, the heartbeat remained off on those boards while the console continued to respond — the same issue seen in ex30 and ex31. A board not mapped by `#error` at compile time instead runs with silent LED.

Data path on **DMA2 Stream3 Channel4** (fixed SDIO mapping on F4xx), reserved for the generic DMA allocator at driver startup.

> **Why `fdisk` and `mkfs` are separate commands.** Partitioning and formatting are two distinct operations, and keeping them in one command means an error can only be attributed to the whole: `fdisk` succeeded and `mkfs` failed, but the user saw only one failed command. Separated, each responds on its own — and one can reformat without repartitioning.
>
> Tested HW on STM32F4VE: `fat fdisk` + `mkfs` + `mount` + `blob` + `ls` + `sdtest` all OK.

81.1.3 os_config.h Configuration

```
#define EN_SDIO 1
#define EN_FAT  1
#define EN_FAT_SERVICE 1    /* FAT service: ca_fat_* + CLI node */
#define EN_CLI_FAT 1        /* the service's 'fat' command */
#define EN_DMA  1           /* required by the F4xx SDIO driver (DMA data path)
    */
```

81.1.4 Architecture

The example relies on the storage subsystem of caOS (FatFS + SDIO driver), documented in detail in the chapter "FatFS su caOS: SDIO driver" (three-level architecture, redirect `ffconf.h` →`caos_ffconf.h` and ODR motivation, glue `fatfs_diskio.c`, HW driver F4xx with DMA, robustness notes). Here only the specific aspects of the example application are reported: static CLI context and commands.

Static FAT Context

> **As of 10/02/2026** the context is split: `FATFS`, the 4 KB work buffer, and the command objects are in the service (`fat_svc_t` in `fat_service.c`, same alignment and same reasons); the example keeps only the read-back of `sdtest` in `ex58_ctx_t`, the `FIL` of `blob` and the logger status. `blob` and `sdtest` borrow the work buffer of the service with `ca_fat_work_buf()`, under `ca_fat_lock()`. The structure below is the original one, before the separation.

The caOS task stack lives in **CCM** (scheduler constraint: not resizable, not DMA-capable), while FatFS with LFN requires large buffers (`FIL`/`DIR`/`FILINFO` ~1.5KB, work buffer `mkfs` 4KB). The example collects everything in a `fat_ctx_t` structure (~7KB) **statically**, aligned to 32 bytes, zeroed in `ca_os_configure()`:

```
typedef struct {
    FATFS   fs;
    bool    mounted;
    u8      work_tx[4096];          /* mkfs/fdisk work buffer (TX) */
    u8      work_rx[512];           /* sdtest read-back (RX)       */
    FIL     fil;
    DIR     dj;
    FILINFO fno;
    char    path[FF_LFN_BUF + 4];
    u8      pattern[256];           /* blob pattern 0x00..0xFF */
    char    sub[32], a1[FF_LFN_BUF + 2], a2[16], a3[4];  /* token CLI */
    FIL     logf;                   /* log: FIL separate from fil */
    bool    logging;
    char    logname[32];
    u32     log_lines, log_lost;
} fat_ctx_t;
```

> **Why static and not on heap.** It's a unique context, of fixed size, that lives as long as the program: the heap brings no advantage and adds failure modes — a silent NULL on full heap, and especially a **placement that changes from board to board**. Static ends up in `.bss` at a known address, which is what the SDMMC IDMA needs: aligned and always reachable. 32-byte alignment avoids every transfer going through the driver's bounce buffer. `ex2` continues to use `ca_memory_allocate()` on purpose (heap is its argument), and `ex53`/`ex56` allocate ramdisk in MB, where a static wouldn't make sense.

CLI commands use `g_ctx->...` instead of local variables: the CLI task stack stays lightweight.

81.1.5 stdout log to file

`fat mount` installs a **repeater** on stdout (`ca_stdout_set_repeater()`): from that moment on, every line printed by anyone is also appended to `<uptime>_cmd_log.log` on the card. `fat umount` closes

the file and uninstalls the repeater, reporting how many lines were written and how many were lost.

The uptime-based name gives a unique file for each boot without needing an RTC, and the files sort chronologically by themselves.

The problem: FatFS is not reentrant

This is the part that makes the example interesting, and also the reason why the code is not trivial. The repeater runs in the **stdout drain thread**, while the commands `fat` run in the **CLI thread**: they are two different tasks. And caOS compiles FatFS with `FF_FS_REENTRANT=0` (`external/caos_fatfs/caos_ffconf.h`), i.e. **without any internal locking**.

Two threads inside FatFS at the same time do not give a clean error: **they corrupt the volume**. And it would have happened at the first `fat blob big 10 M` — 44 seconds into `f_write` — if in the meantime something had printed a single line.

Two **guards** are needed, and they cover different faults:

Guard	What it prevents	Why the other is not enough
mutex	the two threads inside FatFS running together	doesn't stop recursion
flag	the repeater re-entering itself	a mutex is recursive for tasks

The mutex serializes CLI and stdout threads. The repeater takes it with `ca_mutex_trylock`, **never** `ca_mutex_lock`: blocking there would freeze the console for the entire duration of a `blob`, the stdout queue would fill up and lines would be lost anyway — but with a frozen system instead of just one line missing. A rejected lock means "a fat command is in progress": the line is counted and discarded, which is the fair compromise. **The flag** stops the recursion, which the mutex cannot: a mutex is recursive for tasks, so the drain thread would happily re-enter itself. Anything printed *while* we are inside `f_write` — a FatFS error, a line of SDIO driver diagnostics — would re-enter the repeater and call `f_write`, infinitely. Those lines are lost by design: they are the log of the failing logger, and losing them is the price of not blocking the console.

Destructive commands

`fdisk`, `mkfs` and `sdtest` rewrite the sectors on which the open log file lives: they stop the logger **before** touching the card, and say so. Silently losing the log would be worse than a noisy line.

Single entry and exit

The command dispatcher is structured with **a single** `fat_enter()` **and a single** `fat_leave()`. With a `return` per branch — and there are ten branches — a forgotten unlock would silently block the logger **forever**: the defect would not cause a compilation error and would only manifest as "the log has stopped writing".

Declared limits

- During a `fat` command, lines are **discarded**, not queued
- `f_sync` every 16 lines: a reset loses at most the last
- CLI command output **goes to the log** when the console is on UART (`STDOUT_ON_UART=1`), because in that case `CLI_PRINTF_N` expands to `ca_stdout_printf_n` and goes through the same queue. On a separate transport (SSH, HTTP) it would use the CLI sender and not go through there

81.1.6 `fat cat` — the trip through the heap

`fat cat <file>` reads the file into **dynamic memory**, does a hexdump of it and frees it. It is the only example command that goes through the allocator: all others work on the static context on purpose (see above). It therefore also serves as a test that the heap can handle a real load, with allocation and release of blocks of arbitrary size.

The ceiling on size is calculated **at runtime** by `ca_memory_get_avail_memory()`, with a 2 KB margin, instead of being a constant: the relevant limit is the one the allocator can actually satisfy, and a fixed value in the code would go out of sync with the configuration. A file too large is rejected by reporting the requested size and available memory, instead of letting the allocation fail.

> **Beware of `ca_hexdump`**: the second argument is a **byte count**, despite being declared `u16 lines`. The name lies; callers agree on bytes (`cli.c` passes `lines*16`). It is precisely this command that also surfaced a latent defect in the function: the ASCII column was always reading 16 fixed bytes, so on a shorter final line it would go **beyond the caller's buffer**. Invisible until all callers passed multiples of 16; fixed on 08/24. Perform `cat` on the active log file works (uses a second handle), but returns the file as it was at the last `f_sync` — up to 16 lines back. And every line that the dump prints is then appended to that log: the dump describes a file that grows while it is being read.

81.1.7 Expected output (CLI, HW F4VE)

```
fat fdisk
[fat] fdisk 64 MB (131072 settori)...
[fat] fdisk OK - now 'fat mkfs' to format
fat mkfs
[fat] mkfs (attendere)...
[fat] mkfs OK     2370 ms     volume ready
fat mount
[fat] mount OK  fs=FAT32  total=63519 KB  free=63519 KB
fat blob big 2 M
[fat] blob big  2097152 byte scritti
fat sdtest 140000 64
[sdtest] 64 blocchi, 0 word errate     OK
```

The time of `mkfs` (2.37s on F407) reflects multi-block write via `CMD25`; the same formatting with only single-block writes (`CMD24` repeated) measured ~8.3s — chunk writes of 8 blocks with `ACMD23` pre-erase are about 3.5× faster. On H-family with IDMA (H563/H753) formatting drops to ~0.5s. The above output is from F4VE; on H563 the `mkfs` completes in ~478 ms and single-block write remains ~235 KB/s (physical limit of card programming, not the driver — valid for all families).

`fat sdtest` is **destructive**: writes and reads directly via `ca_sdio_write_block`/`ca_sdio_read_block`, bypassing FatFS. Should be used on LBA outside the mounted volume (e.g. beyond the end of the FAT partition) to avoid corrupting the filesystem.

> The source comment says *"use LBA outside the FAT volume"*, but the code **does not verify it**: `fat sdtest 0 2000` accepts and rewrites MBR and boot sector. The damage is **latent** — as long as the volume remains mounted, FatFS works on structures already in RAM and `fat ls` continues to function; on first remount (or reset) `FR_NO_FILESYSTEM` arrives. It is the same pattern as `flash test 0` before the `_etext` guard, with much milder consequences: a card to reformat, not a board to recover with a probe.

File log and cat (HW U575)

```
fat mount
[fat] mount OK  fs=FAT32  total=63519 KB  free=63496 KB
[log] stdout -> '8767_cmd_log.log'
fat ls
  [DIR]  test
       1272  8767_cmd_log.log
[fat] 2 elementi
fat cat 8767_cmd_log.log
[fat] cat '8767_cmd_log.log': 1272 byte @ 0x2009CAC8
0x2009CAC8  5b 66 61 74 5d 20 6d 6f 75 6e 74 20 4f 4b 20 20 |[fat] mount OK  |
0x2009CAD8  66 73 3d 46 41 54 33 32 20 20 74 6f 74 61 6c 3d |fs=FAT32  total=|
...
fat umount
[log] closed '8767_cmd_log.log' - 42 lines, 0 lost
[fat] smontato
```

The file can also be read from a PC by extracting the card: it is plain text terminated `\r\n`.

81.1.8 Fault injection: `inject`

`inject <Pn> <delay_ms> <hold_ms>` arms a task that, after the delay, puts the pin into input mode for the given time and then restores its mode (the alternate function registers are not touched). It tests what the driver does when a transfer does not finish, without pulling wires:

```
inject C12 2000 500           # SDIO CK removed after 2 s, for 500 ms
fat sdtest 5200000 2048       # meanwhile, a 2048-block write
```

Choose a pin the **MCU drives**: CK yes, D0-D3 and CMD no, since the card drives them too. The delay starts at the `inject` command, and the next command arrives a few hundred ms later: with a long write (2048 blocks, about 4 s) the fault surely lands inside it.

`sdtest` writes a fixed pattern per LBA: use it on sectors **never written** before, or old data reads back as if it were new.

A fault can leave the card in an abnormal state that only a power cycle clears: `inject` is a manual tool, not a bench phase.

Result on H753 (19/10/2026): with the specification's timeouts (FatFS chapter, "Timeouts") the write completes without errors, about 1 s longer, and the card stays healthy.

81.1.9 State per family HW

Tested HW on this example: **F407** (STM32F4VE, generic DMA), **H563** (@25MHz), **H753** (@24MHz) and **U575** (@24MHz) — the last three with SDMMC v2 and IDMA. The **F7** family (F746/F767) has no recorded bench round; its driver uses DMA2 Stream3 like the F4.

The porting of H753 and U575 (08/23) required fixing the same defect on both, with opposite symptoms: **the driver assumed a kernel clock that nobody configured**. On U575 the clock was completely **missing** (`SDMMCSEL`→ICLK, only turned on by the USB driver) and the state machine never completed; on H753 it was **240 MHz instead of 48** (PLL1Q with SYSCLK at 480), so the card was driven **5× over spec** — 2 MHz in init instead of the allowed 400 kHz, 120 MHz in transfer instead of 25. Short transactions survived, which is why `sdtest` always passed; `f_mkfs`, which writes the FAT, corrupted data. Now `CLKDIV` is **derived at runtime from the PLL read by RCC**, so a future change to the clock will not silently overclock the card again.

> **Diagnostic rule confirmed twice in a day**: active state machine and **zero error bits** means that the **clock** is missing or unstable, not that the wiring is wrong — incorrect wiring would instead cause a timeout.

Detailed driver status for all families: see chapter “FatFS su caOS: driver SDIO”.

81.1.10 File structure

File	Description
`examples/example_58/ca_os_ex58.c`	CLI `fat`, static context, heartbeat task

For the subsystem architecture (driver `ca_sdio`, glue diskio, build FatFS) see the chapter “FatFS su caOS: driver SDIO”.

Chapter 82

Power Manager: Frequency, Stop and Standby

82.1 Example 59 — Power manager (pwr)

Interactive example for validating the centralized power manager driver. **Silent by design**: no task prints autonomously, all output is on request via CLI — ideal for verifying low-power modes without console noise.

For the driver theory (low-power modes, wake sources, frequency scaling, family-specific quirks) see the "Centralized power manager" chapter (S02.13): this document only covers practical usage via CLI.

82.1.1 What it demonstrates

CLI commands (prefix `pwr`, plus `rtc info`):

```
pwr info           power state (sysclk, vos, standby_resume, peripherals)
pwr freq <1-99>    riduzione frequenza (HPRE) + retune tick/uart/can
pwr restore        ripristino frequenza nominale
pwr alarm <s>      test allarme RTC in RUN (nessuno stop)
pwr sleep <s>      WFI semplice, wake da allarme RTC
pwr stop <s>       STOP, wake da allarme RTC
pwr stopms <ms>    STOP, wake da LPTIM1 su LSI in millisecondi (U5xx/H5xx/H7xx/
    F7xx)
pwr dbg            dump of low-power registers (U5xx/F4xx only, requires
    EN_PWR_DBG)
pwr standby <s>    STANDBY, wake da allarme RTC = reset
rtc info           current RTC time
```

- `pwr info` — complete overview of the power state read from RCC/PWR: current/nominal SYSCLK, voltage scaling (VOS), standby source, list of peripherals with active clock grouped by bus. The list marks with `+` the peripherals turned on **after** init (residual clocks compared to the "cold" baseline) and with `off:  -` those turned off compared to it — useful for identifying residual clocks before/after a stop (see S02.13)
- `pwr freq <1-99>` / `pwr restore` — CPU frequency reduction/restoration via AHB prescaler with coordinated retuning of SysTick, UART, and bxCAN/FDCAN
- `pwr alarm <s>` — RTC alarm test in RUN (IRQ verification without stop)
- `pwr sleep <s>` — Simple WFI with wake from RTC alarm
- `pwr stop <s>` — STOP mode with wake from RTC alarm (seconds) and PLL re-init upon wakeup
- `pwr stopms <ms>` — STOP mode with wake from **LPTIM1** on LSI, in **milliseconds** (not seconds like `pwr stop`): fine resolution (down to ~31 µs), max 262144 ms. Useful for rapid

test cycles or short duty cycles where the 1s granularity of the RTC would be too coarse. Available on **U5xx/H5xx/H7xx/F7xx** (families with LPTIM block; F4xx and F1xx lack it → command rejected)
- `pwr dbg` — raw dump of relevant low-power registers (U5xx/F4xx only, requires `EN_PWR_DBG`)
- `pwr standby <s>` — STANDBY mode: wake from RTC alarm causes a reset; upon restart `pwr info` shows `standby_resume=yes`. With `<s>` at 0 (or omitted, depending on the build) the wake occurs instead from the **WKUP pin** (typically PA0) rather than the RTC alarm — convenient for manual push-button wake during tests, without having to wait for the timeout

82.1.2 Requirements

- Active CLI console (UART_DBG or USB CDC according to `os_config.h`)
- RTC initialized (the example uses `CA_RTC_CLK_LSI`, no crystal required)

82.1.3 Structure

A single silent `hbeat` task (sleep 1s in loop, toggle LED) verifies that the scheduler survives stop/wake cycles. All interaction takes place via the CLI.

Heartbeat task + per-MCU LED

Under `EN_PWR_DBG` the heartbeat task also drives an LED, one per board:

MCU	LED	Pin
F407 (F4VE)	D2	PA6, active low
U575 (Nucleo-U575ZI-Q)	Blue LD2	PB7
H563 / H753 / F746 (Nucleo-144)	Green LD1	PB0
F103 (Blue Pill)	—	PC13, active low

The blinking LED is the fastest way to distinguish "OS alive, only the console is dead" from "wake failed and the system is locked": if the LED continues to blink after a `pwr stop`/`pwr standby` but the console does not respond, the problem is in the console (e.g., USB re-enumeration in progress), not in the scheduler. The heartbeat task counter can still be inspected from the CLI with `task 1`.

82.1.4 Notes

- During STOP, the OS tick is stopped: task sleeps are delayed by the duration of the stop (documented driver behavior, see S02.13)
- With IWDG active, the timeout must exceed the duration of the stop
- **CDC console vs stop/standby**: on USB CDC console, STOP sends the USB link into suspend; upon wake, a host-side re-enumeration may be required before the wake-up print is visible. On **U5xx**, the USB session survives STOP (suspend→resume, no re-enumeration). For testing, the UART console remains cleaner, as the problem does not arise there. To avoid losing the wake-up print while the CDC is re-mounting, the CLI command inserts a `sleep 100ms` plus a newline immediately after returning from `ca_pwr_enter` .

82.1.5 HW Status

`pwr` has been validated via CDC console on **F407** and **U575** (14/07) and on **H563/H753** (13/07): STOP and STANDBY tested with positive results on all four families. It is the only

example dedicated to the power manager driver (removed from `example_2`/`example_4`, where it was initially drafted).

82.1.6 File structure

File	Description
`examples/example_59/ca_os_ex59.c`	CLI `pwr`/`rtc`, heartbeat task, per-MCU LED under `EN_PWR_DBG`

For the driver architecture (low-power modes, wake sources, coordinated frequency scaling, per-family state) see the “Centralized power manager” chapter (S02.13).

Chapter 83

PWM: LED Fade with User Button

83.1 Example 60 — PWM: LED fade with user button

Demonstration example of the **PWM** mode of the timer driver (`ca_timer_init_pwm` / `ca_timer_set_pwm`): the user LED on the board is controlled by a timer channel in PWM mode 1 and the brightness is controlled by the user button.

83.1.1 Behavior

- At boot the LED starts **on** (duty = `DUTY_MAX` = 1000‰).
- **While holding** the user button the duty decreases with a linear ramp; when the low threshold is reached the direction **inverts** and the duty increases: while the button is pressed the LED "breathes" between the two thresholds.
- **Releasing** the button freezes the brightness at the current value.
- Each inversion is printed to stdout (`ex60: min 150/1000, salgo`).

83.1.2 Thresholds

Below 15-20% duty the LED is already visually off: the ramp inversion would happen "in the dark" and the button would seem unresponsive. The thresholds are constants defined at the top of the file:

```
#define PWM_FREQ_HZ   1000U   /* 1 kHz: no visible flicker */
#define DUTY_MAX      1000U   /* high inversion threshold (   ) */
#define DUTY_MIN       150U   /* low threshold: below ~15% the LED is already
    off */
#define DUTY_STEP        5U   /* passo per tick     sweep completo in ~1.7 s */
#define TICK_MS         10U   /* button/ramp polling period */
```

83.1.3 Board mapping

Board	LED	PWM Channel	AF	Button
F4VE	D2 = PA6 (**active low**)	TIM3_CH1	AF2	K0 = PE4 (pressed = 0, pull-up)
NUCLEO-U575ZI-Q	LD2 blue = PB7	TIM4_CH2	AF2	B1 = PC13 (pressed = 1)
NUCLEO-H563ZI	LD1 green = PB0	TIM3_CH3	AF2	B1 = PC13 (pressed = 1)
NUCLEO-H753ZI	LD1 green = PB0	TIM3_CH3	AF2	B1 = PC13 (pressed = 1)

On the F4VE the LED is **active low** (anode at 3.3V): the example inverts the duty applied (`1000 - duty`) under `#define LED_ACTIVE_LOW`, so the logic remains identical on all boards.

83.1.4 Key points of the code

1. **Caller-owned pin** (caOS pattern, like the encoder in ex25):

```
ca_gpio_configure(LED_PORT, LED_PIN, CA_GPIO_MODE_AF,
                  CA_GPIO_OTYPE_PP, CA_GPIO_SPEED_LOW, CA_GPIO_NOPULL, LED_AF);
```

2. **Init and start** — the frequency is per-timer, the duty is per-channel:

```
ca_timer_init_pwm(PWM_TIM, PWM_CH, PWM_FREQ_HZ);
ca_timer_set_pwm (PWM_TIM, PWM_CH, duty);   /* 0-1000     */
ca_timer_start   (PWM_TIM);
```

3. **Duty change glitch-free**: `ca_timer_set_pwm` writes the CCR with preload enabled — the new duty is loaded at the next PWM period, without spurious pulses. It can be called at any rate (here every 10 ms).

4. **Polling, not EXTI**: the button is read every `TICK_MS` by the fade task — simpler than an EXTI ISR and the polling period acts as natural debounce.

83.1.5 Test from CLI

The CLI node `timer` is registered: the duty can be forced from console bypassing the ramp:

```
timer info                TIM3  pwm  cnt=0x...
timer pwm 3 1 500         TIM3 ch1 duty=500/1000
```

83.1.6 Requirements

```
#define EN_TIMER  1
```

No external connection: LED and button are on the board.

Chapter 84

LPTIM: Low-Power Blink

84.1 Example 61 — LPTIM: blink low-power (periodic + one-shot)

Demonstrative example of the **LPTIM** driver (`ca_lptim_init_periodic` / `ca_lptim_init_oneshot`): the user LED blinks on LPTIM1 with kernel clock **LSI 32 kHz**, independent from system clocks. The counter remains active even in Stop: it is the basis for the future tickless idle.

84.1.1 Behavior

The task alternates in loop the phases:

- **Phase A** — periodic 500 ms × 20 toggle (~10 s, slow blink);
- **pause** — one-shot 2000 ms with LED off: the timer generates a single interrupt and stops by itself (SNGSTRT);
- **Phase B** — periodic 100 ms × 50 toggle (~5 s, fast blink);
- **Phase C** (if `EN_PWR`) — periodic 500 ms with **wake=true**: the MCU enters **STOP** and the LPTIM wakes it up at every ARR match — the LED blinks with the CPU stopped (10 toggle), then execution resumes. During Phase C the CDC console is suspended.

The LED toggle occurs in the **ISR callback** (ARR match); the task counts the fires and orchestrates the transitions with `stop` + `deinit` + re-init. Each transition is printed to stdout (`ex61: fase A - periodic 500 ms x 20`).

84.1.2 LPTIM Driver

Times in **milliseconds** (1..262144), automatic prescaler /1../128 for maximum resolution; precision limited by LSI tolerance (±5%).

```
ca_lptim_init_periodic(1, 500, cb, wake);   /* callback on every ARR match */
ca_lptim_init_oneshot (1, 2000, cb, wake);  /* callback once, then stops */
ca_lptim_start (1);
ca_lptim_stop  (1);                         /* disable: CNT restarts from 0 */
ca_lptim_deinit(1);
```

With `wake=true` the instance becomes a wakeup source for the power manager: `ca_pwr_enter(CA_PWR_MODE_STOP, 0, 0)` accepts the input in Stop even without RTC/pin (the pwr interrogates `ca_lptim_wake_active()` and re-enables the LPTIM NVIC by itself; on F7/H7 the EXTI line 23/47 is armed by the driver at start). The kernel clock LSI keeps the counter alive during Stop.

Two IP variants handled in family files:

Family	IP	Notes
F7xx / H7xx	v1	`IER` is writable only when disabled
H5xx / U5xx	v2	`DIER` from enabled, sync on `DIEROK`
F1xx / F4xx	—	LPTIM not present: init → `false`

Note: LPTIM1 is shared with `ca_pwr_enter()` stopms, which arms it on its own: with an active driver instance the pwr **rejects** stopms (guard in `ca_pwr_enter`).

84.1.3 Board mapping

Board	LED
NUCLEO-U575ZI-Q	LD2 blue = PB7
NUCLEO-H563ZI / H753ZI / F746ZG	LD1 green = PB0
F4VE	LPTIM absent on F407: message and exit

84.1.4 Key points of the code

1. **Runtime probe** — on F1/F4 the init fails cleanly:

```
if (!ca_lptim_init_oneshot(1, 100U, NULL, false)) {
    ca_stdout_put_n("ex61: LPTIM not present on this MCU");
    return 1;
}
ca_lptim_deinit(1);
```

2. **One-shot autoterminante**: on fire the dispatch stops the HW and releases the slot *before* calling the callback — inside the callback you can already re-init the same LPTIM.

3. **Callback in contesto ISR**: only short operations (here `ca_gpio_toggle` + increment of a counter `volatile`); the phase logic is in the task.

4. **Blink in STOP** (phase C) — the task re-enters Stop after every wake:

```
ca_lptim_init_periodic(1, 500, cb_blink, true);   /* wake-armed */
ca_lptim_start(1);
while (s_fires < STOP_TOGGLES)
    ca_pwr_enter(CA_PWR_MODE_STOP, 0, 0);   /* the LPTIM wakes it */
```

When waking up, the pwr re-initializes the clock with IRQ disabled, then the LPTIM ISR executes the callback (toggle): the power consumption between one toggle and the other is that of Stop, not Run.

84.1.5 Test from CLI

```
lptim info              LPTIM1  periodic  cnt=0x1F40
lptim stop 1            LPTIM1 stopped (blink congelato)
lptim start 1           LPTIM1 started
```

84.1.6 Requirements

```
#define EN_LPTIM  1
```

No external link: the LED is onboard.

Chapter 85

LPUART: Low-Power Console with Wake from Stop

85.1 Example 62 — LPUART: low-power console with wake-up from Stop

Demonstration example of the **LPUART** driver (`ca_lpuart_init` / `ca_lpuart_put`): the system CLI console migrates to **LPUART1** (115200 8N1) and, thanks to `wake=true`, **receiving a character wakes the MCU from Stop** mode of the power manager. This is the typical battery-powered scenario: MCU almost always in Stop, console responding to the first key press.

85.1.1 Configuration (os_config.h)

The LPUART console is a first-class option, like UART dbg and CDC:

```
#define STDOUT_ON_LPUART   1     /* STDOUT = ca_lpuart_put */
#define STDIN_ON_LPUART    1     /* STDIN  = ca_cli_data_from_isr */
#define LPUART_STD_BAUD    115200U
#define LPUART_STD_WAKE    1     /* console armed as wake source from Sleep/Stop
    */
```

With both active, `EVAL_LPUART_STD` expands to `ca_lpuart_std_cli()` called by `ca_os_init` (before `ca_os_configure`): LPUART init with `on_rx` → `ca_cli_rx_byte` and `wake=LPUART_STD_WAKE`. The example uses the standard pattern (`ca_stdout_set_sender(STDOUT)`), no runtime switch. For testing, turn off the other consoles (`STDOUT_ON_USB_CDC 0`, `STDIN_ON_USB_CDC 0`, and possibly `EN_USB 0`).

85.1.2 Behavior

- The system console is the terminal connected to LPUART1.
- A task prints the uptime every 15 s.
- From the LPUART terminal:

```
pwr stop 60
```

The MCU enters STOP mode (RTC alarm set to a 60 s safety timeout) — by pressing **any key**, the MCU wakes up immediately: the byte is not lost, it is delivered to the CLI after wake-up (a RETURN is harmless).

85.1.3 LPUART Driver

```
ca_lpuart_init(115200, on_rx, true);   /* wake=true     wakes from Stop/Sleep */
ca_lpuart_put(msg);                    /* sender-compatible: STDOUT/CLI     */
ca_lpuart_deinit();
```

Driver choices:

- **Kernel clock HSI16 + HSIKERON**: the baudrate is independent of the sysclk — no retune after `pwr freq` or wake from Stop (the classic dbg UART instead dies with clock changes) — and the oscillator remains alive in Stop: reception is reliable at 115200 even as a wake event.
- **TX polling, RX interrupt-driven** byte-by-byte (FIFO off, RXNEIE).
- With `wake=true`, **UESM** is set and the pwr block automatically re-enables the LPUART NVIC at Stop (`ca_lpuart_wake_active()`, same pattern as LPTIM); on H7, the driver also arms the **EXTI 34** line.

Family	Notes
U5xx	Autonomous APB3 (SMEN+AMEN), direct NVIC wake
H5xx	APB3 (LPEN), direct NVIC wake
H7xx	D3/APB4 (LPEN+D3AMR), wake via EXTI 34 (IMR2)
F1xx / F4xx / F7xx	LPUART not present: init → `false`

85.1.4 Board mapping (external USB-UART adapter, 3.3V)

Board	TX	RX	AF
NUCLEO-U575ZI-Q	PA2	PA3	AF8
NUCLEO-H563ZI	PB6	PB7	AF8
NUCLEO-H753ZI	PA9	PA10	AF3 (do not use together with USB device)

85.1.5 Test without adapter: ST-LINK VCP via jumpers

You can reuse the onboard ST-LINK USB-UART converter: with USB off and the dbg UART **not** initialized, the MCU pins connected to the VCP remain in **high impedance** (GPIOs at reset are in analog mode), so two jumpers are enough — TX line to TX, RX line to RX (the TX/RX crossover is already done on the board between ST-LINK and MCU):

Board	VCP (MCU side)	Jumpers
U575	USART1 PA9/PA10	PA9–PA2 (TX), PA10–PA3 (RX)
H563	USART3 PD8/PD9	PD8–PB6 (TX), PD9–PB7 (RX)
H753	USART3 PD8/PD9	PD8–PA9 (TX), PD9–PA10 (RX)

Warning: disable the board's debug UART — `ENABLE_DBG_UART 0` in `hw/<family>/<board>/objmap.h` (it is a board property, not an os_config one): `ca_os_init` initializes it regardless of `STDOUT_ON_UART`, and its push-pull TX would conflict with the LPUART TX through the jumper. Verified on U575: with USART1 active on PA9/PA10, the LPUART console is silent.

85.1.6 Requirements

```
#define EN_LPUART 1      /* BEFORE the STDOUT block in os_config.h */
#define EN_PWR    1      /* CLI "pwr" for the stop/sleep demo */
#define EN_RTC    1      /* safety alarm for pwr stop <s> */
```

The example calls `ca_pwr_init()` and `ca_rtc_init(CA_RTC_CLK_LSI)` in `ca_os_configure`.

Terminal at 115200 8N1 (ST-LINK VCP with jumpers, or 3.3V USB-UART adapter with crossed TX/RX and GND).

Chapter 86

UART DMA: Variable-Length Protocol

86.1 Example 63 — UART DMA: variable-length protocol

Demonstration example of the **UART driver DMA mode** (`EN_UART_DMA`) in the most general and frequent case in practice: a protocol whose length **is not known a priori**. The header is decoded byte by byte in normal mode; once the length is known, the rest of the message arrives **entirely via DMA**, without any interrupt per byte. This is the reference scheme for framed protocols over serial (e.g., Ethernet-over-UART, extended Modbus RTU, inter-MCU link).

86.1.1 Configuration (os_config.h)

```
#define EN_UART_DMA    1      /* exclusive with ENABLE_UART (classic driver) */
#define EN_DMA         1      /* richiesto */
```

DMA mode is **mutually exclusive** with the classic UART driver (`#error` in os_config). The UART under test is the ST-LINK VCP one: in the board's objmap, `ENABLE_DBG_UART 0` must be set (TX contention) — the example monitor is on the USB CDC console.

86.1.2 The example protocol

```
[SOF 0xCA][type][len_lo][len_hi]   payload[len]   [crc_lo][crc_hi]
```

CRC16-CCITT (poly 0x1021, init 0xFFFF) on type+len+payload. The board responds with an echo containing `type|0x80` and the same payload (max 1024 bytes). Frames with incorrect CRC: counted, no echo.

86.1.3 Header-to-payload flow

1. **Header phase (normal mode)** — `ca_uart_init_dma()` leaves RX on interrupt: every byte arrives at the `on_rx` callback (ISR context), where a small state machine searches for the SOF and accumulates type+len. Bytes out of sync are discarded (counter `resync`).
2. **Switch to DMA — from the ISR itself** — upon `len`, `on_rx` calls `ca_uart_dma_recv( num, buf, len+2)`: RXNEIE off, DMA channel armed one-shot P2M on `buf`. Switching in the ISR of the last header byte guarantees staying within a byte-time (no overrun); any pending RXNE is drained by the DMA upon activation of DMAR.
3. **Payload phase** — the DMA fills the caller's buffer: zero CPU load until transfer-complete.

4. **Frame end (TC, counter at zero)** — the driver's TC callback restores header mode (DMAR off, RXNEIE on) and the channel semaphore wakes the task blocked in `ca_uart_dma_wait()`.
5. **Response** — the task verifies the CRC and transmits the echo with `ca_uart_dma_send()`: TX is also DMA one-shot, the task sleeps on the channel semaphore until TC (no busy waiting).

86.1.4 Driver API (EN_UART_DMA)

```
ca_uart_init_dma(num, baud, on_rx);   /* fase header: byte     on_rx (ISR) */
ca_uart_dma_recv(num, buf, len);      /* da ISR: arma RX one-shot        */
ca_uart_dma_wait(num, CA_WAIT_FOREVER); /* task: sleeps until end of frame */
ca_uart_dma_send(num, buf, len);      /* TX one-shot, task-blocking      */
ca_uart_dma_remaining(num);           /* byte mancanti (diagnosi)        */
ca_uart_dma_abort(num);               /* truncated frame recovery */
```

The **fixed-length** case is a trivial subset: `ca_uart_dma_recv()` is called immediately with the known size, without a header phase.

Under the hood, the driver uses the generic building blocks of the DMA framework: `ca_dma_set_request()` (peripheral request line, family bindings verified against reference manuals) and `ca_dma_set_callback()` (TC callback in ISR, new with this example).

86.1.5 Host test

```
python3 examples/example_63/host_test.py /dev/ttyACM0
```

Sequence: echo ping-pong on sizes 1→1024 B, frame with corrupted CRC (no echo expected), resync after 64 bytes of garbage, throughput on 50 frames of 1024 B. At 115200 8N1 the ping-pong saturates the line (~11 KiB/s round-trip measured on NUCLEO-U575).

CLI on CDC console:

```
u63 info        frame/byte/CRC err/resync + byte DMA mancanti
u63 abort       cancels a stuck reception (truncated frame)
```

Family	Notes
F1xx	fixed DMA mapping per channel (request ignored)
F4xx/F7xx	CHSEL per stream, bind RM0090/RM0385
H7xx	DMAMUX1; **frame buffer in RAM D2** (no DTCM)
H5xx/U5xx	GPDMA REQSEL; HW tested on NUCLEO-U575

Chapter 87

SPI DMA: Full-Duplex Loopback on a Single Board

87.1 Example 64 — SPI DMA: loopback full-duplex on single board

Demonstration example of the **SPI driver DMA mode** (`EN_SPI_DMA`). Unlike UART, SPI is **synchronous**: the master clocks exactly `len` bytes, so the **transfer size is known a priori**. No header phase is needed — the transfer of the desired length is armed directly and the task sleeps until completion, without byte interrupts nor busy waiting.

87.1.1 Configuration (os_config.h)

```
#define EN_SPI_DMA    1      /* exclusive with EN_SPI (classic driver) */
#define EN_DMA        1      /* richiesto */
```

`EN_SPI_DMA` is **mutually exclusive** with the SPI polling/IRQ driver (`#error` in os_config) and requires `EN_DMA`.

87.1.2 Hardware — 2-wire loopback

Single master, no slave: bridge MOSI to MISO so that every transmitted byte returns identical.

```
  SPI1:  PA7 (MOSI)              PA6 (MISO)      SCK PA5 free
```

> **NUCLEO-U575ZI-Q** — does not have Ethernet mounted, so PA5/PA6/PA7 are free and the **default** mapping (`.alternate_gpio = false`) is used. Loopback verified on the **Zio CN7**: **PA7 (MOSI, D11, CN7 pin 14) PA6 (MISO, D12, CN7 pin 12)**; SCK PA5 = D13 = CN7 pin 10 is not needed. Unlike the H563, here the Arduino pins of CN7 are actually wired (UM2861 Table 15).
>
> **STM32F4VE** (black board, F407) — no Ethernet: default PA5/PA6/PA7, loopback **PA7 (MOSI) PA6 (MISO)** on the side headers.

Boards with mounted Ethernet

On Nucleo-144, the PA7 pin is wired to the RMII (`RMII_CRS_DV`) and controlled by the PHY: it cannot be used as MOSI. On these boards, SPI must be opened with `.alternate_gpio = true`, which moves SPI1 to **PB3 (SCK) / PB4 (MISO) / PB5 (MOSI)**.

> **NUCLEO-H563ZI** — loopback verified: **CN12 pin 29 (PB5) CN12 pin 27 (PB4)**, on the morpho connector.

Do not use CN7: PB5 is not reachable from there. Pin 13 (D22) goes through solder bridge SB17, which is open by default; pin 14 (D11) does not carry the signal even though it is listed as PB5 in Table 21 of UM3115. In both cases, MISO reads `FF` constant and the test fails on all boards.

NUCLEO-H753ZI — here the driver already maps SPI1 to PA5 (SCK) / PA6 (MISO) / **PB5** (MOSI) in order to bypass PA7, so `.alternate_gpio` remains `false`. Loopback verified: **CN12 pin 29 (PB5) CN12 pin 13 (PA6)**.

Warning: MOSI falls on the same pin as the H563 (29), MISO **does not** — 13 and not 27, because the two boards use different mappings.

Also avoid CN7 here: pin 14 (D11) is switchable between PA7 and PB5 via SB33/SB35 and is wired to **PA7** by default (UM2407 Table 14, note 3). Also note that on this board `SPI_B` of the connector is **SPI3**, not SPI1.

In general, it is advisable to use the morpho connector on both boards: the Arduino pins go through solder bridges that the documentation does not always reliably report, and the symptom of an unconnected pin (`rx` constant at `FF`, errors on all boards) is indistinguishable from a driver fault.

87.1.3 The synchronous transfer

The core is a single blocking call:

```
u16 ca_spi_dma_xfer(u8 spi_num, const u8 *tx, u8 *rx, u16 len);
```

1. **prepare** — the peripheral is stopped (SPE=0 on IP v3), flags cleared and size set: on SPI v3 (H5/H7/U5) `len` goes to **TSIZE** (EOT after `len` frames); on v1/v2 (F1/F4/F7) only DMA channels count. `RXDMAEN` is enabled.
2. **arm** — both DMA channels are armed: RX in `P2M` (RXDR→buffer) and TX in `M2P` (buffer→TXDR), both at 8 bit.
3. **kick** — `TXDMAEN` is enabled and (on v3) `SPE+CSTART`: the transfer starts here. The DMA writes/reads at the pace of TXP/RXP requests.
4. **wait** — the task blocks on the channels' semaphores (first TX then RX: the last TX fetch always precedes the last RX store).
5. **finish** — the end of the last byte shift is awaited (`EOT` on v3, `BSY` on v1), flags are cleared and the idle master state is restored.

Mode bytes (`tx==NULL` → dummy 0xFF; `rx==NULL` → TX-only with discard of received) make the API useful also for pure write/read operations, in addition to full-duplex.

87.1.4 Driver API (EN_SPI_DMA)

```
ca_spi_init_dma(&cfg);                  /* like ca_spi_init + DMA channel bind */
ca_spi_dma_xfer(num, tx, rx, len);      /* synchronous full-duplex, blocking */
ca_spi_dma_write(num, buf, len);        /* TX-only (rx scartato)              */
ca_spi_dma_read(num, buf, len);         /* RX-only (tx dummy 0xFF)            */
```

Under the hood, the DMA framework bricks are used (`ca_dma_set_request()` with REQSEL/CHSEL checked against reference manuals, `ca_dma_copy_target()`, `ca_dma_wait()`).

87.1.5 Behavior

Nothing happens by itself. At boot, the card is idle; `e64 start` performs **a** pass through the sizes 1, 2, 16, 64, 128, 255 and 256 bytes, with pseudo-random payload (xorshift32), checks `rx == tx` bytes one by one and concludes with a verdict:

```
RUN RESULT : OK   (1/1)       every transfer came back identical
RUN RESULT : FAIL   (0/1)     almeno uno no
```

then it stops. Before it used to cycle from boot printing one line per transfer: there was no moment of silence to read the response of another command (the verdict of `wire`, on H563, did not appear at all) and no notion of "successful cycle", only counters always in motion.

Commands on the UART console:

```
e64 start        one round over all sizes, ends with RUN RESULT
e64 wire         MOSI-MISO jumper continuity on plain GPIO (no SPI, no DMA)
e64 info         trasferimenti OK/ERR + ultima taglia e byte errati
e64 regs         SPI registers (CR1/CR2/CFG1/CFG2/SR) and the two DMA channels'
e64 buf          first 16 bytes of tx and rx of the last transfer
```

`wire` drives MOSI as output and reads MISO with pull-down: a FAIL there means missing wire or wrong pins, not an SPI or DMA problem. It must be run first, with the board at rest.

`regs` and `buf` are diagnostic tools: the first shows whether the peripheral is really in master mode and if the channels have consumed the bytes (`BNDT`), the second distinguishes at a glance a wiring problem (constant `rx`) from a frame problem (`rx` misaligned with respect to `tx`).

87.1.6 DMA Portability by Family

Family	Notes
F1xx	fixed DMA mapping per channel (request ignored); SPI1/2, shared channels with USART
F4xx	SPI v1, CHSEL for stream (RM0090 tab.43/44)
F7xx	SPI v2 FIFO, 8-bit DMA on `&DR` with FRXTH=1 (RM0385)
H7xx	SPI v3 TSIZE/EOT, DMAMUX1; buffers in AXI-SRAM (`.bss`, no DTCM)

Family	Notes
H5xx/U5xx	SPI v3 TSIZE/EOT, GPDMA REQSEL (spi{1,2,3}_rx/tx_dma)

Note on H7 buffers: DMA1/DMA2 channels do not reach DTCM. On H753/H747, `.bss` is mapped in AXI-SRAM (0x24000000), reachable by DMA — thus, the static buffers in the example are valid without dedicated sections.

87.1.7 SPI v3 Erratum — CRCSIZE (H5/H7/U5)

On families with SPI v3, the last byte received in DMA can return **corrupted** even with CRC disabled. This is erratum **ES0499 §2.23.1** (STM32U575/585, with similar behavior on H5/H7): with `CRCEN=0`, `TSIZE > 0` and the `CRCSIZE < 7` field, the data of the last frame in RxFIFO is invalid. The reset value of `CRCSIZE` is 0, so this condition occurs by default.

The symptom observed on U575 was exactly one wrong byte **at the end of the transfer**, with a deterministic pattern `rx = tx & 0x03` (only the two lowest bits arrived). The fix, applied in the SPI init (master and slave) for the three v3 families, forces `CRCSIZE = 7` in `CFG1`. The DMA path does not rewrite `CFG1` from scratch, so the init setting is sufficient.

On H563/H753 the defect had not manifested: it is timing-dependent (PCLK/SCK ratio) and those clock pairs masked it. The fix `CRCSIZE = 7` covers them anyway.

87.1.8 Test Status (Hardware)

Board	SPI IP	Outcome
NUCLEO-U575ZI-Q	v3	all sizes (after CRCSIZE fix)
NUCLEO-H563ZI	v3	
NUCLEO-H753ZI	v3	
STM32F4VE (F407)	v1	(on first try)
NUCLEO-F746ZG	v2	not tested (hardware not available)

Chapter 88

SPI DMA: Master + Slave IRQ on Two Boards

88.1 Example 65 — SPI DMA master (with the slave from example 93)

Extends example 64 to the real case of **two boards**: this one acts as **DMA master**, the other as **IRQ slave** with example 93. The goal is to verify **interoperability** between the two paths on different silicon, under a continuous flow of data.

88.1.1 Connections: same position on both boards

With the default SPI1 mapping, every Nucleo-144 board has the three lines on the same **Arduino pins of CN7**, so the wires go straight from one board to the other:

Signal	Position (on both boards)	MCU Pin
SCK	**CN7-10** (D13)	PA5
MISO	**CN7-12** (D12)	PA6
MOSI	**CN7-14** (D11)	PA7, **PB5 on H7** (PA7 is Ethernet)
CS	**CN7-16** (D10)	PD14, on all (including H563)
GND	**CN7-8**	—

Exception: boards with **Ethernet on PA7** — **H563** (UM3115), **F767** and **F746** (UM1974 note 2: PA7 is D11 and, with JP6 closed, also `RMII_DV` of the PHY) — use the alternative mapping PB3/PB4/PB5, which arrives at the morpho in the same positions on both board families: **CN12-31/27/29**, GND **CN12-9**. The F446 (same board MB1137, without Ethernet) stays on CN7. CS remains on CN7-16 (PD14) even on the H563. `s65 wire` and `s93 wire` print this table, with the pins of the board they run on, before the measurements.

88.1.2 Hardware — reference pair H563 + H753

The reference configuration is **NUCLEO-H563ZI (master)** + **NUCLEO-H753ZI (slave)**, connected with 3 wires plus ground.

> **The wires do not connect matching pins.** The two boards use different mappings: the H563 has Ethernet on the default SPI1 pins and adopts the alternative mapping (`alternate_gpio = true` → PB3/PB4/PB5), while the H753 uses the default driver mapping for h7xx (PA5/PA6/PB5). Only MOSI happens to fall on the same pin by chance.

Signal	H563 — master	H753 — slave
SCK	PB3 → **CN12-31**	**CN12-11** ← PA5
MISO	PB4 → **CN12-27**	**CN12-13** ← PA6
MOSI	PB5 → **CN12-29**	**CN12-29** ← PB5
GND	**CN12-9**	**CN12-9**

All on the **morpho CN12** connector of both boards. Do not use the Arduino connectors: different pins are disconnected by open solder bridges from the factory, and the symptom (data constantly at `FF`) is indistinguishable from a driver fault — see the note in example 64. NSS software (`SSM=1` on both): the slave peripheral is always active. From 10/13, however, there is a **CS wire** (D10, PD14, CN7-16): the master pulls it low around every frame, and the slave, with an EXTI interrupt on the falling edge, calls `ca_spi_slave_sync()` at the beginning of every frame. Without it, a slave started while the master was transmitting would remain out of sync, or on SPI v3 (H5/H7/U5) blocked by an overrun never cleared: tested on H753, 0 frames received. CPOL=0/CPHA=0 (SPI mode 0) on both boards.

The role is the example flashed: **ex65** on the master board, **ex93** on the slave, on any pair of MCUs. It is advisable to put the slave on the faster board, because it receives **one byte per interrupt** and is the side that saturates first when the speed is increased.

88.1.3 Hardware — alternative pair U575 + F407

If you don't have the H563/H753 pair, the example has also been validated on **NUCLEO-U575ZI-Q (master) + STM32F4VE / F407 (slave)**. Here **neither** of the two boards has Ethernet which occupies PA5/PA6/PA7, so both use the **default** mapping (`alternate_gpio = false`) and — unlike the reference pair — **the pins are identical**.

Signal	U575 — master (Zio CN7)	F407 — slave
SCK	PA5 → **CN7-10** (D13)	PA5
MISO	PA6 → **CN7-12** (D12)	PA6
MOSI	PA7 → **CN7-14** (D11)	PA7
GND	GND	GND

All three wires plus ground are needed: from 10/13 the master **verifies the MISO** (see below), so without that wire every frame results in `miso=BAD`.

88.1.4 Why two examples (master 65, slave 93)

Until 10/13/2026, master and slave were a single example, with the role deduced from `MCU_ID` . However, the two roles require **mutually exclusive** configuration flags (`EN_SPI_DMA` for the master, `EN_SPI` for the slave, with `#error` if both are set), and one example has **a single** config: one of the two boards would always be compiled with the wrong flag and remain silent. For this reason, the example was split into two:

Role | Example | Config |
|———|– ——|———| | Master | **ex65** | `EN_SPI_DMA 1`, `EN_DMA 1` | | Slave | **ex93** | `EN_SPI 1` |

The role is now **which example is flashed**, on any pair of boards, and the configuration is no longer changed from one build to the next.

88.1.5 Flow

- **Master** — every 500 ms it composes a frame of `EX65_FRAME` (64) bytes: `byte[0]` = progressive counter, `byte[1..]` = pattern `(i + seq)`. It sends it with `ca_spi_dma_xfer()` (blocking until

TC) and **checks the MISO**: the example slave 93 responds to every byte with `0x5A` (`slave_tx_fill` of `ca_spi_config_t`), so every received byte must be `0x5A`. A disconnected MISO wire reads `0x00` or `0xFF` constant. The periodic line says `miso=ok|BAD`, and `s65 info` counts good and bad frames with the first wrong byte of the last bad frame.

- **Slave** (example 93) — receives the bytes in ISR (`ca_spi_recv_handler`, wired in the handlers of each family). When the frame is complete, the callback `slave_cb` verifies the pattern against `seq` and updates the counters. The callback **does not print**: it runs in interrupt context and `ca_stdout_printf_n()` enqueues with `ca_queue_static_send()` at timeout 0, which is *blocking* and does not drop — calling it from ISR means potentially blocking the interrupt when the queue is full, exactly under the fast flow that this example wants to measure. The prints are done by a dedicated task that observes the counters.

`s65 wire 0|1` (master) and `s93 wire 0|1` (slave) check the wires at static levels. A single board cannot judge a wire, because a pin is driven **or** read: the master drives SCK, MOSI and CS at the given level and reads MISO, the slave drives MISO and reads SCK, MOSI and CS, all inputs with pull-down. A level is set on one board and read on the other, then the inverse:

```
master: s65 wire 1      -> WIRE M: drive SCK=MOSI=CS=1  read MISO=..
slave : s93 wire 0      -> WIRE S: drive MISO=0  read SCK=1 MOSI=1 CS=1
master: s65 wire 1      -> ... read MISO=0
(then the same with the levels swapped: SCK=MOSI=0 on the slave, MISO=1 on the
    master)
```

A detached wire always reads 0 (pull-down): the 1 reading discovers it, while the 0 reading discovers a high-blocked line. `s65 wire end` / `s93 wire end` reboot the board and return the pins to SPI. Without argument, `wire` prints the link table. The bank (`test_homo_ex65`) executes the sequence by itself on the two consoles.

Each board has its own console: `s65 info` on the master (frames sent, MISO good/bad), `s93 info` and `s93 buf` on the slave (frames, errors, last `seq`, length, `gap`, first 16 bytes).

88.1.6 Speed: why the default is DIV256

The default is deliberately **cautious**:

```
#define EX65_BR      CA_SPI_BR_DIV256  /* ~625 kHz con PCLK ~160 MHz */
#define EX65_PERIOD  500U              /* ms between one frame and the next */
```

The **slave is the bottleneck**: it receives one byte per interrupt and must read `SPI->DR` before the next one arrives. If the master clocks too fast, the unread byte gets overwritten → **overrun (OVR)** → byte lost. With the U575/F407 pair at `DIV64` (~2.5 MHz, one byte every ~3 µs) the slave was losing about **one byte every 2–3**: `s93 buf` showed the ramp of the pattern `(i+seq)` with jumps (`4E 51 52 54 55` instead of `4E 4F 50 51`), all frames were `err` and the count was off. At `DIV256` (~625 kHz, one byte every ~13 µs) the ISR had plenty of margin: **`err=0, gap=1` stable**.

The `s93 buf` command on the slave is the tool that distinguishes the two failure modes:

- **ramp with jumps** (missing bytes) → **OVR**: the slave cannot keep up with the rate, reduce the baud (or lighten the ISR / switch the slave to DMA).
- **clean but shifted ramp** (correct pattern, shifted by k) → **frame shift**: the slave has locked onto the middle of a frame. Without a CS line to delimit frames, misalignment, once introduced, is permanent.

For high-speed testing, we proceed in steps — `DIV128`, `DIV64`, ... — monitoring `s93 info`/`s93 buf` on the slave. Two indicators:

- `err` increasing → corrupted bytes or (more often here) lost due to OVR.

- `gap` different from 1 → **lost** entire frames.

It is exactly the rate limit of the architecture with one byte per ISR that this example is meant to find.

88.1.7 Why master DMA + slave IRQ

The master knows the frame length in advance → **synchronous DMA** ideal (zero CPU load during transfer). The slave does not know when bytes will arrive → **IRQ per byte** reception with accumulation up to `frame_size` is the natural choice, reusing the already validated slave path (example 29). Any potential slave DMA would require circular RX and framing management on the receiver side, outside the scope of this example.

88.1.8 Notes per family

Family	Notes
F1xx	slave only SPI1/2 (no SPI3); master DMA with fixed channel mapping
F4xx/F7xx	CHSEL/FIFO as in example 64
H7xx	master buffer in AXI-SRAM (`.bss`, no DTCM)
H5xx/U5xx	GPDMA REQSEL

With a different pair than the reference one, **derive the pins from both sides** before wiring: they depend on whether the board uses `alternate_gpio` or not, and on Nucleo-144 boards with Ethernet mounted, the default SPI1 pins are not available.

88.1.9 Test status (hardware)

Pair	Master	Slave	Outcome
Alternative	U575 (v3 DMA)	F407 (v1 IRQ)	at DIV256: `err=0`, `gap=1` stable
Reference	H563 (v3 DMA)	H753 (v3 IRQ)	not tested (hardware not available)

The interoperability **master v3 (U575) slave v1 (F407)** confirms that the two paths are independent of the IP: the master generates the clock and frames, the slave samples them, and the verification protocol works regardless of the silicon generation. From 10/13/2026 the pair is tested also at the bench: `test_homo_ex65` runs on the master board and reads the slave's console (ex93, manually prepared) from a second port, `CAOS_TTY65S`. See example 93.

Chapter 89

Crypto Self-Test: SHA-256, SHA-512, X25519, Ed25519

89.1 Example 66 — Cryptographic self-test (SHA-512, X25519, Ed25519, P-256)

89.1.1 Purpose

Validate the cryptographic primitives that form the basis of the SSH server stack and the TLS 1.3 (HTTPS) server, each against the official vectors of its own standard.

Primitive	Standard	Test	Role in the SSH stack
SHA-256	NIST FIPS 180-4	6	Session KDF + fingerprint (SW fallback where IP is missing)
SHA-512	NIST FIPS 180-4	6	Ed25519 prerequisite
X25519	RFC 7748	8	key exchange `curve25519-sha256`
Ed25519	RFC 8032	8	host key + user authentication
HMAC / HKDF / PBKDF2 (SHA-256)	RFC 4231 / 5869 / 7914	7	key derivation from password (`kdf.c`, app_3 encrypted link)
ECDSA P-256 (SHA-256)	RFC 6979 A.2.5	10	TLS 1.3 (HTTPS) server certificate signature

The Edwards/Montgomery curves and SHA-512 do not have an accelerator on these families and therefore run in software. SHA-256 has the HASH IP on H5/H7 but not on F1/F4/F7: the software version validated here is the **fallback** that makes SSH/KDF portable even where the accelerator is missing (see ex26 for HW/SW dispatch). The self-test runs on the software path, which is the same across all families.

Validation is not a formality: an incorrect primitive still produces output that looks random, and the error would only emerge much further downstream as a handshake that fails without explanation.

89.1.2 Configuration

```
/* os_config.h */
#define EN_SHA256_TEST   1   /* opzionale: valida il SHA-256 software */
#define EN_SHA512        1
#define EN_SHA512_TEST   1
```

```
#define EN_X25519         1
#define EN_X25519_TEST    1
#define EN_ED25519        1   /* richiede EN_X25519 + EN_SHA512 */
#define EN_ED25519_TEST   1
#define EN_ECDSA_P256       1   /* richiede EN_SHA256 */
#define EN_ECDSA_P256_TEST  1
#define EN_CLI_ECDSA_P256   1   /* comando 'p256' */
```

The task is compiled if at least one of `EN_SHA512_TEST`, `EN_X25519_TEST`, or `EN_ED25519_TEST` is active; `EN_SHA256_TEST` adds the SHA-256 battery to the beginning of the sequence.

No specific hardware, except for `ed25519 keygen` and the `keygen + sign + verify` di P-256, che usano il RNG. L'esempio chiama `ca_rng_init()` test in `ca_os_main()`: until 10/23/2026 it did not do so, and `ed25519 keygen` always responded "RNG not available".

89.1.3 Behavior

At startup, the task executes the three batteries in sequence and prints the overall result with the time taken.

```
=== Example 66: crypto self-test ===
SHA-512 (FIPS 180-4), X25519 (RFC 7748), Ed25519 (RFC 8032)

sha256: NIST FIPS 180-4 known-answer tests
  empty                         PASS
  abc                           PASS
  two-block (56B)               PASS
  1M x 'a'                      PASS
  incremental == one-shot       PASS
  padding boundary 55..65       PASS
sha256: ALL PASS (6/6)

sha512: NIST FIPS 180-4 known-answer tests
  empty                         PASS
  abc                           PASS
  two-block (112B)              PASS
  1M x 'a'                      PASS
  incremental == one-shot       PASS
  padding boundary 111..129     PASS
sha512: ALL PASS (6/6)

x25519: RFC 7748 test vectors
  RFC7748 5.2 #1                PASS
  RFC7748 5.2 #2                PASS
  6.1 alice public              PASS
  6.1 bob public                PASS
  6.1 shared secret             PASS
  shared agreement              PASS
  100 iterations stable         PASS
  small-order rejected          PASS
x25519: ALL PASS (8/8)

ed25519: RFC 8032 test vectors
  RFC8032 TEST1 (0 byte)        PASS
  RFC8032 TEST2 (1 byte)        PASS
  RFC8032 TEST3 (2 byte)        PASS
  tampered signature            PASS
  tampered message              PASS
  wrong public key              PASS
  non-canonical S               PASS
  200B sign+verify              PASS
ed25519: ALL PASS (8/8)

p256: RFC 6979 A.2.5 test vectors
```

```
  public from private          PASS
  RFC6979 "sample"             PASS
  RFC6979 "test"               PASS
  tampered signature           PASS
  tampered message             PASS
  public key off the curve     PASS
  r = 0                        PASS
  s >= n                       PASS
  private key 0 rejected       PASS
  keygen + sign + verify       PASS
p256: sign 43 ms, verify 36 ms
p256: ALL PASS (10/10)

ex66: durata totale 2870 ms
ex66: primitive validate - pronte per SSH
```

Actual measurement **on NUCLEO-U575ZI-Q (Cortex-M33 @ 160 MHz)**: 2870 ms for the SHA-512, X25519, and Ed25519 batteries (the SHA-256 battery, added at the beginning, only adds its 1 MB test, in the order of ~1 s). About 1360 ms are from SHA-512 (dominated by the 1 MB test); the remaining ~1500 ms cover the curve operations of X25519 and Ed25519, which equate to ~**30-50 ms per scalar multiplication**. A complete SSH handshake (one X25519 plus one Ed25519 signature) is therefore around **100 ms** on this board, paid once at login.

This data is valid **only for U575**. Other families have different cores and clocks and must be measured separately: H753 (M7 @ 480 MHz, with I/D cache) will be significantly faster, F407 (M4 @ 168 MHz) slower. The code is pure 32-bit calculation without accelerators, so it essentially scales with the core's clock and IPC.

89.1.4 CLI

Command	Effect
`sha256 test`	re-runs NIST vectors (if `EN_SHA256_TEST`)
`sha256 kdf [N]`	HMAC/HKDF/PBKDF2 vectors (RFC 4231, 5869, 7914) and time for a PBKDF2 with N iterations (default 10000)
`sha512 test`	re-runs NIST vectors
`x25519 test`	re-runs RFC 7748 vectors
`ed25519 test`	re-runs RFC 8032 vectors
`ed25519 keygen`	generates a pair from the RNG, prints **only** the public key
`p256 test`	re-runs RFC 6979 vectors and prints the ms for signing and verification
`p256 keygen`	generates a P-256 pair from the RNG, prints **only** the public key (`04 XY `)

`sha256 kdf` measures how much a password costs on the MCU: on H753 (480 MHz) 10000 iterations = 227 ms, 100000 = 2.25 s (about 22 us each), keys equal to Python's `hashlib.pbkdf2_hmac`. The number of iterations for an app is chosen from here: every attempt by an attacker costs the same amount of time.

`ed25519 keygen` fails cleanly if the RNG is not available (F1xx, lacking the peripheral) instead of producing weak keys. The seed is never printed.

89.1.5 The tests that matter

Many tests are chosen because they expose errors that canonical vectors let pass:

- **SHA-512** `1M x 'a'` — multi-block path and 128-bit counter.
- **SHA-512 padding 111..129** — the boundary where an extra block is needed.
- **X25519** `small-order rejected` — a peer can send a small-order point to force a null shared secret; `ca_x25519()` returns `false` and the handshake must abort.
- **Ed25519** `non-canonical S` — with `S >= L` from a valid signature, others just as valid can be derived for the same message (malleability). Verification rejects them.
- **P-256** `public key off the curve` — a public key that is not on the curve must be rejected before any calculation; otherwise, an attacker can choose a point on a weak curve.
- **P-256** `RFC6979 "sample" / "test"` — compare the deterministic signature byte by byte: they test both the curve arithmetic and the nonce generation together.

89.1.6 Note on constant time

X25519 and Ed25519 operate on secret material, so execution times must not depend on the data:

- the Montgomery ladder performs **255 fixed iterations**, without branching on the scalar bit; swaps use arithmetic masks (`fe25519_cswap`) and not `if`;
- Ed25519 scalar multiplication *always* calculates the sum and adopts it with `fe25519_cmov`, without tables indexed by the secret (no observable cache patterns);
- the final signature comparison has no early-exit.

It is slower than a wNAF with a precomputed table, but it does not expose timing patterns.

89.1.7 An instructive bug: `fe25519_sq2`

During development, Ed25519 failed **all** RFC 8032 vectors while X25519 passed them all. The cause was in `fe25519_sq2` (shared):

```
fe25519_sq(h, f);
for (i = 0; i < 10; i++) h->v[i] += h->v[i];   /* limbs fuori range */
```

`fe25519_sq` leaves the limbs close to the 25/26-bit representation limit; doubling them without propagating the carries pushes them over, and `ge_p2_dbl` adds to them. X25519 did not expose this because the Montgomery ladder does not use `sq2` on the same path.

The decisive diagnostic symptom: **the same point, when doubled, gave different results depending on the projective representation** — which is impossible for a correct doubling, given that the Z coordinate is arbitrary. Fortunately, the values remained below the threshold up to bit 91 of the scalar; from bit 92 onwards, they did not.

Fix: carry propagation after doubling the limbs.

89.1.8 API

```
/* Key exchange */
u8 priv[32], pub[32], shared[32];
ca_rng_fill(priv, 32);
ca_x25519_base(pub, priv);
if (!ca_x25519(shared, priv, peer_pub)) { /* punto degenere: abortire */ }

/* Firma */
u8 seed[32], pk[32], sig[64];
ca_ed25519_keygen(pk, seed);
ca_ed25519_sign(sig, msg, len, seed, pk);
bool ok = ca_ed25519_verify(sig, msg, len, pk);
```

89.1.9 Implementation notes

- **Stack**: SHA-512 compression uses `W[80]` of `u64` = 640 bytes per block; curve operations use various `fe25519` (40 bytes each). The task uses `STACK_LARGE`.
- Secret material on the stack (clamped scalars, nonces, hash contexts) is zeroed out upon function exit.

89.1.10 P-256: MCU timings (10/23/2026)

MCU	Sign	Verify
H753	17 ms	13 ms
F767	36 ms	29 ms
H563	43 ms	36–41 ms
U575	67 ms	132 ms
F446	70 ms	140 ms

The test suite passes 10/10 on the 5 Nucleo boards (bench class `test_ex66`). Before writing it to the MCU, the implementation was tested on PC against the Python `cryptography` library (72/72, including 20 random keys). Details in the cryptography chapter.

89.1.11 Next step

These primitives are the building blocks of the **SSH server stack** (Example 67): X25519 for key exchange `curve25519-sha256`, Ed25519 for host keys and user authentication, SHA-256/SHA-512 for KDF and signatures. Once validated here against the official vectors, the complete stack — transport + AES-256-GCM record + userauth + channel/interactive shell — was finalized and HW-tested on U575, H563, and H753 (see Example 67). ECDSA P-256 is instead used for the HTTPS server (Examples 45 and 80).

Chapter 90

SSH Server: Transport, Ed25519 Userauth and Shell

90.1 Example 67 — SSH Server: transport, userauth Ed25519 and interactive shell

90.1.1 Introduction

This example brings a **complete SSH server** on top of the caOS stack: from the PC one connects with the standard `ssh` client, authenticates with an Ed25519 key, and gets an **interactive shell** which is the caOS CLI. It is the endpoint of the crypto journey that started with Example 66 (SHA/X25519/Ed25519 primitives validated against official vectors) and Example 26 (AES-256-GCM HW/SW).

The transport is **wired Ethernet** (RMII PHY): the board connects to the network with a cable and responds to the static IP `192.168.10.67`. The net core — ARP, ICMP, TCP — receives frames from the integrated MAC through a `ca_net_iface_t`, the same abstraction that decouples the stack from the physical medium.

> Therefore, the example requires a board with **ETH MAC and PHY**: it runs on H753 and H563, **not** on U575 nor F4VE (`MCU_HAS_ETH 0` in `objmap.h`). On boards not listed in the source, the file forces `EN_ETH 0` and the example compiles empty. This is a change from early versions, which used USB-NCM to run everywhere.

The three negotiated algorithm suites are one per category (the server offers **only** these):

Category	Algorithm	Standard	caOS Primitive
Key exchange	`curve25519-sha256`	RFC 8731	X25519 + SHA-256
Host key / signature	`ssh-ed25519`	RFC 8709	Ed25519
Cipher (record)	`aes256-gcm@openssh.com`	RFC 5647	AES-256-GCM

The sequence is the canonical SSH-2: **transport** (version exchange → KEXINIT → KEX X25519 → NEWKEYS), then the **GCM record layer**, then **userauth** publickey Ed25519, and finally the **connection layer** (session channel + shell). From NEWKEYS onward, every packet is encrypted and authenticated.

90.1.2 Hardware and families

The example adapts to the board via `MCU_ID`: LED heartbeat GPIO, RMII pins, and SSH task stack size. **An ETH MAC with PHY is required**: this is the requirement that distinguishes usable boards.

MCU	Board	ETH MAC	Heartbeat	Crypto	HW Status on ETH
H753	NUCLEO-H753ZI		PB7 (LD2)	AES **HW CRYP**	end-to-end (19/08)
H563	NUCLEO-H563ZI		PB0 (LD1)	AES **software**	branch ready (RMII_TXD1 PB15, JP6 ON), not retested after switching to ETH
U575	NUCLEO-U575ZI-Q		PC7 (LD1)	AES **software**	not executable: the part lacks ETH MAC
F407	STM32F4VE	(on the part)	PA6 (D2)	AES software	board lacks wired RMII PHY

U575 and F407 no longer run this example. While the transport was USB-NCM, both ran end-to-end; with wired ETH, U575 is excluded from the part (`MCU_HAS_ETH 0`) and F4VE lacks the PHY. Their `MCU_ID` branches remain in the source because they are needed for the equivalent NCM example. **AES hardware or software:** the AES driver chooses the path based on the device (see Example 26). On H753 it uses **CRYP hardware**; on the others, AES-256 software. The SSH record is identical on both paths. The bring-up on H753 required four fixes to the CRYP driver — see *Lesson* at the bottom.

The SSH task stack is `STACK_LARGE`, except on F4xx where extra headroom is needed (`STACK_XLARGE + STACK_MEDIUM`).

90.1.3 Handshake flow

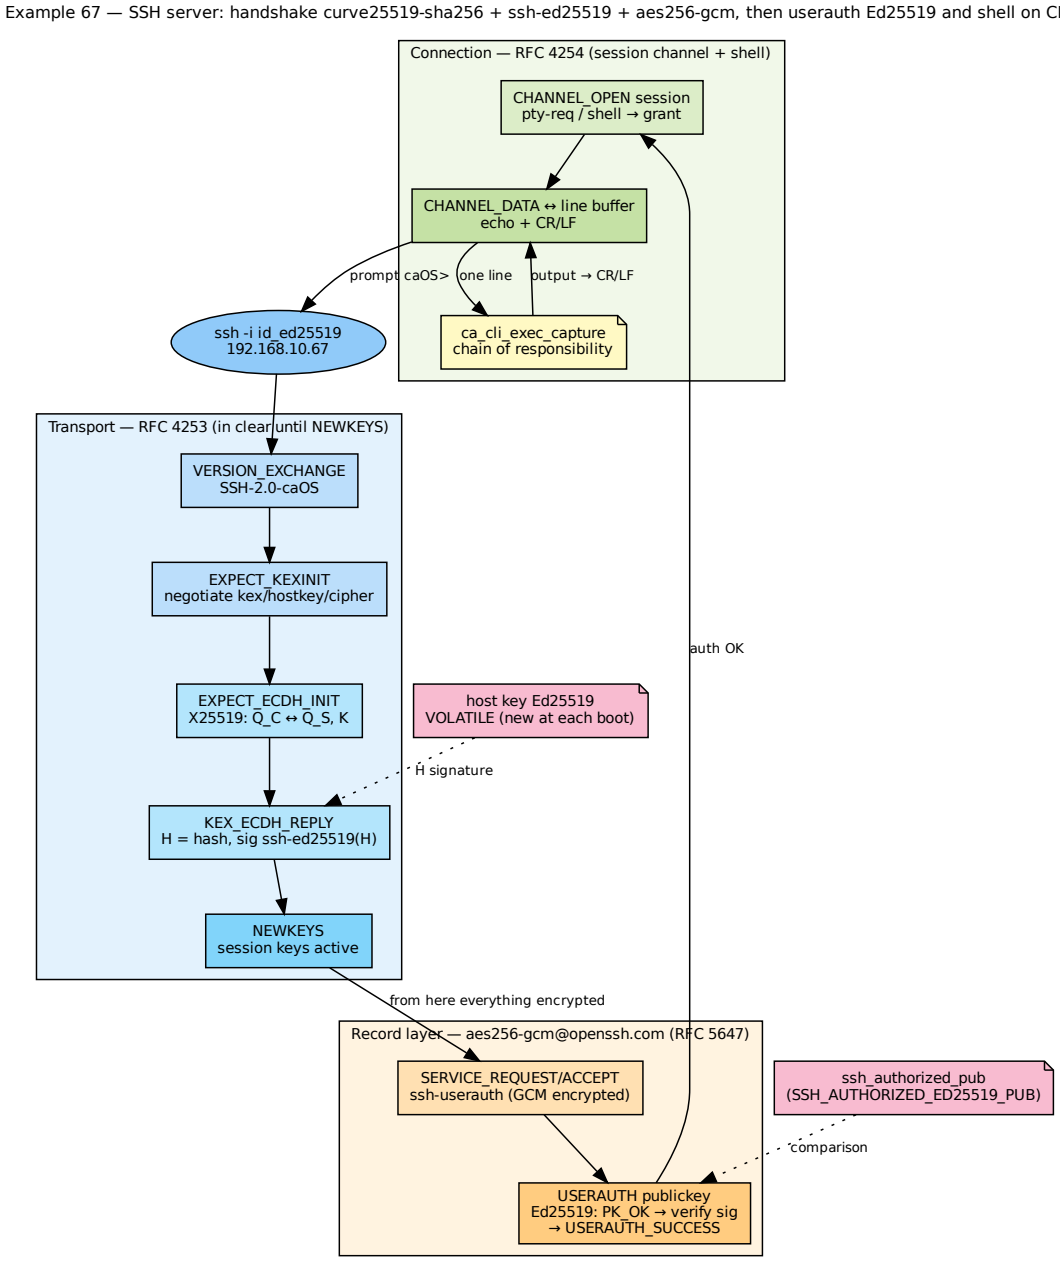

Figure 90.1: Example 67 — SSH handshake and shell

The transport FSM (`ssh_state_t`) goes through these states:

State	What happens
`VERSION_EXCHANGE`	exchange of `SSH-2.0-...` strings
`EXPECT_KEXINIT`	negotiation: kex, host key, cipher (one per category)

State	What happens
`EXPECT_ECDH_INIT`	X25519: the server receives `Q_C`, computes `Q_S` and the secret `K`
`KEX_REPLY_SENT`	sends `KEX_ECDH_REPLY` { host key, `Q_S`, signature of `H` }, then `NEWKEYS`
`NEWKEYS`	session keys derived, GCM record layer active
`ESTABLISHED`	transport ready; from here userauth and connection

After `ESTABLISHED` (all encrypted in GCM):

1. **SERVICE_REQUEST/ACCEPT** — the client requests `ssh-userauth`.
2. **Userauth publickey Ed25519** (RFC 4252 §7): OpenSSH first probes the key without signature (the server responds `USERAUTH_PK_OK`), then resends the signed request. The server reconstructs the signed blob (session id `H` + fields of the request) and verifies the signature with `ca_ed25519_verify` against the authorized key. Only `publickey` + `ssh-ed25519` are accepted; password is not.
3. **Connection** (RFC 4254): `CHANNEL_OPEN` of type `session`, grants `pty-req` and `shell`. The channel is then a bidirectional bridge to the CLI.

The single remote command (`exec`) is **not** supported: it is rejected, the shell is only interactive.

90.1.4 The shell: channel CLI

Once the `shell` is granted, the bytes of `CHANNEL_DATA` feed a line buffer with key echo and backspace (DEL/BS) handling; on CR/LF the complete line is passed to `ca_cli_exec_capture_stream`, which executes the command and forwards its output **to stream**, calling a callback `sender` as the command prints. The output is then re-emitted with `\n` → `\r\n` translation because the client terminal is in raw mode.

> The *streaming* variant was born from a real bug (08/17): the shell used `ca_cli_exec_capture`, which accumulates in a **fixed buffer of 1024 bytes**, and long-output commands — `config`, `top` — arrived **truncated** at the client. Without an intermediate buffer there is no ceiling on the response length. `ca_cli_exec_capture` remains available for those who want output in memory (used by Example 45).

```
caOS SSH shell     type 'help'
caOS> help
...
caOS>
```

> The remote shell requires `EN_CLI_CAPTURE=1`: it is the mechanism by which `ca_cli_exec_capture` intercepts the CLI output. Without it, the shell opens but no command produces output (a `#warning` reports this at compile time).

90.1.5 Keys: volatile host key and authorized key

Two distinct Ed25519 keys, not to be confused:

- **Host key** of the server: generated **at first init, new at every boot** (`hostkey_ready`, static volatile struct). It is not in the key-store, it is not persistent. It signs the `H` hash exchange during KEX.
- **Authorized user key** (`ssh_authorized_pub`): the **public** key of the allowed client, compiled from `SSH_AUTHORIZED_ED25519_PUB` into `os_config.h`. Authentication succeeds only if the offered public key matches this one.

  Since the host key changes at every reboot, the client will see a **warning known_hosts** ("host key changed") at every board restart. This is expected: use the `-o UserKnownHostsFile =/dev/null -o StrictHostKeyChecking=no` options to avoid polluting `~/.ssh/known_hosts`.

90.1.6 Required configuration in `os_config.h`

```
#define EN_NET           1
#define EN_ETH           1   /* transport: Ethernet RMII */
#define EN_TCP_SERVICE   1
#define EN_SSH_SERVICE   1   /* server SSH */
#define EN_HASH          1   /* SHA-256 (KDF)     HW or SW fallback */
#define EN_CLI_CAPTURE   1   /* the remote shell captures the CLI output */

#define SSH_LISTEN_PORT 22U
#define EN_SSH_TRACE     0   /* per-state handshake trace: turned on by hand when
    needed */
#define EN_SSH_TEST      1   /* 'ssh test' command     BPP framing self-test */

/* Public key of the authorized client (32 raw bytes) */
#define SSH_AUTHORIZED_ED25519_PUB { \
    0x.., 0x.., ... /* 32 byte */ }
```

`ca_ssh_service_init()` requires a working hardware RNG: if the RNG fails, the service **refuses to start** in order not to generate weak keys. It also depends on `ca_hash_init`, `ca_keys_store_init` and `ca_rng_init`.

90.1.7 CLI

Command	Effect
`ssh test`	re-executes the binary packet protocol framing vectors (offline, `ca_ssh_bpp_selftest`)

The BPP self-test runs at startup before opening the port, as a sanity check of the RFC 4253 §6 framing.

90.1.8 Linking procedure

1. **Generate a client key pair** (once), and insert the public one in `SSH_AUTHORIZED_ED25519_PUB`:

```
ssh-keygen -t ed25519 -f caos_ed25519/id_ed25519 -N ''
```

2. **Connect the Ethernet cable** and configure the PC interface on the same subnet (replace `<eth-iface>` with the actual name, e.g. `enp3s0`):

```
sudo ip addr add 192.168.10.1/24 dev <eth-iface>
sudo ip link set <eth-iface> up
```

   The board uses **static IP** `192.168.10.67`, therefore there is no DHCP binding to confirm that the cable is properly connected: instead, the board reports the PHY link status with `ETH LINK UP` / `ETH LINK DOWN` on the console.

3. **Connect** (script `run_ssh_client.sh` in `examples/example_67/`):

```
ssh -o IdentitiesOnly=yes -v \
    -o UserKnownHostsFile=/dev/null -o StrictHostKeyChecking=no \
    -i caos_ed25519/id_ed25519 192.168.10.67 -p 22
```

   The flag `-v` shows the client-side handshake; on the board side, the trace `EN_SSH_TRACE` shows the same sequence from the server's point of view — it is **off** in the example's config and turns on when needed (`python3 tools/caos_config.py --on EN_SSH_TRACE 67`).

90.1.9 Expected output

At startup:

```
=== Example 67: SSH transport bring-up ===
curve25519-sha256 + ssh-ed25519 + aes256-gcm over Ethernet

=== EX67: SSH server su ETH ===
IP  192.168.10.67  port 22
Set the PC iface to 192.168.10.1/24, then: ssh -v 192.168.10.67
ETH LINK UP
```

Trace of a session (with `EN_SSH_TRACE=1`), from `NEWKEYS` onward:

```
svc: SERVICE_REQUEST ssh-userauth (GCM record verified)
svc: sent SERVICE_ACCEPT     awaiting USERAUTH
auth: PK_OK (probe accepted), awaiting signature
auth: publickey verified     USERAUTH_SUCCESS (user 4 bytes)
chan: shell granted     bridging CLI
```

90.1.10 Lesson: crypto HW always known-answer

The bring-up of SSH on H753 (AES **hardware** path via CRYP) required four fixes to the driver, invisible until the AES validation remained a simple round-trip encrypt→decrypt:

1. **GCM IV counter**: the driver loaded `ctx->iv[3]` instead of the fixed value `0x00000002` required by the initial block.
2. **Data endianness**: with `DATATYPE=0` the CRYP expects word big-endian, but AAD and payload were little-endian → `__REV` on DIN/DOUT (GCM, ECB, CTR).
3. **Missing `ca_aes_init()` in `ca_ssh_service_init`**: without it, `aes_hw_ready` remained `false`, the GCM path returned without encrypting, and the AES software masked the defect. It was **the** blocker.

4. **Backpressure TCP**: `ca_tcp_send` returning `false` on inflight-full/window-0 is **transient**; it closed the session on long output (e.g. `help`). Fix: retry in `ssh_send_packet_gcm` (atomic because the record is MSS).

A round-trip hides symmetric bugs (wrong byte order in both directions still returns correct). Hence the rule, also applied to Example 26 (`aes_nist`): **crypto hardware always validated with known-answer vectors, never with round-trip.**

> **F407 in Release (fixed 23/07/2026):** on STM32F4VE in Release `-O3` the shell would hang on command `help`. It was neither crypto nor CLI capture: it was the **stack of thread `SSH_SVC` too small** in `ssh_transport.c`, now sized via `SSH_STACK_TASK`. An instructive case of misleading symptom — the hang appeared only in Release because `-O3` changes stack usage, and pointed to crypto only because it was the new code.

90.1.11 Summary

1. **Full SSH-2 server** on Ethernet: transport, record GCM, userauth, shell.
2. **Algorithms**: `curve25519-sha256`, `ssh-ed25519`, `aes256-gcm@openssh.com` — one per category, offered exclusively.
3. **Authentication**: only Ed25519 publickey against `SSH_AUTHORIZED_ED25519_PUB`; no password.
4. **Host key volatile**: new on every boot → expected warning in known_hosts.
5. **Shell = CLI**: the channel is a bridge to `ca_cli_exec_capture_stream` (requires `EN_CLI_CAPTURE=1`), forwarding output to stream instead of accumulating in a fixed buffer; `exec` single not supported.
6. **Tested HW on ETH** end-to-end on H753; H563 has the branch ready but not retested after switching from NCM to ETH. U575 and F407 are no longer executable on this transport (no ETH MAC / no PHY).
7. **AES HW on H753**: four driver CRYP fixes, lesson from known-answer tests.

Chapter 91

Fault Test Bench: MPU, Bus, Usage and HardFault

91.1 Example 68 — Fault Test Bench: MPU, Bus, Usage and HardFault

91.1.1 Introduction

This example is the **fault handling system test bench** of caOS. It deliberately triggers, one at a time, **19 different hardware and software faults** of various categories and shows that in every case the RTOS **survives**: the faulty task is handled according to its recovery policy and the rest of the system continues to run.

It is the practical counterpart of Chapter 12 (*SafeGuard and Fault Recovery*): there the mechanisms are described (dedicated handlers for MemManage/BusFault/UsageFault, task-specific recovery, MPU stack guards, PSP range-checks, escalated declassified HardFault); here they are all exercised on real hardware.

The test bench console is intentionally **direct UART/CDC** (`ca_stdout_*`): in a fault context, the log queue and buffered channels (ITM, CDC with queues) may truncate output, whereas synchronous stdout printing always arrives.

91.1.2 Hardware and Families

The example adapts to the board via `MCU_ID`: end of RAM and Flash are family-specific (they are needed to produce deterministic *out-of-bounds* accesses), because memory cuts differ (F407: 128K/512K, U575: ~628K/2MB, ...). RAM base `0x20000000` and Flash base `0x08000000` on all these parts.

MCU	Core	Board	HW Status
F407	Cortex-M4	STM32F4VE / DISCOVERY	
H753	Cortex-M7	NUCLEO-H753ZI	
H563	Cortex-M33	NUCLEO-H563ZI	
U575	Cortex-M33	NUCLEO-U575ZI-Q	16/16
F746	Cortex-M7		
F103	Cortex-M3 (no FPU)		

Architectural note. Some faults do not manifest the same way on all cores:

- `null_r` / `null_w` (access to `0x0`): on M4/M7 with BOOT0=0 Flash is aliased to `0x0`, so reading **does not** fault and writing is *absorbed* by the Flash interface (FPEC locked) without bus error. On M33 (U5/H5) instead, access to `0x0` does generate a fault. This is not a kernel defect: it is the memory map of the part.

91.1.3 The 19 Cases, by Fault Category

The cases are grouped by the type of exception they trigger.

BusFault (data fetch or instruction fetch out of bounds)

Case	Trigger	Expected Fault
`null_r`	read `*(u32*)0`	BusFault (or none on M4/M7, see note)
`null_w`	write `*(u32*)0`	BusFault/MemManage (or absorbed on M4/M7)
`ram`	access beyond end of RAM	BusFault
`flash`	read beyond end of Flash	BusFault (PRECISERR)
`ibuserr`	fetch code beyond end of Flash	BusFault **IBUSERR**

MemManage (MPU violation)

Case	Trigger	Expected Fault
`ro`	writing to own stack canary (RO region)	MemManage **DACCVIOL**
`stack`	writing within 32B canary band below `stack_end`	MemManage **DACCVIOL**
`stackjmp`	writing *well below* `stack_end` (jumping over the 32B band)	MemManage **DACCVIOL**
`cross`	deliberate write **into the stack of another task**	MemManage **DACCVIOL**, with the victim's name
`xn`	execution from a data buffer **covered by an XN region**	MemManage **IACCVIOL** at first fetch
`runaway`	execution from a data buffer **without region**: the twin of `xn`	a fault **further ahead** from the buffer, not on it (see §"Divergences")

The case `stackjmp` exists because the single 32-byte canary band can be bypassed by a deep stack jump: the MPU guard has been extended below `stack_end` precisely to catch this too (see §12.3).

The case `cross`: the victim is not chosen at random `cross` verifies **cross-task diagnosis**: that the panic handler knows *whose* memory was hit, instead of attributing the write to the current task as a false "stack overflow". The task writes into the stack of another task and the dump must name the victim.

However, there is a non-obvious constraint that the code respects explicitly: the victim **cannot be chosen freely**. The MPU guard only covers the window under the `stack_end` of the current task — on ARMv7-M limited by alignment (see §12.3) — and a victim whose stack falls **outside** that window receives the write **silently**, without any fault. `task_cross` therefore scans

the task list and chooses a victim whose stack **intersects** the guarded window; if none exists, the case is declared *skipped* instead of faking an outcome.

> The constraint is not theoretical: on the first run on H753, the chosen victim was 6 KB lower, outside the 4 KB guard, and the silent corruption surfaced five cases later disguised as "`f_victim` stack overflow" — a completely misleading diagnosis. This is exactly the kind of mistake this case exists to make visible.

The dump distinguishes where the hit address falls relative to the victim. Below its `stack_end` one is in the **canary** of the victim and the offset is not printed (it would be an underflow); from `stack_end` onwards the offset `+N` inside its stack is printed:

```
>> CROSS-TASK WRITE into 'idle' CANARY (end=0x2001C020)
>> CROSS-TASK WRITE into 'idle' +512 (end=0x2001C020)
```

If instead no task owns that address, the dump falls back to the classic `STACK GUARD: overflow N bytes below stk_end` message — which is the correct diagnosis only in that case.

PSP range-check (software protection, not a CPU fault)

Case	Provocation	Outcome
`stackup`	caused by **another** task, corrupting upwards the saved PSP of the victim	the victim task is removed at the **PSP check on entry** during context switch

This is not a hardware exception: it is the range-check `stack_end psp stack_start` that the scheduler applies on the saved PSP *before re-arming it*. It catches a corruption that occurred at a distance, while the victim was not running — a case that the MPU guard (which triggers upon access) would not see.

UsageFault

Case	Provocation	Expected Fault
`div0`	division by zero (with `DIV_0_TRP` enabled)	UsageFault **DIVBYZERO**
`unalign`	`u32` access to odd address (with `UNALIGN_TRP` local)	UsageFault **UNALIGNED**
`undef`	undefined instruction (`UDF.W`)	UsageFault **UNDEFINSTR**
`invstate`	branch to non-Thumb address	UsageFault **INVSTATE**

`DIV_0_TRP` is enabled globally in `ca_bus_error_init`. `UNALIGN_TRP` instead **is not** global (it would break init and libraries doing legitimate unaligned accesses): case `unalign` enables it locally, causes the fault and relies on recovery to bring the system back to a clean state.

HardFault escalated → downgraded to per-task policy

Case	Provocation	Outcome
`forced`	disables `USGFAULTENA` and performs a `div0` → the UsageFault **escalates** to HardFault (HFSR.FORCED)	downgraded to the **same remove-policy** as the three dedicated handlers

This is the most significant case: it shows that even a *forced* HardFault (fault bank disabled, or fault-in-fault) generated by a task, with a valid PSP frame and PSP in range, does not halt the entire RTOS. The gate is conservative: a HardFault from kernel code (MSP), from vector table, or with invalid task still goes to **controlled reset** (`NVIC_SystemReset`, gated by `PANIC_REBOOT_ON_HARDFAULT`).

Restart of a task (only from CLI, outside the normal sequence)

All other cases use the `CA_FAULT_ASSERT` policy (removal). This is the only one that goes through **restart**: a task `CA_FAULT_RESTART_THREAD` performs a division by zero **only on first execution**, the kernel renews it with `ca_thread_renew()` (stack cleaned, stack guard rewritten and rearmed) and the task restarts.

Case	Provocation	Outcome
`restart`	`div0` on first execution of a task with RESTART policy	`Mode: RESTART`, then `restart: run 2` and `alive after restart, canary OK`: one single fault, kernel alive

Added on 10/04: on M33, rearming the guard during restart caused **IACCVIOL**. The fault that triggered it had been removed, but the path had never been tested, because no test case in the bank traversed it.

Kernel safeguard (only from CLI, outside the sequence)

These are not CPU faults: `CA_SAFEGUARD` is a kernel assertion. When it fails, `ca_safeguard_failed()` prints condition, file, line and task and raises `SVC_SAFEGUARD`, which removes the task. None of the 19 cases go through here.

Case	Provocation	Outcome
`safeguard`	`CA_SAFE_FAIL()` from a task, IRQ enabled	line `[SAFEGUARD]` with message, SVC served, `Mode: RECOVER`, kernel alive
`sg_irq`	`ca_mutex_unlock()` on a mutex no one owns	line `[SAFEGUARD]` on `sync.c`, then HardFault FORCED with `CFSR=0` → **reset**

`sg_irq` resets the board **and it is correct this way**: `sync.c` checks the owner after `ca_spinlock_lock_irq()`, so with PRIMASK=1 the `svc` cannot be served and escalates to an opaque HardFault (`CFSR=0`), which the gate rejects. What the case checks is the **order**: line `[SAFEGUARD]`, which names the

condition, must come out **before** the dump. Without it, the dump would only say `HFSR=FORCED, CFSR=0`. For this reason it is not in the automatic sequence.

Fault inside an ISR (only CLI, requires `EN_TIMER`)

All previous cases cause faults in **thread mode**, where there is a task to blame. `fault irq` arms TIM3 and divides by zero **in the update callback**, i.e. in handler mode with the frame on MSP: there is no guilty task.

Case	Provocation	Outcome
`irq`	division by zero in TIM3 callback	`[USAGE FAULT] DIVBYZERO, Faulted in handler mode` with `EXC_RETURN` bit 2 = 0, `No task to blame: system halted` → **board halted**, no task removed

The kernel must **stop**, not remove the interrupted task (innocent) and return to thread mode with the ISR still active: on M4/M7 it would end up in INVPC, on the M33 in a **mute** block (H563 ex87, 29/09). Measured on F446: `EXC_RETURN=0xFFFFFFF1`, and after the halt the board does not even respond to echo. Also `forced` stays harmless: the callback re-enables `USGFAULTENA`, which that case leaves off, otherwise the division would escalate to HardFault.

91.1.4 How it runs

The example has two modes, both active simultaneously.

Automatic sequence

At boot, the task `monitor` (low priority, with policy `CA_FAULT_RESTART_THREAD`) runs **all** 19 cases in ascending order of severity, one every 2 seconds:

```
=== Example 68: Fault sequence (auto start) ===

--- [1/16] fault: null_r ---
[EX68] provoking: read from NULL (0x0)
...
--- [12/16] fault: div0 ---
[EX68] provoking: divide by zero
=== USAGE FAULT ===
  DIVBYZERO: Divide by zero
CFSR: 0x02000000
Task: "f_div0" [n]
Mode: RECOVER (task removed)
...
=== Fault sequence complete     system still alive ===
EX68 alive  tick=
```

At the end, the monitor periodically prints `EX68 alive`, as proof that the scheduler continues to run after having absorbed 19 faults.

Interactive CLI command

From the console, a single case can be launched at will:

```
fault div0
fault stackjmp
fault forced
fault safeguard       kernel safeguard, task removed
fault restart         div0 once in a RESTART task: renewed, restarts
fault sg_irq          safeguard under PRIMASK: the board RESETS
fault irq             div0 inside the TIM3 ISR: the board HALTS
help                  list of the names
```

Every case is executed by a one-shot task with policy `CA_FAULT_ASSERT` (remove): a *deterministic* fault would cause fault on restart, so removal is the correct policy for the bank.

91.1.5 What the dump shows

The panic handler prints, for each fault:

- the **category** and **sub-type** decoded from the CFSR (e.g., `DIVBYZERO`, `IACCVIOL`, `IBUSERR`);
- the raw **HFSR** and **CFSR** registers and, for address faults, **MMFAR**/**BFAR**;
- the stacked **PC** and **LR** (faulting instruction address);
- the **name and index of the faulty task**;
- the **recovery mode** applied (`RECOVER (task removed)` / `RESTART`).

Historical correction. The UsageFault decoding in the dump used the mask `0xFF0000` (bits 16–23 only): `DIVBYZERO` (bit 25) and `UNALIGNED` (bit 24) were **never** decoded, and the strings for these were inverted. The correct mask is `0xFFFF0000`. The bug was latent in the `panic.c` path (dedicated handlers worked); bank ex68 brought it to light.

91.1.6 Actual output (STM32H753, Cortex-M7 @ 480 MHz)

Complete automatic sequence, significant excerpts (dump with task name printed only once). Each case ends with `Mode: RECOVER (task removed)` and the system arrives alive at the end.

```
=== Example 68: Fault sequence (auto start) ===

--- [3/16] fault: ram ---
[BUS FAULT]
  IMPRECISERR: async write buffer
  CFSR = 0x400
  Stacked PC = 0x08001E7A

--- [4/16] fault: flash ---
[BUS FAULT]
  PRECISERR @ 0x8200000
  CFSR = 0x8200   BFAR = 0x8200000
  Task: flash [4]
  Mode: RECOVER (task removed)

--- [5/16] fault: ibuserr ---
[BUS FAULT]
```

```
  IBUSERR: instruction fetch error
  CFSR = 0x100
  Stacked PC = 0x08200000   (fetch oltre fine Flash)
  Task: ibuserr [4]
  Mode: RECOVER (task removed)

--- [6/16] fault: ro ---   (identico a [7] stack)
[MPU FAULT]
  DACCVIOL: data access violation
  MMFAR = 0x20017000  (valid)   CFSR = 0x00000082
  stk_start=0x20018000 stk_end=0x20017020 psp=0x20017FBC
  >> HIT LOWER CANARY @ 0x20017000
  Task: ro [4]
  Mode: RECOVER (task removed)

--- [8/16] fault: stackjmp ---
[MPU FAULT]
  DACCVIOL: data access violation
  MMFAR = 0x20016F00  (valid)   CFSR = 0x00000082
  >> STACK GUARD: overflow 288 bytes below stk_end (jumped the band)
  Task: stackjmp [4]
  Mode: RECOVER (task removed)

--- [9/16] fault: cross ---
[EX68] provoking: write into ANOTHER task's stack (cross-task)
[EX68] writing into 'idle' stack @ 0x2001C220
[MPU FAULT]
  DACCVIOL: data access violation
  MMFAR = 0x2001C220  (valid)   CFSR = 0x00000082
  >> CROSS-TASK WRITE into 'idle' +512 (end=0x2001C020)
  Task: cross [4]
  Mode: RECOVER (task removed)

--- [11/16] fault: stackup ---
ERROR : Task[4] 'f_victim': stack overflow! 22057
  victim 'f_victim' psp forced to 0x20015040 (stack_start=0x20015000)
  (removed by the PSP range check on entry     not a CPU fault)

--- [12/16] fault: div0 ---
[USAGE FAULT]
  DIVBYZERO: divide by zero
  UFSR = 0x0200   CFSR = 0x02000000
  Task: div0 [4]
  Mode: RECOVER (task removed)

--- [13/16] fault: unalign ---
[USAGE FAULT]
  UNALIGNED: unaligned access
  UFSR = 0x0100   CFSR = 0x01000000
  Task: unalign [4]
  Mode: RECOVER (task removed)

--- [16/16] fault: forced ---
*** HARD FAULT ENTRY ***
=== HARD FAULT ===
  UsageFault: DIVBYZERO: Divide by zero
  Forced HardFault
  HFSR = 0x40000000   CFSR = 0x2000000
  Stacked PC = 0x8000680   LR = 0x80097BF
=== END HARD FAULT ===
  Task: forced [4]
  Mode: RECOVER (task removed)

```

```
=== Fault sequence complete     system still alive ===
```

Note the following in the actual output:

- `stackjmp` shows the extended guard in action: *"overflow 288 bytes below stk_end (jumped the band)"* — the write has overrun the 32 B canary band and the guard has nevertheless intercepted it.
- `cross` shows cross-task diagnosis: the dump **names the victim** (`CROSS-TASK WRITE into 'idle' +512`) instead of attributing the write to the running task, as it used to do by reporting a "never occurred" overflow.
- `stackup` does not produce a CPU fault but the *"stack overflow!"* message from the range-check: the PSP of the victim, forced above `stack_start`, is rejected at assembly during the context switch.
- `forced` goes through the actual HardFault handler (`*** HARD FAULT ENTRY ***`), prints its complete dump (`Forced HardFault`, `HFSR=0x40000000`) and **then** applies the remove-policy like dedicated faults: `Mode: RECOVER`.

91.1.7 Comparison: the same bank on STM32H563 (Cortex-M33 @ 250 MHz)

Some cases behave differently on M33 compared to M4/M7, because the **memory map** and MPU configuration change, not the kernel. Here are the excerpts where the difference is visible (the rest of the dump is identical to H753):

```
--- [1/16] fault: null_r ---
[BUS FAULT]
  PRECISERR @ 0x0
  CFSR = 0x8200
  BFAR = 0x0
  Task: null_r [4]
  Mode: RECOVER (task removed)

--- [3/16] fault: ram ---
[EX68] provoking: access beyond
       RAM end   (no fault)
```

```
--- [2/16] fault: null_w ---
[BUS FAULT]
  PRECISERR @ 0x0
  CFSR = 0x8200
  BFAR = 0x0
  Task: null_w [4]
  Mode: RECOVER (task removed)

--- [10/16] fault: xn ---
[BUS FAULT]
PRECISERR @ 0x17
    BFAR = 0x17
    Stacked PC = 0x20000070  (in the RAM buffer)
    Task: xn [4]
    Mode: RECOVER (task removed)
```

Differences M33 vs M4/M7:

Case	H753 (M4/M7)	H563 (M33)	Why
`null_r` / `null_w`	UsageFault **UNDEFINSTR**	BusFault **PRECISERR @ 0x0**	On M4/M7 `0x0` is Flash aliased → access does not fault and traps the `udf` which the compiler inserts on null-deref (UB); on M33 `0x0` is not readable → immediate BusFault.
`ram`	BusFault IMPRECISERR	**no fault**	The address *beyond RAM* chosen falls, on H563, into a region that does not generate BusFault; on H753 it does. To be refined `ADDR_BEYOND_RAM` for H5.
`runaway`	UsageFault UNDEFINSTR	BusFault **PRECISERR @ 0x17**	Neither of the two buffers was Execute-Never: the `blx` **executes data** and traps later, where it happens.

Fixed on 09/18, and the case has been split. The line above was not a M33/M7 divergence to be explained: it was the case that was not behaving as stated, on **both** cores.

Measures taken on F446, four runs of the same binary:

run	fault	`Stacked PC`
1, 2, 4	UsageFault **UNDEFINSTR**	`0x2000F118`
3	UsageFault **UNALIGNED**	`0x2000F64C`

`g_data_buf` is at `0x2000F040`, 16 bytes of `.bss` all zeros. In Thumb `0x0000` is `LSLS r0,r0,#0` — **a valid instruction**. The `blx` therefore **does not fault**: the core executes eight NOPs and continues inside the `.bss`, stopping 200 bytes after the end of the buffer inside `g_cur_index`, a *live* variable of the scheduler (on run 3 it had advanced 1532 bytes further). The stopping point is decided by the kernel state at that moment: from here both the variability between runs, and the "divergence" between boards.

The fetch is legitimate, and it is not a bug: `MPU->CTRL` has `PRIVDEFENA`, tasks run privileged, and the default ARM map **does not** mark SRAM as execute-never. This also answers the question of why the case originated: yes, **the heap is executable** on these parts, unless a region says otherwise.

From here, the two twin cases, which differ in **only one thing**:

case	buffer	MPU region	outcome
`xn`	`g_xn_buf` (32 B, 32-aligned)	**yes**, `XN=1`	fault **on** the buffer: the first fetch is rejected
`runaway`	`g_data_buf`	**no**	fault **beyond** the buffer: the fetch is allowed and the core continues

The criterion is the PC, not the fault type — and this cost one run. The first version demanded IACCVIOL from `xn` and any-other-thing from `runaway`. The board said no: the two buffers are **28 bytes** apart in `.bss`, so as soon as the region exists the runaway exits its own buffer by NOPs and ends **against that same region** — same fault, same PC. It would have been the layout again deciding the verdict, which is the error from which this whole investigation started.

Measured on F446 after the fix:

case	buffer	`Stacked PC`	delta
`xn`	`0x2000F080`	`0x2000F080`	**+0** — did not execute anything
`runaway`	`0x2000F064`	`0x2000F080`	**+28** — executed, then hit the guard

The fault type is the same for both; the PC separates them unambiguously, and no memory layout can make one look like the other.

The region is armed **once** in `ca_os_configure()` and never disarmed: doing so inside the case would mean disarming it afterwards, and the case never returns — the fault removes the task. If there are no free regions, `xn` prints **SKIPPED** instead of looping: without the region it would be `runaway` under a false name, and would pass for the wrong reason.

Why the board didn't notice: `test_ex68.cpp` counted the `Mode: RECOVER` lines asking for at least 12 out of 18. The case did cause a fault, the line was there, the count added up. *Which* fault it was didn't matter to anyone. The `xn_region_is_what_stops_the_fetch` phase now asserts the **type** of fault on both twins. The rest (BusFault flash/ibuserr, MemManage ro/stack/stackjmp, PSP range-check stackup, UsageFault div0/unalign/undef/invstate, HardFault forced) is **identical** on both cores and recovers in all cases.

Note. In early versions the dump printed the task name **twice** in MemManage and UsageFault faults (one local print in the handler + one in `ca_scheduler_manage_fault`). Fixed: now the task appears **only once**, uniformly for all fault types, as seen in the outputs above.

91.1.8 Summary

1. **16 faults** in 5 categories (BusFault, MemManage, PSP range-check, UsageFault, HardFault escalated), all **handled and recovered** without stopping the RTOS.
2. **Full Cortex-M trap coverage**: all CFSR subtypes are decoded by the dump, even those not directly triggered by the bank.
3. **Two modes**: automatic sequence at boot + CLI command `fault <nome>`.
4. **Robust console in fault context**: synchronous stdout, no buffered queues.
5. **The `forced` case** demonstrates the escalation of HardFault to a per-task policy — a forced HardFault from a task no longer kills the system.
6. **The `cross` case** verifies cross-task diagnosis: that the dump names the **owner** of the affected memory, and that the victim is chosen within the actually watched window — outside of it, corruption passes silently and reemerges disguised as something else.
7. **HW tested** on F407 (M4), H753 (M7), H563 and U575 (M33), the latter two 16/16; F746 and F103 remain.

Chapter 92

UDP Server over USB-NCM

92.1 Example 69 — UDP Server on USB-NCM

92.1.1 Introduction

This example is the **USB variant of example 34** (UDP server on Ethernet). The service is identical — port 7961, a dedicated worker for each client, echo with prefix `ECHO:`, idle timeout — but the frames no longer pass through the Ethernet MAC: they travel on a **USB network adapter** (CDC-NCM), that is, on the cable that already powers and programs the board.

The educational point is the practical confirmation of the `ca_net_iface_t` abstraction introduced in example 55: between ex34 and ex69 **the application code does not change by a single line**. Callbacks, server configuration struct, `ca_net_process()` loop are the same. Only *which interface* is passed to `ca_net_init()` changes:

```
/* example 34     Ethernet */          /* example 69     USB-NCM */
eth_gpio_init();                      ca_usb_dev_mng_init(CA_USB_SPEED_FS,
    USB_NUM);
                                      ca_usb_dev_mng_add(&s_ncm.header);
                                      ca_usb_dev_mng_start();
ca_net_init(ca_eth_iface_get(&cfg)); ca_net_init(ca_ncm_iface_get(&s_ncm));
ca_net_proto_init(&net_cfg);          ca_net_proto_init(&net_cfg);   /* identico
    */
```

If ex55 demonstrates the abstraction on the absolute minimum (ARP + ICMP), ex69 demonstrates it where it really counts: **a full application service**, with threads for client and state management, running over two different transports without knowing it.

Feature	Notes
UDP Server on port 7961	`ca_udp_server_start()`, up to 4 simultaneous clients
Worker per client	a dedicated thread for each client (internal to the service)
Echo with prefix	replies with `ECHO: <data>`
Inactivity timeout	disconnects after 10 s of inactivity
USB Ethernet (NCM)	device `usb0` via CDC-NCM
`ca_net_iface_t` abstraction	same UDP service on ETH (ex34) or NCM (ex69)
CLI `ping` / `ip`	with `EN_CLI_NET`

92.1.2 PC Prerequisite: Remove the interface from NetworkManager

When the board enumerates, a new network interface appears on the PC (`enx02ca0500xx` — the name udev derives from the MAC). NetworkManager sees it as any ordinary plugged-in card and **assigns it an address of its own**: it has been observed `172.21.10.100/24`. The board is on `192.168.10.0/24`, so the two end up on different subnets and the board is unreachable.

The symptom is misleading, because the interface **exists and is UP**: `ip link` shows it, and even `ping -I <iface>` responds — that flag bypasses the routing table. What doesn't work is everything else (`socat`, `nc`, the PC scripts of the examples), which follow the routing table.

The rule is versioned in the repository:

```
sudo cp tools/99-caos-ncm.conf /etc/NetworkManager/conf.d/
sudo systemctl reload NetworkManager
nmcli -t -f DEVICE,STATE dev status | grep enx    # it must say: unmanaged
```

> **The glob goes on `interface-name`, not on `mac:`.** The form `mac:02:ca:05:00:00:*` seems equivalent but it is not: it requires a full MAC and fails **silently** with a wildcard character — no error, and the interface remains managed.

The bank address does not set this rule: it is set by `sudo ./tools/bench_net.sh usb` or the example PC script.

92.1.3 Hardware

No PHY, no Ethernet cable: only the USB device port of the board is needed.

MCU	`USB_NUM`	Connector	LED heartbeat
U575 (NUCLEO-U575ZI-Q)	0	USB user	PC7 (LD1)
H753 (NUCLEO-H753ZI)	1	CN14 (OTG_FS)	PB7 (LD2)
F407 (STM32F4VE)	0	USB device	PA6 (D2)
H563 (NUCLEO-H563ZI)	0	USB user	PB0 (LD1)

On other families the example disables itself (`#undef EN_USB`) and prints the message from the `#else` branch.

92.1.4 os_config.h Configuration

```
#define EN_NET          1     /* net core: pool buffer, ARP, ICMP,     */
#define EN_USB          1     /* driver USB DWC2 + stack mgmt */
#define EN_USB_NCM      1     /* CDC-NCM class (the network transport) */
#define EN_UDP_SERVER   1     /* the service being shown */
#define EN_ARP_SERVICE  1     /* MAC     IP resolution */
#define EN_CLI_NET      1     /* optional: CLI commands 'ping' / 'ip' */
```

Off relative to ex34:

```
#define EN_ETH        0     /* no Ethernet MAC */
#define EN_CLI_ETH    0     /* see note below */
#define EN_USB_CDC    0     /* the USB port acts as a network card, not a serial
    port */
```

Why `EN_CLI_ETH` should be turned off. The commands `eth link` / `eth stats` / `eth pool` are inside `#if EN_ETH` in `caos/drivers/src/eth.c`: with `EN_ETH=0` they are not compiled at all. Leaving `EN_CLI_ETH=1` would not cause a build error — it would remain an active flag but **inactive**, i.e. a configuration that declares something that does not exist in the firmware. This is the type of defect that `caos_config.py --find --inert` reports. The pool counters remain accessible by the `net` command.

The configuration is generated and modified **only** with the agent:

```
python3 tools/caos_config.py --new 69 --from ex34 \
        --set EN_ETH=0 --set EN_USB=1 --set EN_USB_NCM=1 --set EN_USB_CDC=0
python3 tools/caos_config.py --off EN_CLI_ETH 69
```

92.1.5 Architecture

```
        PC (usb0)                          Board

       nc -u ... 7961                      udp_server (7961)

    worker per client

                                                    ca_net_process()

                                        net core: ARP/ICMP

                                                    ca_net_iface_t      l'unico
    punto

        that changes
                        USB CDC-NCM                      ca_usb_ncm (push)
```

The UDP service and the net core are **the same logical binaries** as in ex34: the replacement happens underneath, at the interface level.

Where initialization lives

In ex34 `ca_net_init()` lives in `ca_os_configure()`, before the scheduler. In ex69 **it cannot**: the NCM interface exists only after the USB device has been enumerated, so USB bring-up and `ca_net_init()` are together inside `task_net`. It's the same choice as in ex55.

There is also no `eth_mon` task: without a PHY, there is no link to query with `ca_eth_link_poll()`. The "link" is the USB enumeration, readable with `ca_usb_ncm_is_up()`. For the same reason, GARP is not sent: the host learns the device's MAC from the NCM descriptors.

> **The NCM link is not up just when the device is enumerated.** `s_up` goes high only when the host selects the **alt setting 1** of the data interface, i.e., when the PC actually brings up `usb0`. Before that moment `ca_usb_ncm_send_frame()` discards every frame and returns `false`.
>
> However, this example is purely **reactive** — it responds, never speaks first — so it doesn't need to wait: when the first packet arrives, the link is by definition already up. **And the wait should not be added**: blocking the net task before the loop

would prevent the enumeration itself (the Linux kernel would report `device not accepting address`), because the stack needs this task to already be serving frames. For a service that instead *initiates* the conversation, the gate is really needed, but it must be placed **inside** the loop: see example 70.

92.1.6 Expected UART output

```
=== EX69: UDP server porta 7961 su USB-NCM ===
MAC  02:CA:05:00:00:69
IP   192.168.10.69
USB NCM UP
UDP server ready - bring up usb0, then: nc -u 192.168.10.69 7961
UDP[7961] client 0: 192.168.10.1:54321 connesso
UDP[7961] client 0: rx 6B ('hello.') da 192.168.10.1:54321
```

92.1.7 Test from PC

When the cable is connected, a new network interface appears (`usb0`, or `enxNN` with systemd's predictable names):

```
ip link | grep -i usb                          # find the real name
sudo ip addr add 192.168.10.1/24 dev usb0
sudo ip link set usb0 up

echo "hello" | nc -u 192.168.10.69 7961        # reply: ECHO: hello
nc -u 192.168.10.69 7961                       # interactive session
```

Two simultaneous `nc` terminals show the per-client workers: the log reports `client 0` and `client 1` with different source ports.

Inverse Ping (device → host) from serial CLI

```
ping 192.168.10.1 count=3
```

92.1.8 Technical Notes

Comparison with ex34: what really changes

	ex34 (ETH)	ex69 (NCM)
Bring-up	`eth_gpio_init()` (9 pin RMII)	`ca_usb_dev_mng_*()`
Interface	`ca_eth_iface_get(&eth_cfg)`	`ca_ncm_iface_get(&s_ncm)`
RX Model	pull (DMA descriptor)	push (`ca_net_rx_push`)
Link	`ca_eth_link_poll()` + task `eth_mon`	USB enumeration, `ca_usb_ncm_is_up()`
GARP	sent after bring-up	not needed
Init	in `ca_os_configure()`	in `task_net` (after enumeration)
UDP Callback, `net_cfg`, loop	— **identical** —	

Two MACs, one for each side

`s_mac` (`02:CA:05:00:00:69`) is the **device** MAC; `s_ncm.mac` (`02:CA:05:00:00:A9`) is the one announced to the **host side**. These are the two ends of the same cable and must be different. The first byte `0x02` marks the address as *locally administered*.

Bandwidth

USB Full Speed provides 12 Mbit/s raw bandwidth, compared to ~33 Mbps measured on Ethernet in ex44. For a UDP service with short packets it is irrelevant, but must be kept in mind if this scheme is reused for volume transfers.

92.1.9 File Structure

```
examples/example_69/
          ca_os_ex69.c          entry point
          os_config_ex_69.h     configurazione (generata da ex34)
```

The test does not require scripts: `nc -u` is sufficient, as in ex34.

Chapter 93

DHCP Client over USB-NCM

93.1 Example 70 — DHCP Client over USB-NCM

93.1.1 Introduction

USB-NCM variant of **example 35** (DHCP client over Ethernet). The services are the same — DHCP client with DORA and renewal, ARP, ICMP echo, UDP server on port 7961 — but the transport is the USB port instead of the Ethernet MAC.

Compared to example 69 (UDP server over NCM, static address), here the address is **dynamically assigned**, and this is precisely what makes the example interesting on a point-to-point link: it shows that the caOS DHCP client does not depend on the transport, but requires **someone to act as a server** on the other end of the cable.

Feature	Notes
DHCP Client	Full DORA + T1/T2 renewal
GARP	sent at every bound/renew
ARP service	Initial IP 0.0.0.0, updated at bound
ICMP echo reply	responds to `ping` on the obtained address
UDP server 7961	up to 2 simultaneous clients
USB Ethernet (NCM)	device `usb0` / `enxNN`

93.1.2 PC Prerequisite: detach the interface from NetworkManager

When the board enumerates, a new network interface appears on the PC (`enx02ca0500xx` — the name that udev derives from the MAC). NetworkManager sees it as any newly connected card and **assigns its own address to it**: `172.21.10.100/24` has been observed. The board is on `192.168.10.0/24`, so the two end up on different subnets and the board is unreachable.

The symptom is misleading, because the interface **exists and is UP**: `ip link` shows it, and even `ping -I <iface>` responds — that flag bypasses the routing table. What does not work is everything else (`socat`, `nc`, the PC scripts of the examples), which follows the routing table.

The rule is versioned in the repository:

```
sudo cp tools/99-caos-ncm.conf /etc/NetworkManager/conf.d/
sudo systemctl reload NetworkManager
nmcli -t -f DEVICE,STATE dev status | grep enx    # deve dire: unmanaged
```

> **The glob goes on `interface-name`, not on `mac:`.** The form `mac:02:ca:05:00:00:*` seems equivalent but it is not: it expects a full MAC and fails **silently** with a wildcard character — no error, and the interface remains managed.

The bank address is not set by this rule: it is set by `sudo ./tools/bench_net.sh usb` or the PC script in the example.

93.1.3 The critical point: there is no DHCP server

On Ethernet (ex35) the DHCP server is the LAN router. On a point-to-point USB cable **it does not exist**: on one side there is the board, on the other the PC, and neither of the two offers default addresses.

The PC must therefore act as a server. The script provided with the example configures `dnsmasq` on the NCM interface:

```
sudo examples/example_70/test_dhcp_ncm_pc.sh
```

The script **finds the interface on its own**, searching for the one whose MAC starts with `02:ca:05` (the host-side MAC announced by the NCM descriptors), and waits up to 30 s for it to appear — because unlike `eth0`, the USB interface **is created when the board enumerates**. You can still pass it manually:

```
sudo examples/example_70/test_dhcp_ncm_pc.sh enx02ca050000b0
```

Then the script: assigns `192.168.10.1/24` to the PC, starts `dnsmasq` with pool `.100 .200`, waits for the ACK by reading it from the log, and finally tests ping, UDP echo, and two simultaneous clients. Upon exit, it performs cleanup (stops dnsmasq, removes the IP).

93.1.4 Hardware

MCU	`USB_NUM`	Connector	Heartbeat LED
U575 (NUCLEO-U575ZI-Q)	0	USB user	PC7 (LD1)
H753 (NUCLEO-H753ZI)	1	CN14 (OTG_FS)	PB7 (LD2)
F407 (STM32F4VE)	0	USB device	PA6 (D2)
H563 (NUCLEO-H563ZI)	0	USB user	PB0 (LD1)

93.1.5 os_config.h configuration

```
#define EN_NET            1
#define EN_USB            1
#define EN_USB_NCM        1
#define EN_NET_DHCP       1     /* protocollo DHCP nel net core */
#define EN_DHCP_SERVICE   1     /* task client DHCP */
#define EN_UDP_SERVER     1
#define EN_ARP_SERVICE    1
```

Off compared to ex35: `EN_ETH 0`, `EN_CLI_ETH 0`, `EN_USB_CDC 0`.

```
python3 tools/caos_config.py --new 70 --from ex35 \
        --set EN_ETH=0 --set EN_USB=1 --set EN_USB_NCM=1 --set EN_USB_CDC=0
python3 tools/caos_config.py --off EN_CLI_ETH 70
```

93.1.6 Startup sequence

The order is more delicate than on Ethernet, because the "link" is not the PHY but the USB enumeration:

```
task_net:
  1. ca_usb_dev_mng_init/add/start      bring-up USB
  2. ca_net_init(ca_ncm_iface_get())    NCM diventa l'iface del net core
  3. ca_net_proto_init(&net_cfg)        stack con IP = 0.0.0.0
  4. ca_net_proto_bind_udp(68,    )       porta 68 per OFFER/ACK
  5. ca_udp_server_bind()               porta 7961
  6. loop: appena il link    su     ca_dhcp_service_net_ready()     parte il
    DORA
           poi ca_sem_timedwait() + ca_net_process()
```

The gate of step 6 is specific to NCM, and it is not a formality. In ex35 the equivalent is `ca_eth_link_poll()`: it expects the PHY to see the cable. Here it expects the host to **select alt setting 1** of the data interface, which is what raises `s_up` in `usb_ncm.c`. As long as it is zero, `ca_usb_ncm_send_frame()` **discards every frame and returns** `false`:

```
bool ca_usb_ncm_send_frame(const u8 *eth, u16 len)
{
    if (!s_up || eth == NULL || ...) return false;   /* silenziosamente perso */
```

A DISCOVER sent too early is therefore not *delayed*: it is **lost**. And the DHCP client would consume the entire retry budget (`DHCP_DISCOVER_RETRY_N` × `DHCP_OFFER_TIMEOUT_MS` = 3 × 4 s) talking into a closed pipe.

> **Where to place the wait — and where not to.** The gate **must be inside the loop**, not before it. Blocking the net task while waiting for the link *before* serving frames prevents enumeration itself: the host fails to complete the SET_ADDRESS and the Linux kernel reports `device not accepting address NN, error -62, unable to enumerate USB device`. It waits for an event that cannot happen as long as it is waiting. For the same reason, the loop uses `ca_sem_timedwait(&ca_net_rx_sem, 100)` and not `ca_sem_wait()`: before the link is up, no frames arrive, so a wait without a timeout would park the task and the gate would never be re-evaluated.
>
> **Power-on order**: first the board, then the script on the PC. The firmware waits as long as necessary; it is the script that needs the interface to be already present in order to configure it.

The link monitor

`task_ncm_mon` is the NCM counterpart to `task_eth_mon` in ex35: it samples `ca_usb_ncm_is_up()` every 500 ms and signals transitions. If the link comes back up **while a lease is already active** (cable reattached, `usb0` reconfigured), it requests a renew, so the address is revalidated instead of being taken for granted until T1. When there is no lease, however, it does nothing: the DORA cycle is already retrying on its own.

> **Why `ca_dhcp_service_bind()` must not be called in the net task** (this also applies to ETH): it is blocking, and it would block the task that needs to run `ca_net_process()` → the OFFER would never be processed → deadlock. The IP arrives via callback `on_dhcp_bound` from the DHCP task.

93.1.7 Expected UART output

```
=== EX70: DHCP + ARP + ping + UDP server su USB-NCM ===
MAC  02:CA:05:00:00:70
IP   --- (in attesa DHCP)
USB NCM DOWN - attendo che l'host porti su l'interfaccia...
USB NCM UP
DHCP: avvio DORA...
DBG DHCP DISCOVER attempt 1 xid=0x05000031

DHCP BOUND  IP=192.168.10.100  mask=255.255.255.0
            GW=192.168.10.1  DNS=8.8.8.8
UDP[7961] client 0: 192.168.10.1:51234 connesso
UDP[7961] cid=0 rx 10B ('hello caOS') from 192.168.10.1:51234
```

93.1.8 Technical notes

Two MACs, one for each side

`s_mac` (`02:CA:05:00:00:70`) is the device MAC; `s_ncm.mac` (`02:CA:05:00:00:B0`) is the one announced to the host side — this is what the `enx02ca050000b0` interface name on the PC is derived from, and it is what the script looks for.

The dynamic IP and the three mirrors

Upon binding, the address must be propagated to three subsystems, or they will remain misaligned:

```
ca_net_proto_set_local_ip(ip);        /* stack IP: filtro dei pacchetti in
    ingresso */
ca_udp_server_set_local_ip(ip);       /* server UDP: indirizzo sorgente delle
    risposte */
ca_arp_service_update_local_ip(ip);   /* ARP: a quale IP rispondere */
```

It is the same sequence as ex35: it does not change with transport.

93.1.9 File structure

```
examples/example_70/
          ca_os_ex70.c            entry point
          os_config_ex_70.h       configurazione (generata da ex35)
          test_dhcp_ncm_pc.sh     setup dnsmasq su usb0 + test automatico
```

Chapter 94

DHCP and NTP Client over USB-NCM

94.1 Example 71 — DHCP Client + NTP over USB-NCM

94.1.1 Introduction

Variant USB-NCM of **example 36** (DHCP + NTP over Ethernet). The services are the same — DHCP client with DORA and renewal, NTP client, ARP, ICMP echo, UDP server on port 7961 — but the transport is the USB port instead of the Ethernet MAC.

Compared to example 70 (DHCP over NCM), the novelty is only one, and it's worth isolating: the **NTP client is downstream of the DHCP**. It has no gate directly on the USB link, because it is already protected by the DHCP's gate: when a lease exists, the link is necessarily up. It is the first NCM clone where two services are chained, and it shows that the chaining remains identical to that of ex36 — the abstraction `ca_net_iface_t` is not visible.

Feature	Notes
DHCP Client	Full DORA + T1/T2 renewal
NTP Client	server from opt42, fallback to gateway
GARP	sent at every bound/renew
ARP service	initial IP 0.0.0.0, updated at bound
ICMP echo reply	replies to `ping` on the obtained address
UDP Server 7961	up to 2 simultaneous clients
USB Ethernet (NCM)	device `usb0` / `enxNN`

94.1.2 PC Prerequisite: Remove the interface from NetworkManager

When the board enumerates, a new network interface appears on the PC (`enx02ca0500xx` — the name udev derives from the MAC). NetworkManager sees it as any ordinary attached card and **assigns it an address of its own**: this has been observed `172.21.10.100/24`. The board is on `192.168.10.0/24`, so the two end up on different subnets and the board becomes unreachable.

The symptom is misleading, because the interface **exists and is UP**: `ip link` shows it, and even `ping -I <iface>` responds — that flag bypasses the routing table. What fails is everything else (`socat`, `nc`, the PC scripts of the examples), which follow the routing table.

The rule is versioned in the repository:

```
sudo cp tools/99-caos-ncm.conf /etc/NetworkManager/conf.d/
sudo systemctl reload NetworkManager
nmcli -t -f DEVICE,STATE dev status | grep enx    # it must say: unmanaged
```

The glob goes to `interface-name`, not to `mac:`. The form `mac:02:ca:05:00:00:*` seems equivalent but it is not: it requires a full MAC and fails **silently** with a wildcard character — no error, and the interface remains managed.

The address of the bank does not set this rule: it is set by `sudo ./tools/bench_net.sh usb` or the example PC script.

94.1.3 The critical point: the PC must act as a server twice

On Ethernet (ex36) the DHCP server is the LAN router, and the NTP server is typically a different host. On a point-to-point USB cable **there is nothing else but the two ends**: the PC must simultaneously act as gateway, DHCP server and NTP server.

This has a consequence that is not visible on ETH: the firmware fallback and DHCP option 42 **point to the same address**. The code chooses the NTP as (identical to ex36):

```
ca_ipv4_t ntp_ip = ca_dhcp_service_get_ntp_server();   /* opt42 */
if (ntp_ip.addr == 0U) ntp_ip = gw;                  /* fallback: the gateway */
ca_ntp_service_set_server(ntp_ip);
ca_ntp_service_net_ready();
```

On a point-to-point link the gateway **is** the PC, so both routes arrive at destination. The test remains valid, but does not distinguish the two paths: to verify that option 42 is really read it is necessary to check the log (`grep ntp /tmp/dnsmasq-caos.log`) — on ETH it would distinguish ex37, where the resolver received in the lease was different from the default.

The provided script configures both services:

```
sudo examples/example_71/test_dhcp_ntp_ncm_pc.sh
```

In ex70 **it finds the interface by itself**, searching for the one whose MAC starts with `02:ca:05` and waits up to 30 s for it to appear, since the USB interface is created during enumeration. Moreover, compared to ex70: stops the system NTP service (`ntpd`, `chrony`, `systemd-timesyncd` — it would occupy port 123), starts a minimal NTP responder in Python and adds `dhcp-option=option:ntp-server` to the dnsmasq configuration.

The Python responder **responds immediately**, without needing to be synchronized itself: here it is important that the board receives a timestamp and converts it correctly, not absolute accuracy. At exit, the script performs a complete cleanup, including restarting the system NTP service that it had stopped.

94.1.4 Hardware

MCU	`USB_NUM`	Connector	LED heartbeat
U575 (NUCLEO-U575ZI-Q)	0	USB user	PC7 (LD1)
H753 (NUCLEO-H753ZI)	1	CN14 (OTG_FS)	PB7 (LD2)
F407 (STM32F4VE)	0	USB device	PA6 (D2)
H563 (NUCLEO-H563ZI)	0	USB user	PB0 (LD1)

94.1.5 os_config.h configuration

```
#define EN_NET            1
#define EN_USB            1
#define EN_USB_NCM        1
#define EN_NET_DHCP       1     /* DHCP protocol in the net core */
#define EN_DHCP_SERVICE   1     /* task client DHCP */
#define EN_NET_NTP        1     /* NTP protocol in the net core */
#define EN_NTP_SERVICE    1     /* task client NTP */
#define EN_UDP_SERVER     1
#define EN_ARP_SERVICE    1
```

Off with respect to ex36: `EN_ETH 0`, `EN_CLI_ETH 0`, `EN_USB_CDC 0`.

```
python3 tools/caos_config.py --new 71 --from ex36 \
        --set EN_ETH=0 --set EN_USB=1 --set EN_USB_NCM=1 --set EN_USB_CDC=0
python3 tools/caos_config.py --off EN_CLI_ETH 71
```

Compared to ex70, the config differs by **exactly three flags** — `EN_NET_NTP`, `EN_NTP_SERVICE`, `EN_CLI_NTP` — verifiable with:

```
python3 tools/caos_config.py --diff 70 71
```

94.1.6 Boot Sequence

```
task_net:
  1. ca_usb_dev_mng_init/add/start      bring-up USB
  2. ca_net_init(ca_ncm_iface_get())    NCM becomes the net core iface
  3. ca_net_proto_init(&net_cfg)        stack con IP = 0.0.0.0
  4. ca_net_proto_bind_udp(68,    )       porta 68 per OFFER/ACK
  5. ca_udp_server_bind()               porta 7961
  6. ca_ntp_service_bind()              porta 123
  7. loop: as soon as the link is up     ca_dhcp_service_net_ready()     the
    DORA starts
           then ca_sem_timedwait() + ca_net_process()

on_dhcp_bound (callback, from the DHCP task):
      ca_ntp_service_set_server(opt42 | gw)
      ca_ntp_service_net_ready()          unblocks the NTP task
```

The gate at step 7 is specific to NCM, and not just a formality. In ex36 the equivalent is `ca_eth_link_poll()`: it expects the PHY to see the cable. Here we expect the host **to select alternate setting 1** of the data interface, which is what sets `s_up` in `usb_ncm.c`. As long as it is zero, `ca_usb_ncm_send_frame()` **discards every frame and returns** `false`: a DISCOVER sent too early is not *delayed*, it is **lost**.

> **Where the wait should go — and where it should not.** The gate **must be inside the loop**, not before. Blocking the net task waiting for the link *before* serving frames prevents enumeration itself: the host does not complete SET_ADDRESS and Linux reports `device not accepting address NN, error -62`. It expects an event that cannot happen until it waits. For the same reason the loop uses `ca_sem_timedwait(& ca_net_rx_sem, 100)` and not `ca_sem_wait()`: before the link is up no frames arrive, so a wait without timeout would block the task and the gate would never be re-evaluated.

Why NTP does not have its own gate

It is the difference this example adds to ex70. The NTP client **speaks first** — sends a request, does not respond to one — so in theory it would fall into the same trap as DHCP. In practice no gate is needed, for two independent reasons:

1. `ca_ntp_service_net_ready()` is called **inside** `on_dhcp_bound`: the NTP task remains blocked until a lease exists, and a lease cannot exist if the link is not up.
2. At the time of the first request the source IP is already valid — which is then the reason why the same chain exists also on ETH in ex36, where the link issue does not arise at all.

`ca_ntp_service_bind()` instead is at step 6, **before** the gate: registering port 123 does not send anything on the network, and must be done before a response can arrive.

The link monitor

`task_ncm_mon` is the NCM counterpart of `task_eth_mon` in ex36: it samples `ca_usb_ncm_is_up()` every 500 ms and reports transitions. If the link comes back up **while a lease is already active** it requests a renew. The renew also carries NTP: a new bound calls `on_dhcp_bound` and then `ca_ntp_service_net_ready()`.

94.1.7 Expected UART output

```
=== EX71: DHCP + NTP + ARP + ping + UDP server su USB-NCM ===
MAC  02:CA:05:00:00:71
IP   --- (waiting for DHCP)
waiting for the host to bring the interface up...
USB NCM UP
DHCP: avvio DORA...
DBG DHCP DISCOVER attempt 1 xid=0x05000031

DHCP BOUND  IP=192.168.10.100  mask=255.255.255.0
            GW=192.168.10.1  DNS=8.8.8.8
NTP SYNC  unix=1787299886  2026-08-21 08:11:26 UTC
UDP[7961] client 0: 192.168.10.1:51234 connesso
UDP[7961] cid=0 rx 10B ('hello caOS') da 192.168.10.1:51234
```

The order `DHCP BOUND` → `NTP SYNC` is not random and is the visual verification of the chain: if `NTP SYNC` appeared first, or without a bound, it would be a defect.

94.1.8 Technical notes

Two MACs, one per side

`s_mac` (`02:CA:05:00:00:71`) is the device MAC; `s_ncm.mac` (`02:CA:05:00:00:B1`) is the one announced to the host side — it is from this that the name `enx02ca050000b1` of the interface on the PC derives, and it is this that the script searches for. The two **must differ**.

The timestamp conversion

`unix_to_dt()` is copied identical from ex36: it converts unix time into a readable date handling leap years (complete rule, including the centennial exception). It does not use the RTC — it is pure arithmetic on the received value — therefore the comparison between the line `NTP SYNC` and the PC server log verifies end-to-end both the protocol and the conversion.

The dynamic IP and the three mirrors

At the bound, the address must be propagated to three subsystems, or they will remain misaligned:

```
ca_net_proto_set_local_ip(ip);        /* IP stack: filter for incoming packets */
ca_udp_server_set_local_ip(ip);       /* UDP server: source address of the replies */
ca_arp_service_update_local_ip(ip);   /* ARP: a quale IP rispondere */
```

It is the same sequence as in ex36 and ex70: it does not change with transport.

94.1.9 File structure

```
examples/example_71/
          ca_os_ex71.c                  entry point

          test_dhcp_ntp_ncm_pc.sh       setup dnsmasq + NTP su usb0 + test automatico
```

Chapter 95

DHCP, NTP and DNS Client over USB-NCM

95.1 Example 72 — DHCP, NTP and DNS client over USB-NCM

95.1.1 Introduction

USB-NCM variant of **example 37** (DHCP + NTP + DNS over Ethernet). The services are the same — DHCP client with DORA and renewal, NTP client, DNS client, ARP, ICMP echo, UDP server on port 7961 — but the transport is the USB port instead of the Ethernet MAC.

Compared to example 71, a **DNS client** is added with a demo task that resolves three names as soon as the lease is active. It is the third service in the chain, and confirms the rule that emerged in ex71: **a gate on the NCM link is only needed for the first service that communicates**.

Feature	Notes
DHCP client	Full DORA + T1/T2 renewal
NTP client	server from opt42, fallback to gateway
DNS client	resolver from opt6 of the lease, fallback to gateway
DNS demo	3 resolutions at startup + CLI `dns resolve`
GARP	sent at every bound/renew
ARP service	initial IP 0.0.0.0, updated at bound
ICMP echo reply	responds to `ping` on the obtained address
UDP server 7961	up to 2 simultaneous clients
USB Ethernet (NCM)	device `usb0` / `enxNN`

95.1.2 PC Prerequisite: detach the interface from NetworkManager

When the board enumerates, a new network interface appears on the PC (`enx02ca0500xx` — the name that udev derives from the MAC). NetworkManager sees it as any other newly connected card and **assigns its own address to it**: `172.21.10.100/24` has been observed. The board is on `192.168.10.0/24`, so the two end up on different subnets and the board is unreachable.

The symptom is misleading, because the interface **exists and is UP**: `ip link` shows it, and even `ping -I <iface>` responds — that flag bypasses the routing table. Everything else (`socat`, `nc`, the PC scripts of the examples) does not work, because it follows the routing table.

The rule is versioned in the repository:

```
sudo cp tools/99-caos-ncm.conf /etc/NetworkManager/conf.d/
sudo systemctl reload NetworkManager
nmcli -t -f DEVICE,STATE dev status | grep enx    # it must say: unmanaged
```

> **The glob goes on `interface-name`, not on `mac:`.** The form `mac:02:ca:05:00:00:*` seems equivalent but it is not: it expects a complete MAC and fails **silently** with a wildcard character — no error, and the interface remains managed.

The bank address is not set by this rule: it is set by `sudo ./tools/bench_net.sh usb` or the PC script in the example.

95.1.3 The critical point: the PC must act as a server three times

On Ethernet (ex37) DHCP, NTP and DNS are typically distinct hosts on the LAN. On a point-to-point USB cable **there is nothing else but the two ends**: the PC is simultaneously gateway, DHCP server, NTP server and DNS resolver.

The provided script mounts all three services:

```
sudo examples/example_72/test_dhcp_dns_ncm_pc.sh
```

As with the other clones, it **automatically finds the interface** by searching for the one whose MAC starts with `02:ca:05` and waits up to 30 s for it to appear, because the USB interface is created upon enumeration. Then:

- stops `systemd-resolved` / `named` / `bind9` (they occupy port 53) and starts a **Python DNS resolver** that statically resolves the names `.caos.local` and forwards the rest to a public upstream;
- stops the system NTP service and starts the **Python NTP responder** from ex71;
- starts `dnsmasq` **only for DHCP** (`port=0` disables its DNS), announcing `option:dns-server` and `option:ntp-server` = PC address.

> **Beware of test ambiguity.** On point-to-point, the gateway *is* the PC, so the DHCP option and the firmware fallback point to the same address: the test passes through both paths and **does not distinguish between them**. To verify that the option is actually read, you need the log (`grep -i dns /tmp/dnsmasq-caos.log`). On ETH, this distinction was visible in ex37, where the lease resolver differed from the default.

95.1.4 Hardware

MCU	`USB_NUM`	Connector	Heartbeat LED
U575 (NUCLEO-U575ZI-Q)	0	USB user	PC7 (LD1)
H753 (NUCLEO-H753ZI)	1	CN14 (OTG_FS)	PB7 (LD2)
F407 (STM32F4VE)	0	USB device	PA6 (D2)
H563 (NUCLEO-H563ZI)	0	USB user	PB0 (LD1)

95.1.5 os_config.h configuration

```
#define EN_NET            1
#define EN_USB            1
#define EN_USB_NCM        1
#define EN_NET_DHCP       1     /* DHCP protocol in the net core */
#define EN_DHCP_SERVICE   1     /* task client DHCP */
#define EN_NET_NTP        1
#define EN_NTP_SERVICE    1
#define EN_NET_DNS        1     /* DNS protocol in the net core */
#define EN_DNS_SERVICE    1     /* task client DNS */
#define EN_UDP_SERVER     1
#define EN_ARP_SERVICE    1
```

Switched off compared to ex37: `EN_ETH 0`, `EN_CLI_ETH 0`, `EN_USB_CDC 0`.

```
python3 tools/caos_config.py --new 72 --from ex37 \
        --set EN_ETH=0 --set EN_USB=1 --set EN_USB_NCM=1 --set EN_USB_CDC=0
python3 tools/caos_config.py --off EN_CLI_ETH 72
```

Compared to ex71, the configuration differs by **exactly three flags** — `EN_NET_DNS`, `EN_DNS_SERVICE`, `EN_CLI_DNS`:

```
python3 tools/caos_config.py --diff 71 72
```

95.1.6 Boot sequence

```
task_net:
  1. ca_usb_dev_mng_init/add/start      bring-up USB
  2. ca_net_init(ca_ncm_iface_get())    NCM becomes the net core iface
  3. ca_net_proto_init(&net_cfg)        stack con IP = 0.0.0.0
  4. ca_net_proto_bind_udp(68,    )       porta 68 per OFFER/ACK
  5. ca_udp_server_bind()               porta 7961
  6. ca_ntp_service_bind()              porta 123
  7. ca_dns_service_bind()              porta 53
  8. loop: as soon as the link is up     ca_dhcp_service_net_ready()     the DORA starts
          then ca_sem_timedwait() + ca_net_process()

on_dhcp_bound (callback, from the DHCP task):
      ca_ntp_service_set_server(opt42 | gw) + net_ready()
      ca_dns_service_set_server(opt6  | gw) + net_ready()
      post su s_dns_demo_sem                 sblocca task_dns_demo
```

The step 8 gate is specific to NCM. The NCM link only comes up when the host selects alt setting 1: as long as it is down, `ca_usb_ncm_send_frame()` **discards every frame and returns** `false`, so a DISCOVER sent too early is not delayed, it is **lost**.

> **Where to place the wait — and where not to.** The gate **must be inside the loop**, not before: blocking the net task waiting for the link *before* serving frames prevents enumeration itself (the host reports `device not accepting address`). For the same reason, the loop uses `ca_sem_timedwait(&ca_net_rx_sem, 100)` and not `ca_sem_wait()`.

A single gate, for the first one to speak

This is the point that this example makes evident by having **three** services in a chain. NTP and DNS both speak first — they send a request, they do not respond to one — and in theory, they would fall into the same trap as DHCP. In practice, neither of them needs its own gate:

- `ca_ntp_service_net_ready()` and `ca_dns_service_net_ready()` are called **inside** `on_dhcp_bound`;

- `task_dns_demo` waits for `s_dns_demo_sem`, which is posted by the same callback;
- **a lease cannot exist if the link is down**, so the DHCP gate already protects the entire chain.

The `bind()` instead are all **before** the gate (steps 5–7): registering a port sends nothing over the network, and must be done before a response can arrive.

> **The `trywait` before the `post` is not a refinement.** In `on_dhcp_bound` the demo semaphore is first emptied and then reposted:
>
> ```
> ca_sem_trywait(&s_dns_demo_sem);   /* consumes any residual count */
> ca_sem_post(&s_dns_demo_sem);
> ```
>
> The semaphore is created with `max_count = 1`, and `ca_sem_post()` **triggers `CA_SAFEGUARD` if the count exceeds the maximum**. At the first bound, the demo consumes the token and everything returns to zero; but if a renewal were to arrive *before* `task_dns_demo` has started, the token would still be there and the second `post` would be an overflow — that is, a system halt, not a demo executed twice. The `trywait` makes the operation idempotent and the sequence safe at every rebind.

The link monitor

`task_ncm_mon` is the NCM counterpart to `task_eth_mon` of ex37: it samples `ca_usb_ncm_is_up()` every 500 ms and signals transitions. If the link comes back up while a lease is active, it requests a renew, which also propagates NTP and DNS by passing through `on_dhcp_bound` again.

95.1.7 Expected UART output

```
=== EX72: DHCP + NTP + DNS + ARP + ping + UDP server su USB-NCM ===
MAC  02:CA:05:00:00:72
IP   --- (waiting for DHCP)
waiting for the host to bring the interface up...
USB NCM UP
DHCP: avvio DORA...

DHCP BOUND  IP=192.168.10.100  mask=255.255.255.0
            GW=192.168.10.1  DNS=192.168.10.1
NTP SYNC  unix=1787316943  2026-08-21 12:55:43 UTC

DNS: avvio risoluzioni demo...
DNS  test.caos.local           ->  192.168.10.1
DNS  gateway.caos.local        ->  192.168.10.1
DNS  pool.ntp.org              ->  162.159.200.1
DNS: demo completato - usa CLI 'dns resolve <hostname>'
```

The first two names are resolved **statically** by the Python resolver; the third goes through **upstream forwarding**, so its success depends on the PC's Internet connectivity — if it is missing, `FAILED` is expected and is not a firmware defect.

95.1.8 Technical notes

Two MACs, one for each side

`s_mac` (`02:CA:05:00:00:72`) is the device MAC; `s_ncm.mac` (`02:CA:05:00:00:B2`) is the one announced to the host side — hence the name `enx02ca050000b2` of the interface on the PC, which is what the script looks for. The two **must differ**.

`ca_dns_resolve` is blocking

`task_dns_demo` runs on its own task (`dns_demo`, LEVEL3) and not in the net task, because `ca_dns_resolve()` **blocks** until the response or timeout (10 s here). Calling it from the net task would stop `ca_net_process()` and therefore the response itself — the same reason why `ca_dhcp_service_bind()` must not be called there.

The dynamic IP and the three mirrors

At bind, the address must be propagated to three subsystems, or they will remain misaligned:

```
ca_net_proto_set_local_ip(ip);        /* IP stack: filter for incoming packets */
ca_udp_server_set_local_ip(ip);       /* UDP server: source address of the replies */
ca_arp_service_update_local_ip(ip);   /* ARP: a quale IP rispondere */
```

It is the same sequence as ex37, ex70, and ex71: it does not change with transport.

95.1.9 File structure

```
examples/example_72/
          ca_os_ex72.c                entry point
          os_config_ex_72.h           configurazione (generata da ex37)
          test_dhcp_dns_ncm_pc.sh     setup dnsmasq + NTP + DNS su usb0 + test
```

Chapter 96

mDNS Responder over USB-NCM

96.1 Example 73 — mDNS Responder over USB-NCM

96.1.1 Introduction

Variant of **example 38** (mDNS responder over Ethernet) using USB-NCM. The services are the same — DHCP client with DORA and renewal, mDNS responder, ARP, ICMP echo, UDP server on port 7961 — but the transport is USB instead of Ethernet MAC.

The novelty compared to previous clones is the service type: mDNS is **multicast peer-to-peer**, not client-server. It is the only cloned service so far that **does not require a server on the PC**: any existing Bonjour/avahi resolver on the host interrogates it, and the board responds by itself.

Feature	Notes
DHCP Client	Full DORA + T1/T2 renewal
mDNS Responder	responds to `caos-board.local` on 224.0.0.251:5353
Gratuitous Announce	sent on every bound/renew
GARP	sent on every bound/renew
ARP Service	initial IP 0.0.0.0, updated on bound
ICMP echo reply	responds to `ping` on the obtained address
UDP Server 7961	up to 2 simultaneous clients
USB Ethernet (NCM)	device `usb0` / `enxNN`

96.1.2 PC Prerequisite: Remove the interface from NetworkManager

When the board enumerates, a new network interface (`enx02ca0500xx` — the name udev derives from the MAC) appears on the PC. NetworkManager sees it as any regular attached card and **assigns it an address**: it has been observed `172.21.10.100/24`. The board is on `192.168.10.0/24`, so the two end up on different subnets and the board becomes unreachable.

The symptom is misleading, because the interface **exists and is UP**: `ip link` shows it, and even `ping -I <iface>` responds — that flag bypasses the routing table. What fails is everything else (`socat`, `nc`, PC scripts from the examples), which follows the routing table.

The rule is versioned in the repository:

```
sudo cp tools/99-caos-ncm.conf /etc/NetworkManager/conf.d/
sudo systemctl reload NetworkManager
nmcli -t -f DEVICE,STATE dev status | grep enx    # it must say: unmanaged
```

The glob goes to `interface-name`, not to `mac:`. The form `mac:02:ca:05:00:00:*` seems equivalent but it is not: it requires a full MAC and fails **silently** with a wildcard character — no error, and the interface remains managed.

The address of the bank does not set this rule: it is set by `sudo ./tools/bench_net.sh usb` or the PC script of the example.

96.1.3 mDNS does not need a server

This is the difference with ex70/71/72. There, the PC had to act as DHCP, NTP and DNS server, because on a point-to-point cable there is no one else. mDNS instead **has no server** by definition: it is a multicast query to which the one who owns the name responds directly. The PC is only needed as *querying* device.

The script therefore mounts `dnsmasq` only for DHCP (which remains necessary to assign an address to the board) and uses avahi as **client**:

```
sudo examples/example_73/test_mdns_ncm_pc.sh
```

Find the interface from MAC `02:ca:05` by itself, then perform three independent tests:

1. `avahi-resolve -n caos-board.local` — passes through the system daemon;
2. `ping caos-board.local` — verifies that the resolution is usable by the entire PC stack, not just the tool;
3. a **raw mDNS query in Python**, which bypasses avahi entirely: this is the test that isolates the firmware from the PC configuration.

The bug that this test has already paid for once. The raw query sets `IP_MULTICAST_IF`, and that `setsockopt` **requires an address that is actually assigned to the interface**: if an IP that the NIC does not have is passed, it fails with `Errno 99` *before even sending*, and the error message would wrongly blame the card. The script therefore reads the real IP from `ip -4 -br addr show $IFACE` instead of assuming `192.168.10.1` — correction from 21/08, inherited intact from ex38.

96.1.4 Hardware

MCU	`USB_NUM`	Connector	LED heartbeat
U575 (NUCLEO-U575ZI-Q)	0	USB user	PC7 (LD1)
H753 (NUCLEO-H753ZI)	1	CN14 (OTG_FS)	PB7 (LD2)
F407 (STM32F4VE)	0	USB device	PA6 (D2)
H563 (NUCLEO-H563ZI)	0	USB user	PB0 (LD1)

96.1.5 os_config.h Configuration

```
#define EN_NET           1
#define EN_USB           1
#define EN_USB_NCM       1
#define EN_NET_DHCP      1     /* DHCP protocol in the net core */
#define EN_DHCP_SERVICE  1     /* task client DHCP */
```

```
#define EN_NET_MDNS       1     /* mDNS protocol in the net core */
#define EN_MDNS_SERVICE   1     /* task responder mDNS */
#define EN_UDP_SERVER     1
#define EN_ARP_SERVICE    1
```

Off with respect to ex38: `EN_ETH 0`, `EN_CLI_ETH 0`, `EN_USB_CDC 0`.

```
python3 tools/caos_config.py --new 73 --from ex38 \
        --set EN_ETH=0 --set EN_USB=1 --set EN_USB_NCM=1 --set EN_USB_CDC=0
python3 tools/caos_config.py --off EN_CLI_ETH 73
```

Compared to ex70, the config differs by **exactly three flags** — `EN_NET_MDNS`, `EN_MDNS_SERVICE`, `EN_CLI_MDNS`:

```
python3 tools/caos_config.py --diff 70 73
```

96.1.6 Boot Sequence

```
task_net:
  1. ca_usb_dev_mng_init/add/start      bring-up USB
  2. ca_net_init(ca_ncm_iface_get())    NCM becomes the net core iface
  3. ca_net_proto_init(&net_cfg)        stack con IP = 0.0.0.0
  4. ca_net_proto_bind_udp(68,    )       porta 68 per OFFER/ACK
  5. ca_udp_server_bind()               porta 7961
  6. ca_mdns_service_bind()             porta 5353 multicast
  7. loop: as soon as the link is up     ca_dhcp_service_net_ready()     the
    DORA starts
          then ca_sem_timedwait() + ca_net_process()

on_dhcp_bound (callback, from the DHCP task):
      ca_mdns_service_net_ready(ip)       impara l'IP e manda l'announce
    gratuito
```

The gate of step 7 is specific to NCM. The NCM link goes up only when the host selects the alt setting 1: as long as it is down, `ca_usb_ncm_send_frame()` **discards every frame and returns** `false`, so a DISCOVER sent too early is not delayed, it is **lost**.

> **Where to put the wait — and where not to.** The gate **must be inside the loop**, not before: blocking the net task in wait for the link *before* serving frames prevents enumeration itself (the host reports `device not accepting address`). For the same reason the loop uses `ca_sem_timedwait(&ca_net_rx_sem, 100)` and not `ca_sem_wait()`.

mDNS confirms the rule seen in ex71 and ex72: **only the first service that speaks needs a gate**. The gratuitous announce starts from `on_dhcp_bound`, and a lease cannot exist if the link is down. `ca_mdns_service_bind()` instead is placed before the gate, like all the `bind()`: registering port 5353 does not send anything on the network.

The link monitor

`task_ncm_mon` samples `ca_usb_ncm_is_up()` every 500 ms. If the link comes back up while a lease is active it asks for a renew — which here has an additional effect compared to other clones: **it re-announces mDNS as well**, because the announce is tied to `on_dhcp_bound`. This is the correct behavior after a cable reconnection, when the peers might have cached an stale binding.

96.1.7 Note: `task_stats` without `held`

This is the first clone that inherits a `task_stats`, and does not carry it identically. On ETH (ex38) the count is:

```
u16 fc   = ca_net_buf_free_count();
u16 held = ca_eth_pool_held_count();   /* buffers held by the descriptors */
if (fc + held != NET_BUF_COUNT)
```

`ca_eth_pool_held_count()` lives **inside** `#if EN_ETH` (`caos/drivers/src/eth.c:14`), so it is not compiled with `EN_ETH 0`. But the difference is not only compilation-related: on NCM **the concept that that function measures** does not exist. There is no DMA descriptor ring that holds buffers, so at rest the pool must simply be full:

```
u16 fc = ca_net_buf_free_count();
if (fc != NET_BUF_COUNT)       /* "in transit" */
```

On ETH the structural ceiling measured on H753 is `ETH_RX_N + ETH_TX_N` = 24 buffers held at steady state, and the leak criterion is `pool_free + held < NET_BUF_COUNT`. On NCM the criterion simplifies: **any permanent shortfall is a true leak**.

96.1.8 Expected UART Output

```
=== EX73: DHCP + mDNS + ARP + ping + UDP server su USB-NCM ===
MAC          02:CA:05:00:00:73
mDNS         caos-board.local
IP           --- (waiting for DHCP)
waiting for the host to bring the interface up...
USB NCM UP
DHCP: avvio DORA...

DHCP BOUND  IP=192.168.10.100  mask=255.255.255.0
            GW=192.168.10.1
STATS dhcp=BOUND pool=64/64 rx=12 drop=0 tx=8
UDP[7961] client 0: 192.168.10.1:51234 connesso
```

On the PC side, the success is read in the resolution:

```
[ OK ]  avahi-resolve: caos-board.local   192.168.10.100
[ OK ]  ping caos-board.local OK
[ OK ]  mDNS raw OK
```

The third one is the most significant: being independent from avahi, it demonstrates that the reply comes from the firmware and not from a PC cache.

96.1.9 Technical notes

Two MACs, one per side

`s_mac` (`02:CA:05:00:00:73`) is the device MAC; `s_ncm.mac` (`02:CA:05:00:00:B3`) is the one announced on the host side — from which the name `enx02ca050000b3` of the interface on the PC comes, the one the script looks for. The two **must differ**.

The name must match both ends

`MDNS_HOSTNAME` in the firmware and `MDNS_HOSTNAME` in the script must be the same (`caos-board`). Changing it in only one of the two causes the test to fail with an empty resolution — which is indistinguishable from a non-working responder.

The dynamic IP and the three mirrors

At binding, the address must be propagated to three subsystems, or they remain misaligned:

```
ca_net_proto_set_local_ip(ip);        /* IP stack: filter for incoming packets */
ca_udp_server_set_local_ip(ip);       /* UDP server: source address of the replies */
ca_arp_service_update_local_ip(ip);   /* ARP: a quale IP rispondere */
```

More the fourth, specific to this example: `ca_mdns_service_net_ready(ip)`, which is together address update and trigger of the announce.

96.1.10 File structure

          test_mdns_ncm_pc.sh     dnsmasq (DHCP only) + avahi + raw Python query
```

Chapter 97

Syslog Service over USB-NCM

97.1 Example 74 — Syslog service over USB-NCM

97.1.1 Introduction

Variant of **example 39** (syslog client over Ethernet). The services are the same — DHCP client with DORA and renewal, sending RFC 3164 syslog messages over UDP 514, ARP, ICMP echo — but the transport is the USB port instead of the Ethernet MAC.

Compared to previous clones, this example has a feature that sets it apart: the syslog is **transmit-only**. It has no `bind()`, it listens to nothing, and it does not respond to anyone. It is the first cloned service that speaks and that's it, and this makes visible a consequence of the NCM gate that remained hidden in the others.

Feature	Notes
DHCP client	Full DORA + T1/T2 renewal
Syslog service	RFC 3164 to UDP 514, facility `local0`
ARP service	Resolves the MAC address of the syslog server
ICMP echo reply	Replies to `ping` on the acquired address
Drop counter	`ca_syslog_dropped()`, reported in stats
USB Ethernet (NCM)	Device `usb0` / `enxNN`

Message sources:

Source	Severity	Message
`on_dhcp_bound`	INFO	`EX74 BOUND IP=x.x.x.x`
`on_dhcp_expire`	WARN	`EX74 DHCP lease expired`
`task_ncm_mon`	INFO/WARN	`EX74 USB NCM link UP/DOWN`
`task_heartbeat`	DEBUG	`EX74 heartbeat seq=N pool=M` (30 s)
`task_stats`	INFO	`EX74 stats rx= tx= drop= slg_drop=` (60 s)

97.1.2 PC Prerequisite: Remove the interface from NetworkManager

When the board enumerates, a new network interface appears on the PC (`enx02ca0500xx` — the name udev derives from the MAC). NetworkManager sees it as any other newly connected card and **assigns it an address of its own**: it has been observed that `172.21.10.100/24`. The board is on `192.168.10.0/24`, so the two end up on different subnets and the board becomes unreachable.

The symptom is misleading, because the interface **exists and is UP**: `ip link` shows it, and even `ping -I <iface>` responds — that flag bypasses the routing table. What doesn't work is everything else (`socat`, `nc`, the PC scripts of the examples), which follow the routing table.

The rule is versioned in the repository:

```
sudo cp tools/99-caos-ncm.conf /etc/NetworkManager/conf.d/
sudo systemctl reload NetworkManager
nmcli -t -f DEVICE,STATE dev status | grep enx    # it must say: unmanaged
```

> **The glob goes to `interface-name`, not to `mac:`.** The form `mac:02:ca:05:00:00:*` seems equivalent but it is not: it requires a complete MAC and fails **silently** with a wildcard character — no error, and the interface remains managed.

The bank address does not set this rule: it is set by `sudo ./tools/bench_net.sh usb` or the example PC script.

97.1.3 The first "link UP" waits in queue, and arrives together with the bound

This is the point that this example makes visible. In `task_ncm_mon` the link transition sends a syslog message:

```
if (up)
    ca_syslog_send(SYSLOG_SEV_INFO, "EX74 USB NCM link UP");
```

But the **first** time the link goes up, DHCP does not yet have an address: the board is at `0.0.0.0` and the DORA is just starting. However, the message is **not lost**, and this is the difference from network frames: the syslog is decoupled from a queue.

```
void ca_syslog_send(u8 severity, const char *msg)
{

    if (!ca_queue_static_trysend(&s_syslog_q.q, &entry))
        s_dropped++;          /* only if the QUEUE is full */
}
```

`ca_syslog_send()` just queues and that's it; it is the syslog task that sends, and that task is blocked on its own gate until `ca_syslog_service_net_ready()` arrives:

```
while (!s_net_ready)
    ca_os_sleep(200U);
```

The "link UP" message therefore remains queued and **is sent as soon as the lease exists**. And since `EX74 BOUND` also goes through the same `ca_syslog_send()` — there is no synchronous shortcut for bound messages — the two are queued in the same order in which the events occurred:

```
t    task_ncm_mon sees the link come up      queues "link UP"
t    the lease arrives, on_dhcp_bound       queues "BOUND"
t    ca_syslog_service_net_ready()           the task passes the gate and drains
    the queue
```

The queue is FIFO, so on the server events arrive **in event order** — first `link UP`, then `BOUND` — but with the **same timestamp**, because they were sent in burst when the gate opened:

```
[15:21:27.971] 192.168.10.126:514  [INFO  ]  EX74 USB NCM link UP
[15:21:27.971] 192.168.10.126:514  [INFO  ]  EX74 BOUND IP=192.168.10.126
```

It is the same timestamp, not the order, the detail that reveals the decoupling: two separate events delivered at the same instant.

What `slg_drop` means. It does not count messages born without IP — those wait in the queue. It only counts those lost because **the queue was full**, that is because the task was unable to process them. A growing `slg_drop` indicates a real problem: unreachable server, ARP not resolving, or messages produced faster than the network can carry them away. It must remain at zero at steady state.

97.1.4 The PC acts as syslog server and as DHCP server

As for the other clones, on a point-to-point cable the PC must provide DHCP. In addition, here, it must also listen to syslog messages. The script does both:

```
sudo python3 examples/example_74/syslog_server_ncm.py
```

It finds the interface from MAC `02:ca:05` (waiting up to 30 s for it to appear with enumeration), assigns `192.168.10.1/24`, starts `dnsmasq` for DHCP and listens on UDP 514 decoding RFC 3164 priority and severity. On exit (Ctrl+C) it performs full cleanup and **restores the previous IP** of the interface.

Useful variants:

```
sudo python3 syslog_server_ncm.py --iface usb0    # explicit interface
sudo python3 syslog_server_ncm.py --no-dhcp       # syslog only, on 0.0.0.0
```

97.1.5 Hardware

MCU	`USB_NUM`	Connector	LED heartbeat
U575 (NUCLEO-U575ZI-Q)	0	USB user	PC7 (LD1)
H753 (NUCLEO-H753ZI)	1	CN14 (OTG_FS)	PB7 (LD2)
F407 (STM32F4VE)	0	USB device	PA6 (D2)
H563 (NUCLEO-H563ZI)	0	USB user	PB0 (LD1)

97.1.6 os_config.h Configuration

```
#define EN_NET             1
#define EN_USB             1
#define EN_USB_NCM         1
#define EN_NET_DHCP        1     /* DHCP protocol in the net core */
#define EN_DHCP_SERVICE    1     /* task client DHCP */
#define EN_NET_SYSLOG      1     /* syslog protocol in the net core */
#define EN_SYSLOG_SERVICE  1     /* task syslog */
#define EN_ARP_SERVICE     1
```

Off with respect to ex39: `EN_ETH 0`, `EN_CLI_ETH 0`, `EN_USB_CDC 0`.

```
python3 tools/caos_config.py --new 74 --from ex39 \
        --set EN_ETH=0 --set EN_USB=1 --set EN_USB_NCM=1 --set EN_USB_CDC=0
python3 tools/caos_config.py --off EN_CLI_ETH 74
```

Compared to ex70, the config differs by **five** flags, not three as in the previous clones — because ex39 does not have the UDP server that ex34-38 had:

```
EN_NET_SYSLOG      0 -> 1
EN_SYSLOG_SERVICE  0 -> 1
EN_CLI_SYSLOG      0 -> 1
EN_UDP_SERVER      1 -> 0
EN_CLI_UDP_SRV     1 -> 0
```

97.1.7 Boot Sequence

```
task_net:
  1. ca_usb_dev_mng_init/add/start      bring-up USB
  2. ca_net_init(ca_ncm_iface_get())    NCM becomes the net core iface
  3. ca_net_proto_init(&net_cfg)        stack con IP = 0.0.0.0
  4. ca_net_proto_bind_udp(68,    )       porta 68 per OFFER/ACK
  5. loop: as soon as the link is up     ca_dhcp_service_net_ready()     the
    DORA starts
          then ca_sem_timedwait() + ca_net_process()

on_dhcp_bound (callback, from the DHCP task):
      ca_syslog_service_net_ready()       unblocks the syslog task
      ca_syslog_send(INFO, "EX74 BOUND IP=   ")
```

Note the absence of a `bind()` for syslog at step 5: **there isn't one**, because the service receives nothing. It is the `bind()` list that is shorter than all the clones.

The gate of step 5 is specific to NCM. The NCM link only goes up when the host selects alternate setting 1: as long as it is down, `ca_usb_ncm_send_frame()` **discards every frame and returns** `false`, so a DISCOVER sent too early is not delayed, it is **lost**.

> **Where to put the wait — and where not to.** The gate **must be inside the loop**, not before: blocking the net task waiting for the link *before* serving frames prevents enumeration itself (the host reports `device not accepting address`). For the same reason the loop uses `ca_sem_timedwait(&ca_net_rx_sem, 100)` and not `ca_sem_wait()`.

The syslog confirms the rule from ex71/72/73: **only the first service that speaks needs a gate**. `ca_syslog_service_net_ready()` is called from `on_dhcp_bound`, and a lease cannot exist with the link down.

97.1.8 Expected output

Board console:

```
=== EX74: DHCP + Syslog service su USB-NCM ===
MAC          02:CA:05:00:00:74
IP           --- (waiting for DHCP)
Syslog       -> 192.168.10.1:514
waiting for the host to bring the interface up...
USB NCM LINK UP          <- syslog queued: no IP yet, sent after the bound
USB NCM UP
DHCP: avvio DORA...

DHCP BOUND  IP=192.168.10.100  mask=255.255.255.0
            GW=192.168.10.1
```

Server on PC (measured on H753):

```
[15:21:27.971] 192.168.10.126:514  [INFO  ]  EX74 USB NCM link UP
[15:21:27.971] 192.168.10.126:514  [INFO  ]  EX74 BOUND IP=192.168.10.126
[15:21:57.xxx] 192.168.10.126:514  [DEBUG ]  EX74 heartbeat seq=0 pool=64/64
[15:22:27.xxx] 192.168.10.126:514  [INFO  ]  EX74 stats rx=    tx=    drop=0
   slg_drop=0
```

The first two lines have the **same timestamp** even though they describe distinct events: it is the signature of the queue de-coupling, both were issued when the gate opened. `slg_drop` must remain **0**.

The times are long on purpose: heartbeat every 30 s, stats every 60 s. For a quick check, it's enough to look for the bound message, which arrives immediately.

97.1.9 Technical notes

Two MACs, one per side

`s_mac` (`02:CA:05:00:00:74`) is the device MAC; `s_ncm.mac` (`02:CA:05:00:00:B4`) is the one announced to the host side — from which the name `enx02ca050000b4` of the interface on the PC comes, the one the script looks for. The two **must be different**.

ARP is really needed here

In examples that just reply and that's it, ARP is almost implicit: one replies to whoever just wrote, and their MAC is already known. The syslog instead **starts the conversation** toward a configured address, so the server's MAC must be resolved before sending. This is the reason why `EN_ARP_SERVICE` is an explicit requirement of this example, not an accessory.

There is no UDP server

Unlike ex70–73, `EN_UDP_SERVER` is off: ex39 did not foresee it and the clone remains faithful. The UDP echo tests from the other examples here do not apply; the verification is the appearance of messages on the syslog server.

97.1.10 File structure

```

Chapter 98

TCP Client over USB-NCM

98.1 Example 75 — TCP Client (HTTP GET) over USB-NCM

98.1.1 Introduction

USB-NCM variant of **example 40** (TCP client over Ethernet). The services are the same — DHCP client with DORA and renewal, ARP, TCP client that opens a connection, sends a `GET` and reads the response until closure — but the transport is the USB port instead of the Ethernet MAC.

It is the **first TCP clone** of the series: ex69–74 were all UDP. The leap is significant because TCP introduces a connection state — handshake, sequences, retransmissions, orderly closure — which must be exercised for the first time on a point-to-point USB pipe.

Feature	Notes
DHCP client	Full DORA + T1/T2 renewal
ARP service	resolves the TCP server MAC before connect
TCP client	connect → `GET` → recv until closure → close
Reconnection	every `TCP_RETRY_PERIOD_MS` (30 s) after closure or error
ICMP echo reply	responds to `ping` on the obtained address
USB Ethernet (NCM)	device `usb0` / `enxNN`

98.1.2 PC Prerequisite: detach the interface from NetworkManager

When the board enumerates, a new network interface appears on the PC (`enx02ca0500xx` — the name that udev derives from the MAC). NetworkManager sees it as any newly connected card and **assigns its own address to it**: `172.21.10.100/24` has been observed. The board is on `192.168.10.0/24`, so the two end up on different subnets and the board is unreachable.

The symptom is misleading, because the interface **exists and is UP**: `ip link` shows it, and even `ping -I <iface>` responds — that flag bypasses the routing table. Everything else fails (`socat`, `nc`, the PC scripts of the examples), which follows the routing table.

The rule is versioned in the repository:

```
sudo cp tools/99-caos-ncm.conf /etc/NetworkManager/conf.d/
sudo systemctl reload NetworkManager
nmcli -t -f DEVICE,STATE dev status | grep enx    # it must say: unmanaged
```

> **The glob goes on `interface-name`, not on `mac:`.** The form `mac:02:ca:05:00:00:*` seems equivalent but it is not: it expects a complete MAC and fails **silently** with a wildcard — no error, and the interface remains managed.

The bank address is not set by this rule: it is set by `sudo ./tools/bench_net.sh usb` or the PC script in the example.

98.1.3 What changes compared to UDP clones

With UDP, the packet either leaves or is lost, and that's it. With TCP, the connection has a state, and on the NCM path there are two points worth looking at.

ARP becomes a blocking prerequisite. `ca_tcp_connect()` cannot send the SYN before knowing the server's MAC: it resolves the ARP and only then opens. On a point-to-point link, the peer is always the PC, so the resolution is immediate — but it remains a step that, if it were to fail, would cause the connect to fail *before* any TCP traffic.

Retry is integrated into the design. The client loop retries every 30 s in case of error, and this also covers the case where the server on the PC has not yet started. There is no need to synchronize the power-on of the two sides precisely.

> **The first connect may fail — it is known and not part of this example.** On ETH it has been observed (ex42 MQTT, ex43 Modbus, 08/21) that the **first** `connect` fails and the subsequent retry succeeds. The current hypothesis is that the connect starts before the ARP has resolved the peer's MAC. If the line `TCP connect FAILED err=1` followed by a `TCP ESTABLISHED` on the next attempt also appears here, it is that known behavior of the TCP layer, not a defect of the NCM transport.

98.1.4 The PC acts as a DHCP server and a TCP server

As with the other clones, on a point-to-point cable the PC must provide DHCP; here, in addition, it must act as an HTTP server on port 8080. The script does both:

```
sudo python3 examples/example_75/tcp_server_ncm.py
```

It automatically finds the interface from the MAC `02:ca:05` (waiting up to 30 s for it to appear via enumeration), assigns it `192.168.10.1/24`, starts `dnsmasq` for DHCP, and listens on TCP 8080, responding to every `GET` with a text body. Upon exit, it performs cleanup and **restores the previous IP** of the interface.

```
sudo python3 tcp_server_ncm.py --iface usb0     # explicit interface
sudo python3 tcp_server_ncm.py --no-dhcp        # TCP only, on 0.0.0.0
sudo python3 tcp_server_ncm.py --port 9090      # different port (align the
    firmware)
```

98.1.5 Hardware

MCU	`USB_NUM`	Connector	Heartbeat LED
U575 (NUCLEO-U575ZI-Q)	0	USB user	PC7 (LD1)
H753 (NUCLEO-H753ZI)	1	CN14 (OTG_FS)	PB7 (LD2)
F407 (STM32F4VE)	0	USB device	PA6 (D2)
H563 (NUCLEO-H563ZI)	0	USB user	PB0 (LD1)

98.1.6 os_config.h configuration

```
#define EN_NET            1
#define EN_USB            1
#define EN_USB_NCM        1
#define EN_NET_DHCP       1     /* DHCP protocol in the net core */
#define EN_DHCP_SERVICE   1     /* task client DHCP */
#define EN_TCP_SERVICE    1     /* stack TCP */
#define EN_ARP_SERVICE    1
```

Off compared to ex40: `EN_ETH 0`, `EN_CLI_ETH 0`, `EN_USB_CDC 0`.

```
python3 tools/caos_config.py --new 75 --from ex40 \
        --set EN_ETH=0 --set EN_USB=1 --set EN_USB_NCM=1 --set EN_USB_CDC=0
python3 tools/caos_config.py --off EN_CLI_ETH 75
```

Compared to ex70, the configuration differs by **four** flags: `EN_TCP_SERVICE` and `EN_CLI_TCP` enabled, `EN_UDP_SERVER` and `EN_CLI_UDP_SRV` disabled (ex40 did not have the UDP server).

98.1.7 Startup sequence

```
task_net:
  1. ca_usb_dev_mng_init/add/start      bring-up USB
  2. ca_net_init(ca_ncm_iface_get())    NCM becomes the net core iface
  3. ca_net_proto_init(&net_cfg)        stack con IP = 0.0.0.0
  4. ca_net_proto_bind_udp(68,    )       porta 68 per OFFER/ACK
  5. loop: as soon as the link is up     ca_dhcp_service_net_ready()     the
    DORA starts
           then ca_sem_timedwait() + ca_net_process()

on_dhcp_bound (callback, from the DHCP task):
      ca_sem_trywait/post(&s_dhcp_sem)    sblocca task_tcp

task_tcp:
  ca_sem_wait(&s_dhcp_sem)
  loop: connect     send GET     recv until close     close     sleep 30 s
```

No `bind()` for TCP at step 5: the client **opens** the connection, it does not listen. This is the same reason why the syslog of ex74 did not have any.

The gate at step 5 is specific to NCM. The NCM link only comes up when the host selects alt setting 1: as long as it is down, `ca_usb_ncm_send_frame()` **discards every frame and returns** `false`, so a DISCOVER sent too early is not delayed, it is **lost**.

> **Where to place the wait — and where not to.** The gate **must be inside the loop**, not before: blocking the net task waiting for the link *before* serving frames prevents enumeration itself (the host reports `device not accepting address`). For the same reason, the loop uses `ca_sem_timedwait(&ca_net_rx_sem, 100)` and not `ca_sem_wait()`.

The TCP client confirms the rule: **a gate is only needed for the first service that speaks**. `task_tcp` waits for `s_dhcp_sem`, posted by `on_dhcp_bound`, and a lease cannot exist with the link down.

> **The `trywait` before the `post`.** The semaphore has `max_count = 1` and `ca_sem_post()` triggers `CA_SAFEGUARD` in overflow. If a lease renewal arrived before `task_tcp` had consumed the token, the second `post` would be a system halt. The `trywait` drains any residue and makes the pair idempotent — a precaution added in this clone, not present in ex40.

98.1.8 Expected output

Board console:

```
=== EX75: TCP client HTTP GET su USB-NCM ===
MAC          02:CA:05:00:00:75
TCP server   192.168.10.1:8080
waiting for the host to bring the interface up...
USB NCM UP
DHCP: avvio DORA...

DHCP BOUND  IP=192.168.10.100
TCP: DHCP bound, avvio client loop

TCP connect -> 192.168.10.1:8080
TCP ESTABLISHED  h=1  ok=1
TCP send GET  OK
TCP rx 167 byte:
HTTP/1.0 200 OK

TCP session done  total_rx=167 byte
```

On the PC side, the server records the connection with **source port** and bytes sent: comparing the two logs provides the end-to-end verification, just as on ex40 where the source port and count matched exactly.

98.1.9 Technical notes

Two MACs, one for each side

`s_mac` (`02:CA:05:00:00:75`) is the device MAC; `s_ncm.mac` (`02:CA:05:00:00:B5`) is the one announced to the host side — hence the name `enx02ca050000b5` of the interface on the PC, which is what the script looks for. The two **must differ**.

ca_tcp_recv is blocking, and resides on its own task

`task_tcp` is a separate task (LEVEL3) and not the net task, because both `ca_tcp_connect()` and `ca_tcp_recv()` **block**. Calling them from the net task would stop `ca_net_process()` — that is, exactly what needs to run to deliver incoming segments — and the connection would never progress. It is the same constraint as `ca_dns_resolve()` in ex72 and `ca_dhcp_service_bind()` everywhere else.

The read cycle

```
while (ca_tcp_is_connected(h)) {
    bool ok = ca_tcp_recv(h, rx_buf, sizeof(rx_buf) - 1, &got,
    TCP_RECV_TIMEOUT_MS);
    if (!ok || got == 0U) break;

}
```

The exit condition is twofold: the closure seen from the connection state *or* a `recv` that produces no data. Both are needed because the HTTP/1.0 response ends with the server closing the connection (`Connection: close`), and depending on when the FIN arrives, one of the two conditions triggers first.

98.1.10 File structure

```

Chapter 99

TCP Echo Server over USB-NCM

99.1 Example 76 — TCP echo server over USB-NCM

99.1.1 Introduction

Variant USB-NCM of **example 41** (TCP server over Ethernet). The services are the same — DHCP client, ARP, TCP echo server RFC 862 on port 7 — but the transport is the USB port instead of the Ethernet MAC.

It is the **reverse role of ex75**: there the board opened the connection to the PC, here the board stays in `accept` and the PC connects. Together the two examples cover TCP in both directions on NCM.

Feature	Notes
DHCP client	Full DORA + T1/T2 renewal
ARP service	resolves client MAC
TCP port 7 server	RFC 862 echo, one connection at a time
Blocking accept	`ca_tcp_accept()` with timeout, retry in loop
ICMP echo reply	replies to `ping` on the acquired address
USB Ethernet (NCM)	device `usb0` / `enxNN`

99.1.2 PC prerequisite: remove the interface from NetworkManager

When the board enumerates, a new network interface appears on the PC (`enx02ca0500xx` — the name udev derives from the MAC). NetworkManager sees it as any ordinary attached card and **assigns it an address of its own**: it has been observed `172.21.10.100/24`. The board is on `192.168.10.0/24`, so the two end up on different subnets and the board is unreachable.

The symptom is misleading, because the interface **exists and is UP**: `ip link` shows it, and even `ping -I <iface>` responds — that flag bypasses the routing table. What doesn't work is everything else (`socat`, `nc`, the PC scripts of the examples), which follow the routing table.

The rule is versioned in the repository:

```
sudo cp tools/99-caos-ncm.conf /etc/NetworkManager/conf.d/
sudo systemctl reload NetworkManager
nmcli -t -f DEVICE,STATE dev status | grep enx    # it must say: unmanaged
```

> **The glob goes to `interface-name`, not to `mac:`.** The form `mac:02:ca:05:00:00:*` seems equivalent but it is not: it requires a full MAC and fails **silently** with a wildcard character — no error, and the interface remains managed.

The bank address does not set this rule: it is set by `sudo ./tools/bench_net.sh usb` or the example PC script.

99.1.3 The real difference: where `ca_tcp_listen()` is located

This clone is not a mechanical transposition like the previous ones, because in ex41 the listen is in a location that on NCM **is not reachable**.

In ex41:

```
void ca_os_main(void)
{
    ca_tcp_service_start();
    /* listen with temporary IP 0.0.0.0 */
    s_lh = ca_tcp_listen(&lcfg);       /* <-- BEFORE ca_os_run() */
    ca_os_job("net",    );
    ca_os_run(true);
}
```

Here it works because on ETH `ca_net_init()` has already been called in `ca_os_configure()`: the network core exists before the scheduler starts.

On NCM **it cannot be so**. The NCM interface exists only after USB enumeration, so `ca_net_init()` lives inside `task_net` — and a `ca_tcp_listen()` in `ca_os_main()` would operate on a stack that has not yet been initialized. The listen is therefore moved to `task_net`, right after `ca_net_proto_init()`:

```
ca_net_proto_init(&net_cfg);
ca_net_proto_bind_udp(DHCP_CLIENT_PORT, dhcp_udp_handler);
s_lh = ca_tcp_listen(&lcfg);          /* 0.0.0.0, before the gate */
```

It is consistent with the rule that applies to all `bind()` of previous clones: **listening is passive, it puts nothing on the wire**, therefore it should be done before the link gate. What must come after is only what *transmits*.

The double listen

Listening is opened twice, and this is not a mistake:

```
/* in task_net: first listen, IP still 0.0.0.0 */
s_lh = ca_tcp_listen(&lcfg);

/* in on_dhcp_bound: re-armed with the real address */
ca_tcp_unlisten(s_lh);
lcfg.local_ip = ip;
s_lh = ca_tcp_listen(&lcfg);
```

The listening PCB carries with it the local address on which to accept. Open at `0.0.0.0` before the lease, it must be regenerated when the address arrives, or it would accept on an address that the board does not have. It is the same mechanism as in ex41 — on ETH as on NCM the problem is identical, because it stems from DHCP, not from the transport.

> The re-arm happens inside `on_dhcp_bound`, so **every renewal** regenerates the listening. It is intentional: if the lease were to change address, the server would follow.

99.1.4 The PC is the client

Reversal compared to the other clones: here the PC does not act as an application server, but connects to the board. It must still provide **DHCP**, because on a point-to-point cable there is no one else to provide it.

```
sudo python3 examples/example_76/tcp_client_ncm.py
```

The script finds the interface from MAC `02:ca:05`, assigns `192.168.10.1/24`, starts `dnsmasq`, **reads the assigned IP from the log** and connects to its port 7. Then every typed line is sent and read back from the echo.

```
sudo python3 tcp_client_ncm.py --iface usb0                  # explicit
    interface
sudo python3 tcp_client_ncm.py --host 192.168.10.128 --no-dhcp   # DHCP already
    running
```

Type `quit` to close the connection.

99.1.5 Hardware

MCU	`USB_NUM`	Connector	LED heartbeat
U575 (NUCLEO-U575ZI-Q)	0	USB user	PC7 (LD1)
H753 (NUCLEO-H753ZI)	1	CN14 (OTG_FS)	PB7 (LD2)
F407 (STM32F4VE)	0	USB device	PA6 (D2)
H563 (NUCLEO-H563ZI)	0	USB user	PB0 (LD1)

99.1.6 os_config.h configuration

```
#define EN_NET            1
#define EN_USB            1
#define EN_USB_NCM        1
#define EN_NET_DHCP       1
#define EN_DHCP_SERVICE   1
#define EN_TCP_SERVICE    1
#define EN_ARP_SERVICE    1
```

Off compared to ex41: `EN_ETH 0`, `EN_CLI_ETH 0`, `EN_USB_CDC 0`.

```
python3 tools/caos_config.py --new 76 --from ex41 \
        --set EN_ETH=0 --set EN_USB=1 --set EN_USB_NCM=1 --set EN_USB_CDC=0
python3 tools/caos_config.py --off EN_CLI_ETH 76
```

The config is **identical to that of ex75** (`caos_config.py --diff 75 76` does not report differences): client and server TCP turn on the same flags, the only thing that changes is the code. The accept timeout is a config parameter, not a source parameter:

```
#define TCP_TCP_ACCEPT_TIMEOUT_MS     10000U
```

99.1.7 Boot Sequence

```
task_net:
  1. ca_usb_dev_mng_init/add/start      bring-up USB
  2. ca_net_init(ca_ncm_iface_get())    NCM becomes the net core iface
  3. ca_net_proto_init(&net_cfg)        stack con IP = 0.0.0.0
  4. ca_net_proto_bind_udp(68,    )       porta 68 per OFFER/ACK
  5. ca_tcp_listen(0.0.0.0:7)           ascolto passivo, ri-armato al bound
  6. loop: as soon as the link is up     ca_dhcp_service_net_ready()     the
    DORA starts
          then ca_sem_timedwait() + ca_net_process()

on_dhcp_bound (callback, from the DHCP task):
      unlisten + listen again, with the real IP
      ca_sem_trywait/post(&s_dhcp_sem)    sblocca task_server

task_server:
  ca_sem_wait(&s_dhcp_sem)
  loop: accept (timeout 10 s)     recv/send in echo     close
```

The server does not need any link gate: **it only responds**, and when a client manages to reach it, the link is necessarily up. This is the same reason why ex69 (UDP server) did not need it.

> **The `trywait` before the `post`.** The semaphore has `max_count = 1` and `ca_sem_post()` triggers `CA_SAFEGUARD` on overflow. If a renewal arrives before `task_server` has consumed the token, the second `post` would be a halt. This precaution was added in this clone, as in ex75.

99.1.8 Expected output

Board console:

```
=== EX76: TCP echo server su USB-NCM ===
MAC     02:CA:05:00:00:76
Port    TCP:7  (RFC 862 echo)
waiting for the host to bring the interface up...
USB NCM UP
DHCP: avvio DORA...

DHCP BOUND  IP=192.168.10.100
TCP echo server on port 7
TCP server: listening on port 7
TCP accept  h=1  conn#1
  echo 5 byte: ciao
TCP close  h=1  session=5 byte  total=5 byte
```

On the PC side, each typed line returns unchanged. The comparison between the bytes counted by the board (`session=N`) and those sent by the client constitutes the end-to-end verification.

99.1.9 Technical Notes

Two MAC addresses, one for each side

`s_mac` (`02:CA:05:00:00:76`) is the device MAC; `s_ncm.mac` (`02:CA:05:00:00:B6`) is the one announced on the host side — from which the name `enx02ca050000b6` of the interface on the PC comes, which the script searches for. The two **must be different**.

The receive loop distinguishes between timeout and closure

```
bool ok = ca_tcp_recv(h, buf,    , &got, ECHO_RECV_TIMEOUT);
if (!ok) {
    if (ca_tcp_is_connected(h)) continue;   /* timeout only: retry */
    break;                                   /* the peer has closed */
}
```

A failed `recv` does not mean session end: with an interactive client typing slowly the 5 s timeout keeps firing continuously. The distinction is made by `ca_tcp_is_connected()`. Without this check the server would close the connection at every typing pause.

One connection at a time

`ca_tcp_accept()` is blocking and the loop serves one session at a time until closure. A second client waiting is accepted only after. This is the design of ex41, kept: to serve multiple connections in parallel a task per session would be needed, as the UDP server of ex69/70 does with its worker per-client.

99.1.10 File structure

```
examples/example_76/
          ca_os_ex76.c            entry point
          os_config_ex_76.h       configurazione (generata da ex41)
          tcp_client_ncm.py       client echo + DHCP con auto-detect NCM
```

Chapter 100

MQTT Client over USB-NCM

100.1 Example 77 — MQTT Client over USB-NCM

100.1.1 Introduction

Variant of **example 42** (MQTT client over Ethernet) using USB-NCM. The services are the same — DHCP client, ARP, MQTT v3.1.1 client that publishes status and receives commands — but the transport is USB instead of Ethernet MAC.

This is the first clone that implements an **application protocol over TCP**: ex75 and ex76 exercised raw TCP, here there is an MQTT session with CONNECT, SUBSCRIBE, PUBLISH and keepalive to be maintained over time.

Feature	Notes
DHCP Client	Full DORA + T1/T2 renewal
ARP Service	Resolves broker's MAC address
Publish	`caos/status` every 5 s, JSON payload with `seq`/`up`/`ip`
Subscribe	`caos/led` → `on`/`off` → LED
Keepalive	PING every 30 s (under `MQTT_KEEPALIVE_SEC` = 60)
Reconnection	Automatic every 8 s after disconnection
USB Ethernet (NCM)	Device `usb0` / `enxNN`

100.1.2 PC Prerequisite: Remove the interface from NetworkManager

When the board enumerates, a new network interface appears on the PC (`enx02ca0500xx` — the name udev derives from the MAC). NetworkManager sees it as any other newly connected card and **assigns it an address**: it has been observed `172.21.10.100/24`. The board is on `192.168.10.0/24`, so the two end up on different subnets and the board becomes unreachable.

The symptom is misleading, because the interface **exists and is UP**: `ip link` shows it, and even `ping -I <iface>` responds — that flag bypasses the routing table. What doesn't work is everything else (`socat`, `nc`, PC scripts from examples), which follow the routing table.

The rule is versioned in the repository:

```
sudo cp tools/99-caos-ncm.conf /etc/NetworkManager/conf.d/
sudo systemctl reload NetworkManager
nmcli -t -f DEVICE,STATE dev status | grep enx    # it must say: unmanaged
```

> **The glob goes to `interface-name`, not to `mac:`.** The form `mac:02:ca:05:00:00:*` seems equivalent but it is not: it requires a full MAC and fails **silently** with a wildcard character — no error, and the interface remains managed.

The bank address does not set this rule: it is set by `sudo ./tools/bench_net.sh usb` or the example PC script.

100.1.3 The broker is the gateway

On a point-to-point link the PC acts as gateway, DHCP server and MQTT broker. The firmware derives the broker address **from the lease**:

```
ca_ipv4_t broker_ip = s_gw;   /* the DHCP gateway: on p2p it is the PC */
```

It is not an NCM adaptation — it is what ex42 was already doing, where the test PC was also the gateway of the subnet. The advantage is that there is no hardcoded address in the firmware: changing the PC's subnet, the board follows suit.

This means that `ca_mqtt_service_init()` **cannot be in** `ca_os_configure()`: it needs the broker, which is only known after the bind. It therefore lives inside `task_mqtt`, after waiting on the semaphore — as in ex42.

100.1.4 The test that this example carries with it

On ETH it was observed (21/08, ex42 MQTT and ex43 Modbus) that **the first** `connect` **TCP always fails** and the automatic retry succeeds:

```
MQTT DISCONNECTED - riconnessione in corso...
MQTT: tentativo riconnessione...
MQTT CONNECTED  (#1)
```

The current assumption is that the connect starts before ARP has resolved the MAC address of the peer. On **ex75 (TCP client on NCM)**, this phenomenon did not occur: connection succeeded on the first attempt.

This example is therefore discriminant:

- if the first connect **fails here too**, the cause lies in the MQTT client or in the opening sequence, not in the transport layer;
- if it **does not fail**, it remains specific to the ETH path — and the difference with ex75 (which connects to a server already listening) must be sought elsewhere.

In neither case is this a defect of this clone: the automatic reconnection works by design.

100.1.5 Hardware

MCU	`USB_NUM`	Connector	LED MQTT (`caos/led`)	Heartbeat A	Heartbeat B
U575 (NUCLEO-U575ZI-Q)	0	USB user	PC7 (LD1)	PB7	PB14
H753 (NUCLEO-H753ZI)	1	CN14 (OTG_FS)	PB0 (LD1 green)	PB14 (LD3 red)	PB7 (LD2 blue)

MCU	USB_NUM	Connector	LED MQTT (caos/led)	Heartbeat A	Heartbeat B
F407 (STM32F4VE)	0	USB device	PA7 (D3)	PA6 (D2)	PA6 (single)
H563 (NUCLEO-H563ZI)	0	USB user	PB0 (LD1)	PF4 (LD2)	PG4 (LD3)

Three LEDs, three roles

The **green** follows `caos/led`. The **red** and **blue** perform heartbeat in **exclusive alternation**: when one is on, the other is off, and at each beat they swap.

The alternation is not achieved with two independent `toggle`, but by writing both pins together with opposite values:

```
hb = !hb;
ca_gpio_write(HB_A_GPIO_PORT, HB_A_GPIO_PIN, hb ? 1U : 0U);
ca_gpio_write(HB_B_GPIO_PORT, HB_B_GPIO_PIN, hb ? 0U : 1U);
```

With two separate `toggle`, the invariant "one on, one off" would depend on the initial state and could break (a fault, a task restart, a missed cycle): the two LEDs would end up on or off together, and from then on would remain in phase. By writing `hb` and `!hb`, the invariant holds **by construction at every cycle**, regardless of what happened before.

> **Why the heartbeat has its own dedicated pin.** If the heartbeat shared the pin with the MQTT command, every heartbeat write would overwrite the requested state and *on/off* would cease to be readable. On NUCLEO-H753ZI the LEDs are LD1 green PB0, LD2 blue PB7, LD3 red PB14; ex42 on ETH used PB0 for the command, and this clone maintains it.
>
> **On F4VE the alternation does not exist**: the board has only one free LED, so `HB_B` coincides with `HB_A` and the heartbeat remains a simple on/off.
>
> **Where the GPIO is configured.** All three pins are configured in `ca_os_configure()`, before any task starts. This is not a stylistic detail: the LEDs are driven by **different contexts** — the MQTT one from `on_mqtt_message()` (which runs in the MQTT service task), the heartbeat from `task_ncm_mon`. Leaving the `ca_gpio_configure()` inside one of the two tasks, the other could write to a pin not yet configured as output, and the first command would be lost. In other NCM clones this problem does not arise because only one task touches the LED and configures it by itself.
>
> Explicit port initialization is not needed instead: `ca_gpio_configure()` calls `ca_gpio_hw_init_port()` first, which enables the RCC clock of the port (with read-back of the register required by erratum RM0433 against BusFault IMPRECISERR) and is idempotent.

100.1.6 os_config.h Configuration

```
#define EN_NET            1
#define EN_USB            1
#define EN_USB_NCM        1
#define EN_NET_DHCP       1
#define EN_DHCP_SERVICE   1
#define EN_TCP_SERVICE    1     /* MQTT runs on top of TCP */
#define EN_MQTT_SERVICE   1
#define EN_ARP_SERVICE    1
```

Off with respect to ex42: `EN_ETH 0`, `EN_CLI_ETH 0`, `EN_USB_CDC 0`.

```
python3 tools/caos_config.py --new 77 --from ex42 \
        --set EN_ETH=0 --set EN_USB=1 --set EN_USB_NCM=1 --set EN_USB_CDC=0
python3 tools/caos_config.py --off EN_CLI_ETH 77
```

Compared to ex75 (TCP client), it differs by **only two flags**: `EN_MQTT_SERVICE` and `EN_CLI_MQTT`. The rest of the stack is identical, as is appropriate for a protocol that simply sits above TCP.

100.1.7 The PC: MQTT broker + DHCP

```
sudo python3 examples/example_77/mqtt_server_ncm.py
```

Find the interface from MAC `02:ca:05`, assign `192.168.10.1/24`, start `dnsmasq` for DHCP and `mosquitto` as broker, and connect a client `paho-mqtt` that prints messages to `caos/status` and allows sending commands.

Interactive commands after startup: `on` and `off` publish to `caos/led`.

```
apt install mosquitto dnsmasq
pip3 install paho-mqtt
```

100.1.8 Boot Sequence

```
task_net:
  1. ca_usb_dev_mng_init/add/start      bring-up USB
  2. ca_net_init(ca_ncm_iface_get())    NCM becomes the net core iface
  3. ca_net_proto_init(&net_cfg)        stack con IP = 0.0.0.0
  4. ca_net_proto_bind_udp(68,    )       porta 68 per OFFER/ACK
  5. loop: as soon as the link is up     ca_dhcp_service_net_ready()     the
    DORA starts
          then ca_sem_timedwait() + ca_net_process()

on_dhcp_bound (callback, from the DHCP task):
      s_gw stored (= broker address)
      ca_sem_trywait/post(&s_dhcp_sem)    sblocca task_mqtt

task_mqtt:
  ca_sem_wait(&s_dhcp_sem)
  ca_mqtt_service_init(broker = s_gw,    )
  ca_mqtt_service_net_ready()           apre TCP     CONNECT MQTT
  loop: publish every 5 s    ping every 30 s    reconnect every 8 s if dropped
```

No `bind()` for MQTT: it's a client, it opens its own TCP connection to the broker. The gate on the link is only needed for DHCP, which is the first to speak.

The gate of step 5 is specific to NCM. The NCM link goes up only when the host selects alternate setting 1: as long as it's down, `ca_usb_ncm_send_frame()` **discards every frame and returns** `false`, so a DISCOVER sent too early is not delayed, it's **lost**.

> **Where to put the wait — and where not to.** The gate **must be inside the loop**, not before: blocking the net task waiting for the link *before* serving frames prevents enumeration itself (the host reports `device not accepting address`). For the same reason the loop uses `ca_sem_timedwait(&ca_net_rx_sem, 100)` and not `ca_sem_wait()`.

100.1.9 Expected output

Board console:

```
=== EX77: MQTT client su USB-NCM ===
MAC     02:CA:05:00:00:77
Topics  pub 'caos/status'  sub 'caos/led'
waiting for the host to bring the interface up...
USB NCM UP
DHCP: avvio DORA...

DHCP BOUND  IP=192.168.10.100  GW=192.168.10.1
MQTT broker 192.168.10.1:1883
MQTT: avvio connessione...
MQTT CONNECTED  (#1)
MQTT subscribed -> caos/led
MQTT pub -> {"seq":0,"up":12,"ip":"192.168.10.100"}
MQTT LED -> ON
```

On the PC side, client `paho` shows the same payloads. The end-to-end verification is **bidirectional**: `seq` that advances without skipping from the board to the PC, and the command `on`/`off` that from the PC produces line `MQTT LED ->` on the board.

100.1.10 Technical notes

Two MACs, one for each side

`s_mac` (`02:CA:05:00:00:77`) is the device MAC; `s_ncm.mac` (`02:CA:05:00:00:B7`) is the one announced on the host side — from which the name `enx02ca050000b7` of the interface on the PC comes, the one that the script searches for. The two **must be different**.

Topics and payloads are not null-terminated

```
if (topic_len == (u16)(sizeof(MQTT_TOPIC_LED) - 1U) &&
    ca_memcmp(topic, MQTT_TOPIC_LED, topic_len) == 0)
```

The callback receives pointer **and length**, and the data points inside the network buffer: there is no trailing zero. Comparing with `ca_strcmp` would read past the end. It is the same constraint as in ex42, and applies to any callback that exposes raw data from the pool.

Reconnection reinitializes the service

In the reconnection cycle `ca_mqtt_service_init()` is called before `ca_mqtt_service_net_ready()`, with the local IP re-read from `s_ip`. This is needed because a DHCP renewal might have changed the address: starting with the old one would produce packets with wrong source.

Keepalive is not optional

The PING every 30 s is under the 60 s declared in CONNECT (`MQTT_KEEPALIVE_SEC`). If the ping period were to exceed the keepalive, the broker would close the session due to inactivity, and the reconnection cycle would restart continuously — a fault that manifests only after a minute of silence, hence easy to miss in a short test.

100.1.11 File structure

          mqtt_server_ncm.py      mosquitto + paho + DHCP con auto-detect NCM
```

Chapter 101

Modbus TCP Client over USB-NCM

101.1 Example 78 — Modbus TCP Client over USB-NCM

101.1.1 Introduction

Variant USB-NCM of **example 43** (Modbus TCP client over Ethernet). The services are the same — DHCP client, ARP, Modbus TCP client that performs a cycle of four function codes — but the transport is the USB port instead of the Ethernet MAC.

It is the second application protocol over TCP after MQTT (ex77), and it is the most demanding in the series in terms of verification: each cycle performs **reads and writes**, and values must be compared on both sides.

Feature	Notes
DHCP Client	Full DORA + T1/T2 renewal
ARP service	resolves the MAC address of the Modbus server
FC03	reads 4 holding registers (addr 0..3)
FC06	writes a single register (addr 4, setpoint 100→1000)
FC16	writes 2 registers (addr 5..6)
FC01	reads 8 coils (addr 0..7)
Cycle	every `MODBUS_POLL_PERIOD_MS` (3 s)
Reconnection	automatic every 5 s if TCP drops
USB Ethernet (NCM)	device `usb0` / `enxNN`

101.1.2 PC Prerequisite: Remove the interface from NetworkManager

When the board enumerates, a new network interface appears on the PC (`enx02ca0500xx` — the name udev derives from the MAC). NetworkManager sees it as any other newly connected card and **assigns it an address of its own**: it has been observed `172.21.10.100/24`. The board is on `192.168.10.0/24`, so the two end up on different subnets and the board becomes unreachable.

The symptom is misleading, because the interface **exists and is UP**: `ip link` shows it, and even `ping -I <iface>` responds — that flag bypasses the routing table. What fails is everything else (`socat`, `nc`, PC scripts from the examples), which follow the routing table.

The rule is versioned in the repository:

```
sudo cp tools/99-caos-ncm.conf /etc/NetworkManager/conf.d/
sudo systemctl reload NetworkManager
nmcli -t -f DEVICE,STATE dev status | grep enx    # it must say: unmanaged
```

The glob goes to `interface-name`, not to `mac:`. The form `mac:02:ca:05:00:00:*` seems equivalent but it is not: it requires a full MAC and fails **silently** with a wildcard character — no error, and the interface remains managed.

The bank address does not set this rule: it is set by `sudo ./tools/bench_net.sh usb` or the example PC script.

101.1.3 The server is the gateway

As for MQTT in ex77, on a point-to-point link the PC acts as gateway, DHCP server and Modbus server. The firmware derives the server address **from the lease**:

```
ca_ipv4_t server_ip = s_gw;   /* the DHCP gateway: on p2p it is the PC */
```

Therefore, `ca_modbus_service_init()` cannot be in `ca_os_configure()`: it needs the server address, only known after the bind. It therefore lives in `task_modbus`, after waiting on the semaphore — as in ex43.

101.1.4 The confirmation on the first connect

On ETH it is documented (21/08) that **the first TCP `connect` always fails** and the retry succeeds: observed on ex42 (MQTT) *and* ex43 (Modbus). On NCM this phenomenon **has not occurred** neither in ex75 (TCP client) nor in ex77 (MQTT).

This example is the confirmation for the second protocol. If the first connection succeeds here too, the picture is:

	ETH	NCM
Raw TCP	—	first attempt (ex75)
MQTT	first fails (ex42)	first attempt (ex77)
Modbus	first fails (ex43)	← this example

Since the client code is **identical** between ex43 and ex78 (only the transport changes), a positive outcome here definitively excludes the client and the opening sequence, and narrows the cause to the ETH path — where the investigation will have to shift to ARP and driver.

The symptom to look for in the log is:

```
MODBUS: tentativo riconnessione...
```

If it appears **before** the first successful poll cycle, the first connect failed.

101.1.5 Hardware

MCU	`USB_NUM`	LED OK (transaction)	Heartbeat A	Heartbeat B
U575 (NUCLEO-U575ZI-Q)	0	PC7 (LD1 green)	PG2 (LD3 red)	PB7 (LD2 blue)
H753 (NUCLEO-H753ZI)	1	PB0 (LD1 green)	PB14 (LD3 red)	PE1 (LD2 yellow)
F407 (STM32F4VE)	0	PA7 (D3)	PA6 (D2)	PA6 (single)
H563 (NUCLEO-H563ZI)	0	PB0 (LD1 green)	PG4 (LD3 red)	PF4 (LD2 yellow)

The **LED OK** blinks 50 ms at each cycle completed without errors: it is an immediate visual feedback that the FC03→FC06→FC16→FC01 chain has passed entirely.

The two heartbeat LEDs are in **exclusive alternation** — one on, the other off, they swap at each beat. They are written together with opposite values, not with two independent `toggle` that could desynchronize.

> **Pinout verified on manuals** (UM2407 for H753, UM2861 for U575, UM3115 for H563), not deduced. Warning: **PB7 is the LD2 blue LED of the U575 and is not a LED on the H753**, where LD2 is yellow on PE1.

101.1.6 os_config.h Configuration

```
#define EN_NET             1
#define EN_USB             1
#define EN_USB_NCM         1
#define EN_NET_DHCP        1
#define EN_DHCP_SERVICE    1
#define EN_TCP_SERVICE     1     /* Modbus runs on top of TCP */
#define EN_MODBUS_SERVICE  1
#define EN_ARP_SERVICE     1
```

Off with respect to ex43: `EN_ETH 0`, `EN_CLI_ETH 0`, `EN_USB_CDC 0`.

```
python3 tools/caos_config.py --new 78 --from ex43 \
        --set EN_ETH=0 --set EN_USB=1 --set EN_USB_NCM=1 --set EN_USB_CDC=0
python3 tools/caos_config.py --off EN_CLI_ETH 78
```

Compared to ex75 (TCP client), it differs by **only two flags**: `EN_MODBUS_SERVICE` and `EN_CLI_MODBUS` — the same distance that ex77 has from ex75 for MQTT.

101.1.7 The PC: Modbus server + DHCP

```
sudo python3 examples/example_78/modbus_server_ncm.py
```

Find the interface from MAC `02:ca:05`, assign `192.168.10.1/24`, start `dnsmasq`, wait for the board to obtain the lease and open a **simulated Modbus TCP server** on port 502. The registers have values that change over time, so a FC03 that always returned the same numbers would reveal a cache instead of a real read.

```
sudo python3 modbus_server_ncm.py --iface usb0   # explicit interface
sudo python3 modbus_server_ncm.py --no-dhcp      # DHCP already running
    elsewhere
```

101.1.8 Boot Sequence

```
task_net:
  1. ca_usb_dev_mng_init/add/start      bring-up USB
  2. ca_net_init(ca_ncm_iface_get())    NCM becomes the net core iface
  3. ca_net_proto_init(&net_cfg)        stack con IP = 0.0.0.0
  4. ca_net_proto_bind_udp(68,    )       porta 68 per OFFER/ACK
  5. loop: as soon as the link is up     ca_dhcp_service_net_ready()     the
    DORA starts
          then ca_sem_timedwait() + ca_net_process()

on_dhcp_bound (callback, from the DHCP task):
```

```
      s_gw stored (= Modbus server address)
      ca_sem_trywait/post(&s_dhcp_sem)    sblocca task_modbus

task_modbus:
  ca_sem_wait(&s_dhcp_sem)
  ca_modbus_service_init(server = s_gw,    )
  ca_modbus_service_net_ready()         apre la connessione TCP
  loop: FC03/FC06/FC16/FC01 cycle every 3 s    reconnect every 5 s if dropped
```

No `bind()` for Modbus: it is a client, it opens its own TCP connection to the server. The gate on the link is only for DHCP, which is the first to speak.

The gate of step 5 is specific to NCM. The NCM link only comes up when the host selects alt setting 1: as long as it is down, `ca_usb_ncm_send_frame()` **discards every frame and returns** `false`, so a DISCOVER sent too early is not delayed, it is **lost**.

> **Where to put the wait — and where not to.** The gate **must be inside the loop**, not before: blocking the net task waiting for the link *before* serving the frames prevents enumeration itself (the host reports `device not accepting address`). For the same reason the loop uses `ca_sem_timedwait(&ca_net_rx_sem, 100)` and not `ca_sem_wait()`.

101.1.9 Expected output

Board console:

```
=== EX78: Modbus TCP client su USB-NCM ===
MAC     02:CA:05:00:00:78
Modbus  porta 502  unit_id 1
waiting for the host to bring the interface up...
USB NCM UP
DHCP: avvio DORA...

DHCP BOUND  IP=192.168.10.100  GW=192.168.10.1
MODBUS server 192.168.10.1:502
MODBUS: avvio connessione TCP...
FC03 regs[0..3]= 101 201 301 401
FC06 setpoint=100 OK
FC16 config OK
FC01 coils=0x55
cycle done  ok=1 err=0
```

What to look for, beyond the fact that it works:

- **FC03 values must advance over time** (100→101→102…), but **not at every cycle**: the simulator increments the registers every 5 s while the board reads every 3 s, so two consecutive reads often fall in the same window and return the same value. The expected sequence is of the type `100, 101, 102, 102, 103, 104, 104` — a repeated value every two or three cycles is **aliasing between the two periods, not a cache**. An alarm signal would be a value that never changes;
- `err=0` and `ok` advancing at every cycle;
- on the PC side, the FC06 setpoint (100, 200, 300…) and FC16 registers must appear with the same values written by the board;
- the **transaction ids** in the server log must be consecutive, without gaps.

101.1.10 Technical Notes

Two MACs, one for each side

`s_mac` (`02:CA:05:00:00:78`) is the device MAC; `s_ncm.mac` (`02:CA:05:00:00:B8`) is the one announced on the host side — from which the name `enx02ca050000b8` of the interface on the PC comes, the one the script looks for. The two **must differ**.

Modbus functions are blocking

`ca_modbus_read_holding_regs()` and the related functions wait for the server's response, so `task_modbus` is a task by itself (LEVEL3) and not the net task: calling them from there would block `ca_net_process()`, i.e. exactly what must run to deliver the response. This is the same constraint as `ca_tcp_recv()` in ex75 and `ca_dns_resolve()` in ex72.

The chain stops at the first error

```
if (ca_modbus_read_holding_regs(...)) {     } else { ok = false; }
if (ok) { /* FC06 */ }
if (ok) { /* FC16 */ }
```

Every subsequent function code is conditioned on the success of the previous ones. It is not sloth: if the connection has dropped in the middle of a cycle, insisting with the other three requests would produce three additional errors that hide which one was the first to fail.

`last_reconnect` initialized to the current tick

```
u32 last_reconnect = ca_os_tick_ms();   /* avoids immediate double init */
```

Without this, `now - last_reconnect` would immediately be `MODBUS_RECONNECT_MS` and the loop would redo `ca_modbus_service_init()` an instant after the one just executed, resetting the connection in the process of being opened. Detail inherited from ex43.

Chapter 102

iperf TCP over USB-NCM

102.1 Example 79 — iperf TCP over USB-NCM

102.1.1 Introduction

Variant USB-NCM of **example 44** (iperf over Ethernet). The services are the same — DHCP client, ARP, iperf service which acts as client or server on CLI command — but the transport is the USB port instead of the Ethernet MAC.

It is the example that measures the **bandwidth ceiling** of the NCM transport, and for this reason it is also the one where it is easiest to misread the numbers.

Feature	Notes
DHCP client	Full DORA + T1/T2 renewal
ARP service	resolves the peer's MAC
`iperf server`	the board receives, the PC pushes
`iperf client <ip>`	the board pushes, the PC receives
ICMP echo reply	replies to `ping`
USB Ethernet (NCM)	device `usb0` / `enxNN`

102.1.2 PC Prerequisite: Remove the interface from NetworkManager

When the board enumerates, a new network interface appears on the PC (`enx02ca0500xx` — the name that udev derives from the MAC). NetworkManager sees it as any other attached card and **assigns it an address of its own**: it has been observed `172.21.10.100/24`. The board is on `192.168.10.0/24`, so the two end up on different subnets and the board is unreachable.

The symptom is misleading, because the interface **exists and is UP**: `ip link` shows it, and even `ping -I <iface>` responds — that flag bypasses the routing table. What doesn't work is everything else (`socat`, `nc`, the PC scripts of the examples), which follow the routing table.

The rule is versioned in the repository:

```
sudo cp tools/99-caos-ncm.conf /etc/NetworkManager/conf.d/
sudo systemctl reload NetworkManager
nmcli -t -f DEVICE,STATE dev status | grep enx    # it must say: unmanaged
```

> **The glob goes on `interface-name`, not on `mac:`.** The form `mac:02:ca:05:00:00:*` seems equivalent but it is not: it requires a full MAC and fails **silently** with a wildcard character — no error, and the interface remains managed.

The address of the bank does not set this rule: it is set by `sudo ./tools/bench_net.sh usb` or the example PC script.

102.1.3 The numbers: what to expect and what not to believe

USB Full Speed are 12 Mbit/s raw signaling rate. From there, USB overhead, NCM encapsulation and Ethernet/IP/TCP headers must be subtracted. The comparison with the ~27–33 Mbps measured on ETH in ex44 **does not make sense**: here the bottleneck is the bus, not the network stack.

> **The valid measurement is always on the receiving side.** The total printed by the transmitting side counts the bytes accepted by its own kernel with `send()`, not those that arrived at the destination: what remains in the queue at shutdown gets **discarded**. On ex44 this produced a 12× discrepancy (PC: 73 MB sent, board: 5.8 MB received) that seemed like a performance collapse but was actually an artifact of the sender-side measurement.

How to distinguish a real problem

If the two numbers diverge significantly, the board counters tell you which direction to look:

```
eth stats          rx_drop=0  tx_fail=0  err_rbu=0
net                pool_free + driver_held == NET_BUF_COUNT
```

- `rx_drop=0` **and intact pool** → the board has not lost anything: the missing bytes never arrived on the cable, the bottleneck is upstream (sender or link);
- `rx_drop>0` **or declining pool** → actual dropouts due to exhausted buffers, and there's something to investigate in the firmware.

On ETH the measured reference on 08/21 is `pool_free + driver_held = 40+24 = 64` under load, with `rx_drop=0`.

Reference measurement

On NUCLEO-H753ZI, board as server:

```
iperf RESULT: 5689222 bytes  10481 ms  4551376 bps
```

4.55 Mbps, about 38% of the raw 12 Mbit/s of the bus. It is a plausible performance: from the raw signaling bandwidth, the USB transaction overhead (tokens and handshakes for each packet), the NTB/NCM encapsulation, the Ethernet+IP+TCP headers and the return ACKs must be subtracted. On the same hardware ex44 over Ethernet measures ~27 Mbps: **these two numbers are not comparable**, because here the bottleneck is the bus and not the stack.

The trap of duplicate routes

Both the ETH example and this one use **both** `192.168.10.0/24`. If the wired NIC keeps its address from a previous test, the kernel finds two routes for the same subnet:

```
192.168.10.0  0.0.0.0  255.255.255.0  U  0    0 0 enp0s31f6        <-- vince
192.168.10.0  0.0.0.0  255.255.255.0  U  100  0 0 enx02ca050000b9
```

It wins the lowest metric — Ethernet, where the board **is not present**. The symptom is a `timed out` from the client, and the distinction is diagnostic:

- `connection refused` → board reached, port closed (not listening);
- `timed out` → packets leave from the wrong interface, nothing comes back.

Fix: `sudo ip addr flush dev <nic-ethernet>`. The script detects the collision and reports it before starting the test.

102.1.4 Priority: `net` paired with the service

This example is one of three where `task_net` runs at **LEVEL6** instead of the usual LEVEL4 — together with ex44 (iperf over ETH) and ex45 (HTTP).

caOS levels **are not fixed priorities but CPU shares** (`caos/inc/scheduler.h`): LEVEL4 12.6 %, LEVEL6 50 %, doubling at each step. The rule that follows:

> **`net` and the service that consumes what `net` produces must be at the same level.** Pairing them splits the same bandwidth equally. If `net` were above, it would fill queues that the service does not empty in time; if below, the service would run idle.

The iperf service is declared `CA_TH_LEVEL6` in `iperf_service.c`, so `net` follows it. In the other examples, the leading service is at LEVEL0..4 and `net` stays at LEVEL4.

> On NCM, **there is no USB task** under which to place it: the USB stack runs in ISR and delivers frames via `ncm_iface_rx()` → queue + post to `ca_net_rx_sem`. Pairing is always with the application service, never with the transport.

102.1.5 Hardware

MCU	`USB_NUM`	Connector	LED heartbeat
U575 (NUCLEO-U575ZI-Q)	0	USB user	PC7 (LD1 green)
H753 (NUCLEO-H753ZI)	1	CN14 (OTG_FS)	PB14 (LD3 red)
F407 (STM32F4VE)	0	USB device	PA6 (D2)
H563 (NUCLEO-H563ZI)	0	USB user	PB0 (LD1 green)

Pinout verified on board manuals (UM2407, UM2861, UM3115).

102.1.6 os_config.h Configuration

```
#define EN_NET            1
#define EN_USB            1
#define EN_USB_NCM        1
#define EN_NET_DHCP       1
#define EN_DHCP_SERVICE   1
#define EN_TCP_SERVICE    1     /* iperf runs on top of TCP */
#define EN_IPERF_SERVICE  1
#define EN_ARP_SERVICE    1
```

Off with respect to ex44: `EN_ETH 0`, `EN_CLI_ETH 0`, `EN_USB_CDC 0`.

```
python3 tools/caos_config.py --new 79 --from ex44 \
        --set EN_ETH=0 --set EN_USB=1 --set EN_USB_NCM=1 --set EN_USB_CDC=0
python3 tools/caos_config.py --off EN_CLI_ETH 79
```

Compared to ex75 (TCP client), it differs by **only two flags**: `EN_IPERF_SERVICE` and `EN_CLI_IPERF` .

102.1.7 Usage

The service registers the CLI commands by itself; the firmware has no application task.

> **The order is mandatory: first the PC, then the board.** This is not a preference but a circular dependency to break: the board can accept the `iperf` commands **only after obtaining the IP**, and the IP is provided by the DHCP running on the PC. Issuing the command earlier produces `iperf: local IP non disponibile` — the service receives the address from `ca_iperf_update_local_ip()` inside `on_dhcp_bound`, which has not yet occurred.
>
> The scripts are designed for this order: they wait for the board instead of failing immediately.

Board as server (the PC pushes):

```
# 1. PC: configures the interface, starts dnsmasq, then waits for the board
sudo python3 examples/example_79/iperf_peer_ncm.py --mode client

# 2. board: as soon as "DHCP BOUND" appears, on its console
iperf server 5001 30
```

The PC script retries the connection for 60 s and prints `type 'iperf server' on the board console`: there is all the time to give the command after seeing the bound.

Board as client (the board pushes):

```
# 1. PC
sudo python3 examples/example_79/iperf_peer_ncm.py --mode server

# 2. board, after "DHCP BOUND"
iperf client 192.168.10.1 5001
```

> **Be careful with the `accept` timeout: the default is 3 seconds, not 30.** `IPERF_IDLE_TIMEOUT_MS` is `3000U` in the config (the same on ex44), while the CLI help writes `[idle_s=30]` — the help is imprecise. With `iperf server` without arguments the board waits for a connection for **3 s** and then prints `iperf ERR`: it's not a failure, the accept timed out.
>
> Two ways to avoid this: - give an explicit timeout — `iperf server 5001 30` — and then launch the PC; - or launch **first** the peer on the PC, which stays waiting, and only after give the command on the board.
>
> The same timeout also governs inactivity *during* the transfer (`ca_tcp_recv`), so increasing it does not falsify the measurement: it only gives time for the connection to establish.
>
> Both arguments are **required**: the parser reads the port first, then the timeout. `iperf server 30` would interpret `30` as *port*.

If the board already has a lease, the script may not find it. In state `BOUND` the DHCP client sleeps until T1 (one hour): it sends nothing, and no new `DHCPACK` will appear in the log — which `start_dnsmasq()` clears at every boot. The script notices this and after 5 s looks for the address in the ARP table (`ip neigh`, filtering by MAC `02:ca:05`). Two manual options remain:

- `--board-ip 192.168.10.131` to skip the detection entirely;
- `dhcp renew` on the console **while the script is waiting** (not before: the log is cleared at the start of the script).

The script finds the interface by MAC `02:ca:05`, assigns it `192.168.10.1/24`, starts `dnsmasq` and waits for the board's lease.

Cleanup. SIGINT/SIGTERM handlers are installed **before** starting `dnsmasq`, and at startup the script collects any leftover instances. Without this, a Ctrl+C during the lease wait (up to 60 s) would leave `dnsmasq` alive, keeping the IP occupied, and the next test would fail with `failed to create listening socket: Address already in use`.

102.1.8 Boot sequence

```
task_net:
  1. ca_usb_dev_mng_init/add/start      bring-up USB
  2. ca_net_init(ca_ncm_iface_get())    NCM becomes the net core iface
  3. ca_net_proto_init(&net_cfg)        stack con IP = 0.0.0.0
  4. ca_net_proto_bind_udp(68,    )       porta 68 per OFFER/ACK
  5. loop: as soon as the link is up     ca_dhcp_service_net_ready()     the
    DORA starts
          then ca_sem_timedwait() + ca_net_process()

on_dhcp_bound:
      ca_iperf_update_local_ip(ip)        the service learns the address
```

iperf does not need any link gate: it is commanded from the CLI, so it comes into play only after the link is up. It does not even have a `bind()` at startup — it only opens listen or connect when it receives the command.

The gate of step 5 is specific to NCM. The NCM link comes up only when the host selects alternate setting 1: as long as it is down, `ca_usb_ncm_send_frame()` **discards every frame and returns** `false`, so a DISCOVER sent too early is not delayed, it is **lost**.

Where to put the wait — and where not to. The gate **must be inside the loop**, not before: blocking the net task in wait for the link *before* serving frames prevents enumeration itself (the host reports `device not accepting address`). For the same reason, the loop uses `ca_sem_timedwait(&ca_net_rx_sem, 100)` and not `ca_sem_wait()`. The timeout costs nothing under load: as soon as frames flow, the semaphore is posted and the wait returns immediately.

102.1.9 Expected output

```
=== EX79: iperf TCP client/server su USB-NCM ===
MAC  02:CA:05:00:00:79
waiting for the host to bring the interface up...
USB NCM UP
```

```
DHCP: avvio DORA...

DHCP BOUND  IP=192.168.10.100
ready: use 'iperf server' or 'iperf client <ip>'

> iperf server
iperf server listening on port 5001 (idle=3 s)...
iperf SERVER  port=5001  idle=3 s
iperf RESULT: <N> bytes  <T> ms  <bps> bps
```

`iperf RESULT` is **the right measure**: it counts the bytes actually delivered to the application on the board.

102.1.10 Technical notes

Two MACs, one for each side

`s_mac` (`02:CA:05:00:00:79`) is the device MAC; `s_ncm.mac` (`02:CA:05:00:00:B9`) is the one announced to the host side — from which the name `enx02ca050000b9` of the interface on the PC comes, the one the script looks for. The two **must differ**.

The service carries its own CLI

`ca_iperf_service_start()` registers the commands `iperf client` / `iperf server`. For this reason the example has no application task: everything is driven by the console. This is also the reason why the local address must be updated separately, with `ca_iperf_update_local_ip()` inside `on_dhcp_bound` — the service is started before the lease exists.

Boot order

First the board, then the script: the USB interface is created during enumeration. On the firmware side there is no rush — the net task waits for the link as long as needed.

Chapter 103

HTTP Server with CLI over USB-NCM

103.1 Example 80 — HTTP and HTTPS server with CLI via HTTP over USB-NCM

103.1.1 Introduction

USB-NCM variant of **example 45** (HTTP server over Ethernet). The services are the same — DHCP client, ARP, TCP, HTTP server with the four routes — but the transport is the USB port instead of the Ethernet MAC.

The application logic (HTML page, handlers, route table, CLI capture) is **copied identically** from ex45: this is the point of the `ca_net_iface_t` abstraction. Only the interface passed to `ca_net_init()` changes.

Feature	Notes
DHCP client	Full DORA + T1/T2 renewal
ARP service	cache + blocking resolution
HTTP server port 80	GET / POST / HEAD / OPTIONS
HTTPS server port 443	same routes over TLS 1.3 (`EN_HTTPS_SERVICE`)
`GET /`	HTML page with command form
`GET /status`	JSON: IP, uptime, NCM link status
`POST /cli`	executes a CLI command, responds with text
`GET /help`	list of available commands
ICMP echo reply	responds to `ping`
USB Ethernet (NCM)	device `usb0` / `enxNN`

103.1.2 PC Prerequisite: detach the interface from NetworkManager

When the board enumerates, a new network interface appears on the PC (`enx02ca0500xx` — the name that udev derives from the MAC). NetworkManager sees it as any other newly connected card and **assigns its own address to it**: `172.21.10.100/24` has been observed. The board is on `192.168.10.0/24`, so the two end up on different subnets and the board is unreachable.

The symptom is misleading, because the interface **exists and is UP**: `ip link` shows it, and even `ping -I <iface>` responds — that flag bypasses the routing table. Everything else (`socat`, `nc`, the PC scripts of the examples) does not work, as it follows the routing table.

The rule is versioned in the repository:

```
sudo cp tools/99-caos-ncm.conf /etc/NetworkManager/conf.d/
sudo systemctl reload NetworkManager
nmcli -t -f DEVICE,STATE dev status | grep enx    # deve dire: unmanaged
```

> **The glob goes on `interface-name`, not on `mac:`.** The form `mac:02:ca:05:00:00:*` seems equivalent but it is not: it expects a full MAC and with a wildcard it fails **silently** — no error, and the interface remains managed.

The bank address is not set by this rule: it is set by `sudo ./tools/bench_net.sh usb` or the PC script in the example.

103.1.3 The three differences compared to ex45

1. `eth_gpio_init()` → `ca_usb_dev_mng_init()` + `ca_usb_dev_mng_add()` + `ca_usb_dev_mng_start()`
2. `ca_net_init(ca_eth_iface_get(&eth_cfg))` → `ca_net_init(ca_ncm_iface_get(&s_ncm))`
3. `ca_net_init()` moves from `ca_os_configure()` to `task_net`: the NCM interface exists only **after** USB enumeration.

The `eth_mon`, `ca_eth_link_poll()` task and the GARP to the switch disappear (the host learns the MAC from the NCM descriptors). The "link" is `ca_usb_ncm_is_up()`.

The HTTP listener does not move

Unlike ex76 (where `ca_tcp_listen()` had to be moved from `ca_os_main()` to `task_net`), here **no movement is needed**: `ca_http_service_start()` is already called inside `on_dhcp_bound` even in the ETH version, i.e., after the lease. The listening PCB carries the local IP, so opening it before the address would not make sense on either transport.

The gate on the link

The HTTP server **does not need its own gate**: it just responds, and when a browser manages to reach it, the link is necessarily up. The gate is used by DHCP, which speaks first, and is **inside** the `task_net` loop — never before, otherwise it would block the enumeration itself (see ex70).

103.1.4 Test on PC

Power-on order: first the board, then the script. The USB interface does not exist until the device has enumerated.

```
sudo python3 examples/example_80/http_test_ncm.py
```

The script finds the interface from the MAC `02:ca:05:*`, starts dnsmasq, waits for the lease, verifies the four routes, and opens the browser.

Useful variants:

```
sudo python3 examples/example_80/http_test_ncm.py --cmd "top"     # un comando
    CLI
sudo python3 examples/example_80/http_test_ncm.py --status        # solo /status
sudo python3 examples/example_80/http_test_ncm.py --no-browser    # DHCP e
    attesa
```

Expected outcome

```
[1] GET http://192.168.10.180/status
    -> 200  {"ip":"192.168.10.180","uptime_s":42,"link":"up"}
[2] GET http://192.168.10.180/
    -> 200  1024 byte  <!DOCTYPE html><html><head>
[3] GET http://192.168.10.180/help
    -> 200  28 righe di help
[4] POST http://192.168.10.180/cli  cmd=free
    -> 200
 RISULTATO: PASS
```

103.1.5 Unlimited CLI output: chunked response

Unlike ex45, this example **does not use** `ca_cli_exec_capture()` with a fixed buffer. `/cli` and `/help` open a **chunked** response (`Transfer-Encoding: chunked`, RFC 7230 §4.1) and stream the CLI output into it as it is produced, using `ca_cli_exec_capture_stream()` — the same API that on 08/17 solved the SSH shell truncation.

Why SSH streaming was not enough

SSH can send its records as they come. HTTP cannot: it must write `Content-Length` in the header **before** the body, and the service patches it afterwards via `cl_pos` — which requires having the entire body in memory. Chunked encoding breaks this constraint: no `Content-Length`, each piece carries its own length, and a final chunk of zero length closes the body.

Support was added to `http_service.c` in an **additive** way: normal routes do not change, chunked is opt-in per response (`ca_http_resp_begin_chunked()`).

The test

`config` is the longest command (~3 KB) and ends with the SHA-256 hash of the configuration — therefore that line is the perfect probe: if it is there, it did not truncate.

```
sudo python3 examples/example_80/http_test_ncm.py --cmd "config"
```

```
  usb_ncm_ep_data      = 1
  usb_ncm_ep_notif     = 5
--- caOS Config Hash (SHA-256, excl. build_ver) ---
  aa52946f1baeb31872aed6fab71a5ee4ca387b23db6ac857677992669d4144cb
```

Before the modification, the output stopped at `TCP_TCP_ACCEPT_TIMEOUT_MS`, in the middle of the values table.

Requires `EN_CLI_CONFIG=1` (the `config` command) and `EN_SHA256=1` (the hash line); both enabled in this example, disabled in ex45.

103.1.6 HTTPS on port 443

As in ex45, with `EN_HTTPS_SERVICE` the same routes are also served in TLS 1.3. The example has its own identity (`examples/example_80/tls_identity.h`, generated with `tools/gen_tls_identity.py examples/example_80`) and starts it in `on_dhcp_bound`, right after the HTTP server. The operation is described in HTTPS and TLS 1.3.

```
curl --cacert examples/example_80/tls_identity_cert.pem \
     --resolve caos.local:443:192.168.10.180 https://caos.local/status
curl --cacert examples/example_80/tls_identity_cert.pem \
     --resolve caos.local:443:192.168.10.180 -X POST https://caos.local/cli -d "
    cmd=config"
```

Chunked responses also work over HTTPS: each chunk becomes one or more TLS records. The header of each chunk (a few bytes) goes into its own record, with its 22 bytes of overhead; for CLI output, this is a negligible cost.

RAM: a TLS session occupies approximately 24 KB. On F407 and F446 (128 KB), the example was already excluded before HTTPS, because it exceeded the limit by about 4.7 KB (`EX80_RAM_TOO_SMALL`, see the comment at the top of the source code); with TLS, the gap increases.

103.1.7 Status

PASS on H753 hardware (08/22). DHCP, HTTP server, the four routes, and the CLI via HTTP with full output. First example to use chunked responses.

HTTPS (10/23/2026): the `test_ex80` class (10 phases, including the HTTPS one with verified certificate and rejection of TLS 1.2) passes on H563, H753, F767, and U575.

ex81/82/83, written together with this one, remain to be tested.

Chapter 104

IP Defragmentation and UDP Server over USB-NCM

104.1 Example 81 — IP Defragmentation + UDP server on USB-NCM

104.1.1 Introduction

Variant of **example 48** (IP defragmentation over Ethernet) using USB-NCM. The services are the same — DHCP client, ARP, IP defragmentation service, UDP server on port 7961 — but the transport is USB instead of Ethernet MAC.

Feature	Notes
DHCP client	Full DORA + T1/T2 renewal
ARP service	cache + blocking resolution
IP defrag	reassembles fragments (`EN_IP_DEFRAG=1`)
UDP server 7961	payload up to `IP_DEFRAG_MAX_PAYLOAD` (1480 B)
Hardware CRC32	ensures reassembly is byte-exact
ICMP echo reply	replies to `ping`
USB Ethernet (NCM)	device `usb0` / `enxNN`

104.1.2 PC Prerequisite: Remove the interface from NetworkManager

When the board enumerates, a new network interface appears on the PC (`enx02ca0500xx` — the name udev derives from the MAC). NetworkManager sees it as any ordinary plugged-in card and **assigns it an address of its own**: it has been observed `172.21.10.100/24`. The board is on `192.168.10.0/24`, so the two end up on different subnets and the board becomes unreachable.

The symptom is misleading, because the interface **exists and is UP**: `ip link` shows it, and even `ping -I <iface>` responds — that flag bypasses the routing table. What doesn't work is everything else (`socat`, `nc`, the PC scripts of the examples), which follow the routing table.

The rule is versioned in the repository:

```
sudo cp tools/99-caos-ncm.conf /etc/NetworkManager/conf.d/
sudo systemctl reload NetworkManager
nmcli -t -f DEVICE,STATE dev status | grep enx    # it must say: unmanaged
```

> **The glob goes to `interface-name`, not to `mac:`.** The form `mac:02:ca:05:00:00:*` seems equivalent but it is not: it requires a full MAC and fails **silently** with a wildcard character — no error, and the interface remains managed.

The bank address does not set this rule: it is set by `sudo ./tools/bench_net.sh usb` or the example PC script.

104.1.3 Why the test is identical

NCM announces `wMaxSegmentSize` **1514** (`USB_NCM_MAX_FRAME` in `usb_ncm.h`), i.e. the same L2 MTU as Ethernet: 1500 bytes of IP payload. A UDP datagram of 1472 bytes (1480 bytes of IP payload with UDP header) therefore exceeds the MTU **exactly as on ETH** and is fragmented by the sender in the same way.

This is the reason why the reassembly path exercised is identical and the test script did not require adaptations for fragmentation — only for interface detection.

104.1.4 The CRC32 is not a detail

The server calculates the **hardware** CRC32 of the received payload and prints it. Unlike a byte sum, the CRC32 changes even if the bytes are the same but in **different order** — which is precisely what must be demonstrated when reassembling: correct length is not enough, because fragments reassembled out of order would give the same length and wrong content.

`ca_crc32_get()` runs in the UDP worker task, never in ISR, so the internal mutex is safe.

104.1.5 The three differences from ex48

1. `eth_gpio_init()` → USB-NCM bring-up (`ca_usb_dev_mng_*`)
2. `ca_eth_iface_get()` → `ca_ncm_iface_get()`
3. `ca_net_init()` from `ca_os_configure()` to `task_net`

`ca_udp_server_bind()` stays **before** the link gate: registering a port does not put anything on the wire. The UDP server does not need a gate, because it only responds; the gate is needed for DHCP, which speaks first.

104.1.6 Test on PC

Power-on order: first the board, then the script. Requires `scapy` and comes with a minimal DHCP server (no dnsmasq needed).

```
sudo python3 examples/example_81/test_frag_ncm.py
```

Without `--iface`, the interface is searched for by MAC `02:ca:05:*` and waited for up to 30 s. Useful parameters:

```
--size 1472     # UDP data bytes (default; max 1472)
--frags 4       # number of IP fragments
--repeat 3      # repeats the test
--skip-dhcp     # the board already has an IP
```

Expected Outcome

On the board's console:

```
UDP[7961] cid=0  rx=1472 B  crc32=0x........  from 192.168.10.1:54321
  pld[0..7]= 00 01 02 03 04 05 06 07
```

The printed CRC32 must match the one calculated by the script on the sent payload, and the echo must return intact.

104.1.7 Status

PASS on hardware H753 (22/08). 4 fragments (offsets 0/376/752/1128, `MF` correct, last one 352 B) reassembled into 1472 bytes, **intact echo in content** and not only in length — which also excludes out-of-order reassembly.

The same exact offsets measured on ex48 over Ethernet: practical confirmation that the MTU matches and that the reassembly path exercised is the same across both transports.

ex82/83 remain to be tested, written together with this.

Chapter 105

TFTP Client over USB-NCM

105.1 Example 82 — TFTP Client over USB-NCM

105.1.1 Introduction

USB-NCM variant of **example 49** (TFTP over Ethernet). The services are the same — DHCP client, ARP, CLI-driven TFTP client — but the transport is the USB port instead of the Ethernet MAC.

Feature	Notes
DHCP client	Full DORA + T1/T2 renewal
ARP service	cache + blocking resolution
`tftp get <ip> <file>`	download from server on PC
`tftp put <ip> <file> [size]`	upload a pattern generated in RAM
`tftp info`	status of the last transfer
ICMP echo reply	responds to `ping`
USB Ethernet (NCM)	device `usb0` / `enxNN`

105.1.2 PC Prerequisite: detach the interface from NetworkManager

When the board enumerates, a new network interface appears on the PC (`enx02ca0500xx` — the name udev derives from the MAC). NetworkManager sees it as any newly connected card and **assigns it its own address**: `172.21.10.100/24` has been observed. The board is on `192.168.10.0/24`, so the two end up on different subnets and the board is unreachable.

The symptom is misleading, because the interface **is there and is UP**: `ip link` shows it, and even `ping -I <iface>` responds — that flag bypasses the routing table. Everything else fails (`socat`, `nc`, the PC scripts of the examples), which follows the routing table.

The rule is versioned in the repository:

```
sudo cp tools/99-caos-ncm.conf /etc/NetworkManager/conf.d/
sudo systemctl reload NetworkManager
nmcli -t -f DEVICE,STATE dev status | grep enx    # it must say: unmanaged
```

> **The glob goes on `interface-name`, not on `mac:`.** The form `mac:02:ca:05:00:00:*` seems equivalent but it is not: it expects a full MAC and fails **silently** with a wildcard — no error, and the interface remains managed.

The bank address is not set by this rule: it is set by `sudo ./tools/bench_net.sh usb` or the PC script in the example.

105.1.3 Why TFTP does not need a gate

The TFTP client **speaks first**, so in theory it falls into the NCM link trap that caused ex70 to fail. In practice, it does not: it only speaks **when the user types the command**, and by that point the link has been up for a long time.

The general rule for clones applies: a gate is only needed for the first service that speaks on its own initiative — here, DHCP.

`ca_tftp_service_init()` remains in `ca_os_configure()`

Unlike `ca_net_init()`, this function **does not touch the network**: it only registers the CLI node (`tftp_service.c:670`). It can therefore remain where it was on ETH.

The local IP does not need to be propagated manually: the CLI manager reads `s_net_proto_local_ip` at the moment the command is executed (lines 578 and 635 of `tftp_service.c`), so the DHCP lease is collected automatically.

105.1.4 Test on PC

Power-on order: first the board, then the script. The script brings with it both the DHCP server (dnsmasq) and the TFTP server.

```
sudo python3 examples/example_82/test_tftp_ncm.py --put
```

`--put` is required to accept board uploads (`tftp put`). Without `--iface`, the interface is searched for by the MAC `02:ca:05:*`.

Then, from the board console:

```
tftp get 192.168.10.1 test.bin
tftp put 192.168.10.1 upload.bin 4096
tftp info
```

Expected outcome

A GET of an 8192-byte file produces **17 blocks**, not 16: 16 full 512-byte blocks plus a final **empty** block. This is not a defect — RFC 1350 requires that a transfer whose size is an exact multiple of the block size must terminate with an empty block, otherwise the receiver would not know that the file has ended.

105.1.5 Status

PASS on H753 hardware (08/22). Lease `.140`, then both directions:

- `tftp put` → 1024 bytes, intact pattern verified on the PC side (`test.bin_recv.bin`)
- `tftp get` → **17 blocks / 8192 bytes**, i.e., the correct RFC 1350 termination, with the cyclic `00..ff` pattern intact across block boundaries

The same numbers as ex49 on Ethernet.

Pitfall seen in the field: the server IP

The first attempt failed with `TFTP GET FAIL` because it pointed to `192.168.10.150` — the address of the **wired NIC** used in ETH tests. On NCM, the TFTP server is on the IP that the script assigns to the USB interface, i.e., **192.168.10.1** (`--pc-ip`). The board instead takes a `.1xx` from the DHCP pool.

If TFTP times out, `ping 192.168.10.1` from the board immediately distinguishes between the two cases: ping succeeds and TFTP fails = service issue; ping fails = wrong address or interface.

Chapter 106

SSH Server over USB-NCM

106.1 Example 83 — SSH Server over USB-NCM

106.1.1 Introduction

USB-NCM variant of **example 67** (SSH over Ethernet), and the last of the fifteen NCM clones. Minimal SSH server — `curve25519-sha256` + `ssh-ed25519` + `aes256-gcm` — with the transport moved from the RMII PHY to the USB port.

It is no coincidence that it was left for last: it is the most complex service in the series, and ex67 retains the NCM bring-up **commented in the source** precisely as a base for this example.

Feature	Notes
SSH server port 22	KEX X25519, Ed25519 host key, AES-256-GCM record
Authentication	`publickey` Ed25519 (`SSH_AUTHORIZED_ED25519_PUB`)
Interactive shell	RFC 4254, the caOS CLI via SSH
`ssh test`	repeats BPP framing vectors (offline)
ICMP echo reply	responds to `ping`
USB Ethernet (NCM)	device `usb0` / `enxNN`

106.1.2 PC Prerequisite: detach the interface from NetworkManager

When the board enumerates, a new network interface appears on the PC (`enx02ca0500xx` — the name that udev derives from the MAC). NetworkManager sees it as just another connected card and **assigns its own address to it**: `172.21.10.100/24` has been observed. The board is on `192.168.10.0/24`, so the two end up on different subnets and the board is unreachable.

The symptom is misleading, because the interface **exists and is UP**: `ip link` shows it, and even `ping -I <iface>` responds — that flag bypasses the routing table. What does not work is everything else (`socat`, `nc`, the PC scripts of the examples), which follows the routing table.

The rule is versioned in the repository:

```
sudo cp tools/99-caos-ncm.conf /etc/NetworkManager/conf.d/
sudo systemctl reload NetworkManager
nmcli -t -f DEVICE,STATE dev status | grep enx    # it must say: unmanaged
```

> **The glob goes on `interface-name`, not on `mac:`.** The form `mac:02:ca:05:00:00:*` seems equivalent but it is not: it expects a complete MAC and fails **silently** with a wildcard — no error, and the interface remains managed.

The bank address is not set by this rule: it is set by `sudo ./tools/bench_net.sh usb` or the PC script in the example.

106.1.3 Static IP: the simplest clone in the series, not the most complex

Unlike all other clones, ex67 **does not use DHCP**: it has a static IP (192.168.10.67, here 192.168.10.83). This eliminates the DHCP gate and with it the lease monitoring task.

However, the link gate is still needed, for a different reason. `ca_ssh_service_init()` creates the SSH task, which calls `ca_tcp_listen()` using `ca_net_proto_get_local_ip()` (`ssh_transport.c:1367` — the comment in the source warns that otherwise the SYN-ACK would start from 0.0.0.0). With the static address, that value is valid immediately, so the listen itself would be safe even early on; the point is that **the first SYN-ACK must be able to go out**, and until the host has selected alt setting 1, every frame is discarded by `ca_usb_ncm_send_frame()`.

The service is therefore started when the link is up, **inside** the loop of `task_net`. As always in the clones, never before: blocking there would stop the enumeration itself.

106.1.4 Differences compared to ex67

1. `eth_gpio_init()` → USB-NCM bring-up (`ca_usb_dev_mng_*`)
2. `ca_eth_iface_get()` → `ca_ncm_iface_get()`
3. `ca_net_init()` from `ca_os_configure()` to `task_net`
4. `ca_ssh_service_init()` moved **inside the loop**, behind the link gate
5. `task_eth_mon` → `task_ncm_mon`, without lease renewal request (static IP)

`ca_tcp_service_start()` remains before the gate: it does not put anything on the wire until someone connects.

106.1.5 PC Test

Power-on order: first the board, then the script.

```
./examples/example_83/run_ssh_client_ncm.sh
```

The script searches for the interface by MAC `02:ca:05:*`, assigns it 192.168.10.1/24 (it asks for `sudo` only if needed), and launches the client. IP and interface can be forced:

```
./examples/example_83/run_ssh_client_ncm.sh 192.168.10.83
IFACE=usb0 ./examples/example_83/run_ssh_client_ncm.sh
```

The test key pair

`examples/caos_ed25519/` contains a **versioned disposable key in the repo**, only for the demo: it has no security value. `SSH_AUTHORIZED_ED25519_PUB` in `os_config` is its public part.

Why host key options are needed

```
-o UserKnownHostsFile=/dev/null -o StrictHostKeyChecking=no
```

The board **regenerates its own host key at every boot** (it is volatile, held in a static struct and not in the key store). Without these options, `ssh` would refuse the connection on the second boot, signaling a changed host key. `IdentitiesOnly=yes` is instead used to prevent `ssh` from offering agent keys first.

106.1.6 Status

PASS on H753 hardware (08/22), on the first try. Ed25519 publickey authentication, RFC 4254 interactive shell, `help` with full output, `ssh test` **11/11 PASS** on BPP framing vectors.

The result closes an unknown that no other example covered: SSH was only tested over Ethernet (U575, H563, H753) and NCM was tested up to iperf (ex79) — **never the two together**. The heaviest load of the series (crypto + TCP + shell) runs on the USB transport without modifications to the SSH service: only the interface passed to `ca_net_init()` changes, which is exactly what the `ca_net_iface_t` abstraction promised.

With ex83, the **series of NCM clones is complete: 15 out of 15 validated on hardware.**

Chapter 107

L2 Echo: the Driver Measured Without the Transport

107.1 Example 84 — L2 Echo: the driver measured without the transport

107.1.1 Introduction

This is not a tutorial example: it is a **measurement tool**, born from a number that did not add up.

Example 44 measures iperf over Ethernet. On the H753, the two ends of the same transfer disagreed by **13.6 times**: the PC claimed to have sent 76,021,760 bytes at 60.7 Mbps, while the board's iperf counted 5,596,180 at 4.4 Mbps.

The frames had **not** been lost on the wire. The driver counters recorded 52,096 received, with zero errors — and 76,021,760 ÷ 52,096 = **1459.3**, which is exactly the MSS. Every frame had arrived and had been delivered: the bytes were disappearing **above** the driver.

The problem with measuring that phenomenon with iperf is that iperf is TCP. The driver, network task, TCP receive ring, and application all end up in a single number, and a slow result does not say **which** of the four is slow.

This example removes everything above L2.

107.1.2 How it works

A raw EtherType — `0x88B5`, which IEEE reserves specifically for experimental use — is picked up from the receive path via the **network filter**, its source and destination MACs are swapped, and it is sent back immediately.

No IP, no TCP, no receive ring, no application to schedule: just input DMA and output DMA.

Feature	Notes
L2 Echo on `0x88B5`	network filter, src/dst MAC swap, zero-copy
Static IP `192.168.10.84`	no DHCP
ARP	the board responds to requests
ICMP echo reply	responds to `ping`
CLI `echo stats`	rx/tx/drop counters
CLI `eth dump`	ETH driver counters
CLI `eth sync`	rebuilds DMA rings and restarts engines

What the result says

Outcome	Interpretation
the echo **keeps up** with the sender	driver and network task are healthy: the 13.6× is in the transport above them
the echo **does not keep up**	the limit is down here, and iperf only showed it by reflection

Both answers are useful — and that is what makes it a measurement and not a fix.

107.1.3 Why static IP

No DHCP, no TCP, no UDP services: **the fewer things running, the fewer things can explain the number**.

ARP and ICMP echo remain enabled for one reason only: a `ping` from the PC proves that the board is on the network **before** giving credit to any throughput figure. A board that does not respond to a ping has not produced a slow measurement — it has produced no measurement at all.

The address `192.168.10.84` is outside the bench's DHCP pool (`.50`–`.99`), so it is reachable from `192.168.10.1` and cannot collide with a lease.

107.1.4 The network filter (`EN_NET_FILTER`)

The example introduced in `caos/net/` a general mechanism, inspired by the Linux netfilter but stripped to the bone: **a single slot**.

```
ca_net_filter_set(0x88B5U, echo_filter);   /* arma  */
ca_net_filter_clear();                      /* toglie */
u32 n = ca_net_filter_count();              /* how many frames it took */
```

The filter is consulted at the top of `net_handle_frame`, **before** VLAN/EtherType parsing, before `b->meta` population, and before scanning the handler table. The callback receives `buf_idx` and **takes ownership of it**: it either frees it or passes it to transmission.

> **It is a shorter path, not a more urgent one.** The filter runs in the same network task, on the same wakeup, inside the same `ca_net_process()` as every other frame: it does not preempt anything. What it removes is the per-frame work between the driver and the consumer — and, above all, everything above L2.

107.1.5 The two queues, and why they are short

Between the filter (which runs in the network task) and the echo task, there is a **16-slot** queue.

The filter must **never** block: behind it is the entire reception drainage. Therefore, it delivers the buffer and returns.

The queue is intentionally small: if the echo task cannot keep up, frames must be discarded **there and counted**, not silently accumulated until the pool is exhausted. A counted discard is a metric; a hidden discard is a lie about the driver.

The two tasks are at the **same level** (`CA_TH_LEVEL6`): the frame passes from one to the other and both are on the reception path, so giving one of the two a higher quota would shift the queue, not shorten it.

107.1.6 Usage

On the board

```
echo stats      contatori: rx, tx, scarti, "balanced" o "GAP: rx != tx"
echo clear      azzera i contatori
eth dump        ETH driver counters
```

`rx` and `tx` must match. A discrepancy is the responsibility of **this example** — full queue or `ca_net_send` rejecting — and both cases are counted separately, so the driver is never blamed for a frame discarded by this code.

On the PC

```
# first: is the board on the network?
ping -c3 192.168.10.84

# then the measurement (needs root: raw sockets always require it)
sudo python3 examples/example_84/eth_echo_peer.py --iface <if>
sudo python3 examples/example_84/eth_echo_peer.py --iface <if> \
     --count 20000 --size 1500 --json /tmp/echo.json
```

The script sends N frames and counts how many return. A frame that arrives has been resent by the board: nothing else on the network responds to `0x88B5`.

> Loss here **is a data point, not an error**. The board is by design the slowest endpoint, so the interesting figure is not "did they all return" but *how many* return and at what rate when the sender pushes harder than the receiver can send back. The script only considers it a failure if the board has not sent **anything** back.

107.1.7 The offered rate (`--mbps`), and why it is needed

Without `--mbps` the script fires at wire speed. However, that number **measures the PC**: it offers ~98 Mbps because that is what Fast Ethernet does, and the percentage that returns is as much a property of the generator as it is of the board. It cannot be compared between different boards, and it changes if the PC changes.

A rate that the board **can handle** is instead a property of the board alone.

```
sudo python3 examples/example_84/eth_echo_peer.py --iface <if> --mbps 40
```

The rate is calculated starting from the initial instant, rather than sleeping for a fixed interval at each frame: a per-frame wait accumulates its own overhead and the actual rate slips below the required one — which would be read as a board rejecting in advance. The frame time includes preamble, IFG, and CRC (24 bytes beyond the payload), so the requested Mbit/s are those seen on the wire.

The JSON reports `offered_mbps` next to `send_mbps`: if the two diverge, it is the **PC** that failed to keep up with the rate, and that step says nothing about the board.

`first_echoed_seq` and `last_echoed_seq` indicate **where** the losses are. Missing frames at the *beginning* mean that the link was not yet carrying — the receiver had not finished recovering —

while losses scattered throughout the run indicate the receiver is overwhelmed, which is what this example measures. By eye, the two cases are indistinguishable; the sequence numbers separate them exactly.

107.1.8 Searching for the limit (phase `echo_rate_limit`)

The test bench automates the measurement with a **binary search**: it doubles from a rate known to be sustainable until a step is rejected, then halves between the last successful one and the first rejected one. It converges in a handful of runs and prints a number that means the same thing on every family.

> **Each step restarts from a known state**, and this is not a precaution: it is the measurement. A DMA ring stops at the slot where the previous burst left it, and with 4 slots, each run would start from a different phase. Without this measure, the ramp resulted in being **non-monotonic** (100, 100, 3.7, 100, 49, 79, 70, 100 %): the steps were not comparable to each other. The test bench reprograms the board and then calls `eth sync`, which brings the DMA exactly where `ca_eth_hw_init()` leaves it.

A warm-up burst seems like the obvious solution and **it is not**: it warms up the path but leaves the ring on an arbitrary slot, i.e., it produces the problem it is supposed to remove.

The limit found is **recorded, not promoted to a criterion**: the only step that can cause the phase to fail is the starting one, because below it there is nothing to measure. Turning today's performance into a threshold would mean causing a healthy board to fail tomorrow.

107.1.9 Reading `eth dump`

The driver counters are what distinguish a **slow** ring from a **stalled** one, and they have the same format on H5xx, H7xx, and F7xx, so a single reader interprets them all.

```
tx: calls=7176 full=0 spin=0 kick=4115
rx: calls=14353 frames=7176 err=0 ctxt=0 partial=0 runt=0
rx: rbu=1 susp=1
```

Counter	Description
`err ctxt partial runt`	the ring delivered something that **is not a frame**: a fault at any rate, must remain 0
`full`	a transmission found the ring still owned by the DMA — **not** a fault: it is what a receiver does when overwhelmed by the sender
`spin`	cycles burned in active waiting for the DMA to free the slot
`kick`	the ring had suspended and was explicitly restarted
`rbu`	receive descriptors have run out: frames are being lost

> On a v1 MAC (F7xx) `ctxt` equals `none`, not `0`: context descriptors in that silicon **do not exist**, and saying "zero occurrences" would claim a check that cannot happen. The bank decodes the absence instead of judging it.

The fault that these counters found

On the NUCLEO-H563ZI, after a burst offered at 80 Mbps, the board stopped echoing **and would not recover**: 0% even when returning to 20 Mbps, a rate it had just sustained at 100%. Only reprogramming recovered it.

The dump showed `TPS=7` (transmission suspended) with `cur` **beyond** `tail`, `spin=99999`, and `err/ctxt/partial/runt` all at zero: the ring was not broken, it was **stopped**. The engine suspends when the current descriptor reaches the tail pointer, and restarts only with a write that **moves** it; with 4 slots, upon a full lap the tail resumed a value already written and moved nothing.

The condition to monitor is `TBU` in `ETH_DMACSR`, which RM0481 explicitly names in the description of bit `ST`. **Not** the `TPS` field: the value 6 is also the normal idle state of an engine without work, and monitoring that triggered a restart on every transmission, with a 13% cost on throughput.

After the fix, two consecutive bursts at 78 Mbps without touching the board in between:

	burst 1	burst 2	driver
before	40%	**0%** (until reflash)	`full=1 spin=99999 kick=0`
after	43%	**100%**	`full=0 spin=0 kick=4115`

`kick` on 57% of transmissions says that the engine suspends continuously under load and that the restart is what keeps the ring moving.

107.1.10 Configuration

```
EN_ETH 1, EN_NET 1, EN_NET_FILTER 1, EN_ARP_SERVICE 1, EN_ETH_DBG 1
EN_TCP_SERVICE 0, EN_UDP_SERVER 0, EN_DHCP_SERVICE 0
EN_NET_NTP 0, EN_NET_DNS 0, EN_NET_MDNS 0, EN_NET_SYSLOG 0, EN_SDIO 0
```

107.1.11 Hardware notes

`RMII_TXD1` pin changes depending on the board: **PB15** on the NUCLEO-H563ZI (UM3115, JP6 ON / SB10 OFF), **PB13** on H753 and F767. Wiring PB13 fixed leaves TXD1 disconnected on the H563 — and the fault is insidious: the MAC continues to count every frame as transmitted and `tx_fail` remains 0, but half of the data bits never reach the PHY.

Chapter 108

Several Connections at Once: How the Buffer Pool Is Shared

108.1 Example 85 — Multiple connections together: how the buffer pool is shared

108.1.1 Introduction

Like example 84, this is not a didactic example but a **measurement tool**. And like that one, it stems from a question that example 44 cannot answer: example 44 measures **one** connection, and a single connection alone does not show what we are interested in here.

The network buffer pool is **only one** (`NET_BUF_COUNT`). The receive ring of each TCP connection does not own its own buffers: it holds them, taken from that pool. On paper, four connections at full depth require

```
4    (16 rx + 16 inflight) + 8 (driver) = 136 buffer
```

where there are **64**. It is an over-subscription of more than 2:1, and the question is what happens when the connections are really there.

108.1.2 Why it doesn't resolve by shrinking the rings

The obvious answer is to lower `TCP_RX_RING_DEPTH` and `TCP_MAX_INFLIGHT` until the worst case fits. It was measured on example 44, on H563, on 16/09/2026:

configuration	RX	TX
16 / 16	35.9 Mbps	31.8 Mbps
8 / 4	25.9 Mbps **(28 %)**	4.5 Mbps **(86 %)**

Both directions pay, and transmission **plummets**: with four segments in flight the send window is around 5.8 KB, and the sender spends each round waiting for an ACK. The loss rate across the five sessions was **0.01 %**, which is the signature of a structural limit and not of noise.

The point is that a depth chosen to serve four connections badly serves **even worse** the single connection that usually exists.

108.1.3 The quota, calculated when needed

Therefore, the depth remains at maximum and the division moves to **run-time**. `rx_quota()` in `caos/net/src/tcp_service.c` assigns to each connection a portion of what the pool can grant:

```
quota = min( (free + already queued     reserve) / active connections,
             TCP_RX_RING_DEPTH,
             slots already mine + (free     reserve) )
```

Three terms, each for a different reason:

- **Division** redistributes what is available among those who are asking for it;
- `TCP_RX_RING_DEPTH` is a physical limit: the ring is an array of fixed size;
- **the third term** is what makes the reserve truly a reserve. Without it, three already full connections plus a new one would be assigned a quota of 13 slots, which growing would consume the reserve and leave the pool at zero — and the next SYN would fail due to exhaustion, which is exactly the fault the reserve must prevent.

With **one** connection, the quota is the entire ring and nothing changes: example 44 confirms this, 35.1 Mbps against 35.9 of the static version, a difference within the dispersion of measurements.

Buffers already occupied **are never removed** from a connection. They contain data that the peer has sent and that the application has not yet read: discarding them would mean losing bytes already confirmed, i.e., repeating the defect of `rcv_nxt` already corrected. The ceiling applies when one **asks** for a slot, and the return happens by itself as the application reads.

108.1.4 What this example answers

If that quota holds when connections really compete:

outcome	meaning
streams are **equally distributed**	the quota redistributes: this is the main result
one stream stops at **zero**	a connection has starved the others — exactly what the quota must prevent
a connection is **rejected**	the pool ran out before the quota limited anyone: the reserve is too small
the sum **drops** below the value for one connection	dividing costs more than it yields

The measured result, and why it's surprising

On H563, four streams of 10 s (16/09/2026): **4 × 23.7 Mbps, total 95.0 Mbps**, with the four within 0.2 % of each other.

It is not the division of 36 Mbps into four parts: it is almost **three times** what a single connection achieves. And it shows that the measurement for one connection never regarded how much work the board could actually perform.

95.0 Mbps of payload become **100.1 Mbps on the wire** once headers, preamble, and interframe intervals are counted: the Fast Ethernet link is **saturated**, and the bottleneck has moved outside the board.

What limited the single connection was the **round-trip time** — the time spent waiting for an ACK before being able to receive more — and four connections fill in those gaps with

each other. In events per second, the stack went from ~6100 to ~**16 300**, so it wasn't even the per-packet cost that was the ceiling.

From here on, this measurement is **blind upward**: it cannot tell how much the board could do, because the cable runs out first. To discover this, one must offer less than 100 Mbps — fewer streams, or a set rate — and find where it stops scaling.

The fairness among the four, however, remains what this example really verifies: it is the quota that works.

108.1.5 How it works

The server uses the **callback** mode of `ca_tcp_listen()`: `on_accept`, `on_rx` and `on_closed` run in the context of the network task, so N connections do not cost N stacks. This is a substantial point and not a detail: the RAM pool size is being measured, and spending as much in task stacks would falsify the measurement.

This is also the reason why the iperf service from example 44 cannot be reused here: it performs **a single** blocking `ca_tcp_accept()` and then a blocking receive loop, and is therefore mono-connection by design.

Each accepted connection occupies an entry that counts bytes, segments and the instant of the first and last byte. The data is **not stored**: it's a sink, it counts and discards it.

108.1.6 Commands

On the board:

```
msink start [porta]    accetta connessioni e conta i byte (default 5001)
msink stats            totali per connessione e somma
msink stop             closes everything and prints the report
```

On the PC, with the example counterpart:

```
sudo python3 examples/example_85/msink_peer.py --parallel 4 --dur 10
```

You do not need to type anything on the board. Two seconds after receiving the address, the example listens on its own and announces it:

```
msink: listening on 5001 (started automatically)
```

The reason is that the order is mandatory: the DHCP server provides it to the PC script, so the peer is **always** already running when the board discovers its own address — and is already retrying connections. Asking for a typed command at that point would add a person to a sequence that doesn't need one, and the console should write it with the timing implications that this entails.

The two seconds are needed to let the gratuitous ARP go out, so the peer's first SYN doesn't arrive at an address that the network hasn't learned yet.

The commands remain available for another loop or for a different port: `sink_start()` rejects if a listener is already open, so they cannot conflict with automatic startup.

If the board already has an address — for example on the bench, where DHCP handles it on its own — everything is skipped with `--no-dhcp --board-ip <ip>`.

The network interface is passed with `--iface`; if the name doesn't exist on that machine the script lists them and, when there is only one wired one, chooses it by itself.

108.1.7 How to read the report

```
conn 0: h=17 45088768 bytes 30883 segs 10012 ms 36024 kbps
...
accepted=4 refused=0  live=0  slots_used=4/8
TOTAL 180355072 bytes 123532 segs 10031 ms 143829 kbps
```

The sum is measured over the time during which the connections **overlapped**, not the sum of their individual durations: they run together, so adding the durations would count the bytes roughly N times too many and report a quarter of the actual rate.

To be watched alongside the report, on the board's console:

- `tcp buf` — the pool distribution by owner, the historic minimum of free buffers and the rejected allocations. `low_water` near zero or `fail` different from zero indicates that the pool was indeed the bottleneck;
- `tcp rxdrop` — discarded segments due to full ring, and the transmission accounting (`retrans` must stay at zero: if it rises, contention is causing retransmissions).

`refused > 0` is not a pool defect: it means that more connections arrived than the slots in this example, which are `TCP_MAX_CONN`.

108.1.8 Requirements

`os_config.h`: `EN_ETH 1`, `EN_NET 1`, `EN_TCP_SERVICE 1`, `EN_ARP_SERVICE 1`, `EN_NET_DHCP 1`.

Hardware: NUCLEO-H753ZI, NUCLEO-H563ZI or NUCLEO-F767ZI (RMII, LAN8742A).

Chapter 109

callto: Calling an Address from the Console

109.1 Example 86 — `callto`: calling an address from the console

109.1.1 Introduction

The console can already **read** any address: `mem` reads a word, `hexdump` dumps a block. This example serves the command that **calls** one.

The value is not in the call itself — with the probe attached, `gdb` already does `call`. It is in the case where the probe **does not connect**, which on this bench has happened often enough to deserve a memory of its own. There, `mem` and `hexdump` are the only way to look inside a live board, and `callto` extends that from reading to executing.

> `EN_CLI_CALLTO` **is a debug flag.** It is arbitrary execution from the console: a build that carries it hands over everything the firmware holds, `keys_store` included. It is off by default and `config` reports it, so a firmware can be asked whether it has it. It is on here because it is what the example is about.

109.1.2 The call runs in a task of its own

This is not a convenience, it is the point.

From the CLI thread, a wrong address brings down **the console** — and the console is the very channel the answer is supposed to come back on. In a separate task:

choice	what it buys
`JOB_SAFE`	the stack canary watches a callee that overruns
`CA_FAULT_ASSERT`	a fault **removes that task** and nothing else
name `"callto"`	`top` and `taskall` show it, `kill <n>` stops it

So a callee that never returns is **visible and killable** instead of fatal. The command does not wait: it launches, gives the prompt back, and the result arrives on a line of its own when the call finishes.

109.1.3 Syntax

```
callto <addr hex> [param hex]    call the address, with an optional u32
callto                           what the last call did
```

Without a parameter the target is called as `u32(void)`, not with a zero: under AAPCS the two forms produce the same instructions, but the prototype is the one that was asked for and the one that gets reported — printing `param 0x00000000` would claim an argument that nobody passed.

The command sets the Thumb bit. On Cortex-M a `BLX` to an even address is a UsageFault INVSTATE, and the even form is what a listing shows: it is the mistake everyone makes once. The effective address is printed, so the correction is visible rather than silent.

The address is validated with `ca_valid_pointer()`, i.e. against the board's `CA_MEMMAP_TABLE`. Mind what that means: it answers **mapped**, not **executable**. An address in RAM passes. It rules out the typo that would fault on the first fetch, not an address that simply holds no code.

109.1.4 The three targets

At boot the example prints the addresses of its three functions, so they can be called without a map file and without a debugger:

```
example_86: callto targets
ex86: u32  0x08004A11  f(x) = x*2+1
ex86: void 0x08004A19  f()  = 0xCA05CA05
ex86: spin 0x08004A21  never returns
example_86: ready
```

target	what it proves
`u32`	the parameter arrives in `r0` and the result comes back. `x*2+1`, not `x*2`: with `+1` a callee that was never entered, returning `r0` at zero, cannot look correct
`void`	the call without an argument, and the magic `0xCA05CA05` that nobody prints by chance
`spin`	never returns (it sleeps, it does not burn CPU): it proves the task stays findable in `taskall` and stops with `kill`

109.1.5 Typical session

```
> callto 08000209 15
callto: launching 0x08000209 (param 0x00000015) - 'callto' for its thread
> callto: 0x08000209 returned 0x0000002B

> callto
callto: last 0x08000209 (param 0x00000015) -> 0x0000002B

> callto FFFF0000
callto: 0xFFFF0000 is not in this board's memory map

> callto 08000239
```

```
callto: launching 0x08000239 (no param) - 'callto' for its thread
> callto
callto: 0x08000239 still running as thread[4] - 'kill 4' stops it
> kill 4
thread[04] named 'callto' killed
```

Why the thread number is not in the launch line

Because it would **already be wrong** by the time you read it.

A `thid` is a **position** in the task list, and `TaskList_Remove` (`scheduler.c:323`) does *swap-with-last*: it moves the last task into the freed slot and **rewrites** its `->index`. Every CLI command then runs in a throw-away task of its own (`cli_cmd`, `cli.c:653`), created **before** the `callto` task and destroyed as soon as the command returns — which slides `callto` right into its slot.

Measured on U575 at the first run: the launch line said `thread[5]`, `top` showed the task at `4`, and `kill 5` hit an **EMPTY** slot and answered nothing.

The stable handle is the **task handle** (`ca_task_handle_t`: slot + generation), fixed for the task's whole life: `ca_os_thid_from_handle()` turns it back into the index that is valid *now*. That is what `callto` keeps, and the index is resolved at the moment it is printed. It used to keep the stack base, which is not an identity: the PSP area of a finished task is reused by the next task created, and an old base could recognise the newcomer as the `callto` still running. The handle's generation prevents that. Same class of defect as the TCP handle that named the slot and outlived the connection.

The result outlives the task that produced it, and that is why `callto` without arguments exists: the kernel **saves** what a task returned, in `task->result`, but the very next line marks the task `REMOVE` and the scheduler frees struct and stack. There is no API to read the result of a finished task, and the slot is recycled. The value therefore has to land somewhere that is not the task — an input **and** output struct, passed as `p1`.

That single struct also serialises the command: one call at a time, and a second `callto` while the first is still running is refused instead of overwriting a result that nobody has read yet.

109.1.6 Portability

No peripheral, no LED, no jumper: the command is MCU-independent and so is the example. It runs on every board.

109.1.7 Automated test

`test/hw_test/src/test_ex86.cpp`, 9 phases. The addresses are taken **from the board** — from the boot transcript — not from a map file: what gets called is what is on the part, not what the host believes it built.

The phases that matter are not "does it call?", they are the two that would fail silently: the **even** address passed on purpose (if the command did not set the Thumb bit, the phase would not give a wrong value — it would bring the task down), and the callee that **never returns**, where the test checks that the console still answers, that `callto` reports it as running and that `kill` ends it.

Chapter 110

Lost Wake-up Bench

110.1 Example 87 — Lost wakeup bench

110.1.1 Introduction

Blocking kernel waits all follow the same pattern: under lock, the task registers itself to the wait list, releases the lock, and **only afterwards** calls `ca_os_wait()`, which marks it `BLOCKED`. A wakeup occurring between the unlock and `ca_os_wait()` finds the task still `RUNNING`, and `ca_os_signal()` acts only on a `BLOCKED` task: the signal is lost. Then the task blocks outside of any list and no one wakes it up anymore.

The defect emerged on 09/23 on U575 in the stdout drain, where it silenced the entire console. This example searches for it in **all** other primitives.

The window is only a few cycles wide. Waiting for it is useless: you must **sweep** it.

110.1.2 How it works

element	role
TIM3, every 50 µs	produces **one** element from the ISR, and the next one only after it has been processed
`e87_rx`	consumer waiting **without timeout** on the phase primitive
`e87_rxt`	second consumer, **with** timeout, only in phase `mixed`
random pause	after each element, the consumer spins for 0..1 period

The random pause shifts the next tick along the entire consumer path, including the window. Critical sections mask with `PRIMASK`: a tick that expires while the consumer holds the lock starts **exactly at the unlock**, i.e., inside the window.

The ping-pong transforms a lost wakeup from a delay into a **block**: the ISR does not produce anymore until the confirmation arrives. The ISR itself monitors the consumer: if it remains `BLOCKED` for 100 ms with pending work, or outside of any list, it counts it, classifies it, and wakes it up, so the pass reaches the end.

The three forms of the defect

counter	observed state	cause
`lost_in_list`	`BLOCKED`, in list, pending work	the element arrived between the “empty?” check and the registration, performed in two different critical sections
`lost_off_list`	`BLOCKED`, **not** in list, pending work	the wakeup arrived between the unlock and `ca_os_wait()`
`orphan`	`BLOCKED`, in no list, nothing pending	the task was detached from the list by someone else
`late`	element not taken for 200 ms, none of the forms above	an unclassified block

`orphan` concerns the timeout branches of `queue.c`: at each attempt, the task registers itself again without having removed itself, and registering an already connected task truncates the list behind it. Phase `mixed` puts a consumer with timeout and one without on the same queue on purpose to make it emerge.

For `notify` the in/out of list division is not observable (notify has no registration): every block is counted as `lost_off_list`.

110.1.3 The phases

phase	primitive	producer (ISR)
`queue`	`ca_queue_static_receive( , CA_WAIT_FOREVER)`	`ca_queue_static_send_isr`
`qheap`	`ca_queue_heap_receive( , CA_WAIT_FOREVER)`	`ca_queue_heap_send_isr`
`qsend`	`ca_queue_static_send( , CA_WAIT_FOREVER)` on a queue of 1, full	`ca_queue_static_receive_isr` frees the slot
`notify`	`ca_notify_wait(true, CA_WAIT_FOREVER)`	`ca_notify_send_isr`
`event`	`ca_event_wait_any( , CA_WAIT_FOREVER)`	`ca_event_set_isr`
`stream`	`ca_stream_receive( , 0 xFFFFFFFF)`	`ca_stream_send_isr`
`message`	`ca_message_receive( , 0 xFFFFFFFF)`	`ca_message_send_isr`
`mixed`	`queue`, plus a second receiver with 3 ms timeout	`ca_queue_static_send_isr`
`mv_queue`	like `queue`, with the consumer **changing index** while waiting	check: wait lists hold pointers
`mv_event`	like `event`, same	`waiters[]` was indexed by position
`mv_stream`	like `stream`, same	`waiting_task` was a position
`mv_msg`	like `message`, same	`waiting_task` was a position

phase	primitive	producer (ISR)
`mv_mem`	a task that **owns heap blocks** changes index 8 times, then terminates without freeing them	ownership was registered by index
`fair`	two receivers **with timeout** on the same queue	one task, one element every 2 ms (no ISR)
`tmo`	`ca_queue_static_receive( , T)` on a queue that no one feeds, T = 1..20 ms	none
`kill`	a waiter (with and without timeout) **removed** while in the list, another one behind	one task, one element after removal

The phases of waits with timeout: `fair`, `tmo`, `kill`

Since 09/27, a waiter with timeout registers in the wait list like one without, parked in `SLEEP` until expiration (S2_02 §8.8). Previously, it performed polling every 10 ms outside the list. These three phases do not use the ISR: each has its own runner.

- `fair` — two consumers with 20 ms timeout on the same queue; each element carries the tick in which it was sent. It passes if the elements alternate (the least served one has at least 40%), none are lost, and each arrives within 3 ms. On the kernel with polling: `lat_max=30/8 ticks` (H563), FAIL.
- `tmo` — the timeout must expire **never before** T and at most 2 ms after.
- `kill` — the victim puts itself in the list, the survivor behind it; the victim is removed. Its context must **exit the list** before being reused (`stale=0`: then a specific task is created that reuses it) and the survivor must receive the next element (`lost=0`). On the previous kernel: `stale=25` over 25 rounds without timeout, and the victim with timeout never entered the list (`unlisted=25`).

```
e87 fair    : a=1250 b=1250 sent=2500 lat_max=0/15 ticks  PASS
e87 tmo     : n=478 early=0 late=0 got=0 over_max=0/10 ticks  PASS
e87 kill    : rounds=50/50 stale=0 lost=0 unlisted=0  PASS
```

The other primitives are verified in examples 5, 6, 7, 9, 14, 15, 17, and 20 (command `twait`, and `twkill` in ex20).

The `mv_*` phases: the consumer changing index

A `thid` is a **position** in the task list, and removing a task moves the last one into the freed spot, overwriting its index. A primitive that remembers who is waiting by index wakes up the wrong position. In the `mv_*` phases, the consumer is created last, above 8 "plug" tasks: each plug that terminates makes it move down one spot **while it is waiting** (production is suspended during the move, so the consumer is definitely waiting), and it remains the last one, so the next plug moves it again. `moves=8/8` confirms that the moves have occurred; less than 8 is `TOO_FEW_MOVES`.

On the kernel prior to stable task handles, `mv_event`, `mv_stream`, and `mv_msg` lost one wakeup for every move (8 out of 8), while `mv_queue` passed. Now the primitives remember who is waiting by slot (event) or by task handle (stream, message), which do not move.

The console thread is **not** a phase. It is the channel on which the test bench responds, and putting it into execution meant driving the dispatching of CLI commands (command slots, inline execution) instead of its waiting. Its waiting is `ca_queue_static_receive( , CA_WAIT_FOREVER)`, already covered by the `queue` phase.

Consumers are held by **context**, not by index: every console command creates and destroys a task, and this reshuffles the indices (see example 86). The index is read at the moment it is needed.

110.1.4 Commands

```
e87 start [fase|all] [sec]   one pass, closed by RUN RESULT
e87 lat [sec]                only the IRQ latency probe, no phase
e87 info                     timer, periodo, soglia, jitter
```

A second `e87 start` sent while a pass is in progress is **rejected**. The CLI executes the command in its own thread when `cli_cmd` is busy: without the guard, two passes of the same phase would run together (seen on `fair`: two producers on a full queue whose consumers had already finished, the console busy for two minutes — it looked like a kernel hang).

By default `start` executes all phases, 3 seconds each. One line per phase:

```
e87 queue   : iter=41230 lost_in_list=0 lost_off_list=0 orphan=0 late=0  PASS
...
RUN RESULT : OK  (16/16)
```

Each phase using the ISR also prints the **interrupt latency** measured by the probe on TIM3 (maximum, PC interrupted, histogram):

```
e87 queue   : irq_lat max=16.25 us pc=0x00000000  <1:625 <2:40232 <5:1708
    <10:15570 <20:1965 <50:0 <87:0 >=87:0
```

`pc=0` means that the maximum occurred inside a handler (PendSV), not in a task code section with interrupts disabled.

A phase passes if all counters are zero, the consumer exits cleanly at the end of the phase, and the number of cycles is at least 50 per second.

A PASS means "not hit in N thousand attempts", not "impossible". For this reason, the criterion also requires the number of cycles. The true test of the bench is the other direction: **on code with the defect, it must return FAIL**. A bench that also passes on broken code does not prove the fix.

110.1.5 Configuration

flag	value
`EN_TIMER`	1
`EN_EVENT`, `EN_NOTIFY`	1
`EN_STREAM`, `EN_MESSAGE`	1
`ENABLE_CLI`	1

No wiring: TIM3 is only used as an interrupt source.

20 task slots are required (`MAX_TASK`): on F103 (5), the example does not run: it prints `EXAMPLE IS DISABLED FOR UNSUPPORTED HARDWARE` and the reason.

110.1.6 Test

`test/hw_test/src/test_ex87.cpp`: one test phase per primitive, so a regression names the primitive. `CAOS_E87_SEC` changes the duration of each phase.

```
./hw_test.sh -n ex87
CAOS_E87_SEC=10 ./hw_test.sh -n ex87
```

Chapter 111

CLI Echo on the USB CDC Console

111.1 Example 90 — Echo of CLI on USB CDC console

111.1.1 Description

Example 90 demonstrates that, with the console on **USB CDC**, a character typed by the user never ends **inside** a line printed by another task.

The example starts idle (`ex90: idle`). `e90 start` launches a task `talker` that prints a fixed-format line every `EX90_PERIOD_MS` (20 ms):

```
EX90 seq=<n> tick=<ms> END
```

While lines scroll, type on the CDC console. The typed characters may appear **between** a line and the next one, but never inside: every line that contains `EX90 seq=` must end exactly with the format above. The check is done on the format, not by eye, and consecutive `seq` also indicates if a line was lost.

Hardware: boards with USB device used by ex52 (U575, H753, F407, F446, F767, H563). Test target: **NUCLEO-H753ZI**, user USB port (CN13).

111.1.2 Why this example

The defect: echo inside lines

Until 09/23 the CLI echo started **from the receive ISR**: every byte received was immediately re-sent to the console, while the stdout task could be in the middle of a line from another task. The typed character ended up in the middle of a line:

```
19788t37          <- a 't' typed inside a number
lA   113 ...      <- corrupted table row
```

It wasn't just a visual annoyance: lines like this ended up in an **archived capture** (the app_2 guide, log from 08/31). They remain plausible and are false, and a capture is meant to be re-read months later.

The fix

Starting from 09/23, the echo is no longer written from the ISR: it goes into a dedicated queue (`ca_stdout_echo()`, 128 slots of one byte, ISR-safe) and the **stdout task is the only writer to the console**. The task empties the echo only **between** one line and the next. Lost echoes due to full queue are counted (`echo dropped` in `cli_stat`).

The case **between** lines (for example `upti` + one line from the monitor + `me`) remains, and it's a choice: this is the standard behavior even on PC (bash with a background job that prints), and the command still arrives intact.

What was missing: the CDC console

The fix had been tested on the **UART** console: U575 by hand (09/23), H563 (09/30), and U575 (10/02) Release with emulated typing on ex68. On CDC, bytes don't come from the UART ISR but from the USB callback, which calls the same `ca_cli_rx_byte()`: the echo path is the same, but it had never been tested. No existing example allowed it: ex63 has the console on CDC but no task that continuously prints. Hence ex90.

111.1.3 os_config.h configuration

Created with `caos_config.py --new 90 --from ex63 --set EN_UART_DMA=0 --set EN_DMA=0`: the console from ex63 (CDC) without its UART DMA protocol.

```
#define EN_USB              1
#define EN_USB_CDC          1
#define EN_USB_FS           1
#define STDOUT_ON_USB_CDC   1
#define STDIN_ON_USB_CDC    1
#define ENABLE_CLI          1
```

`ENABLE_DBG_UART` is off as in ex63: nothing comes out on the ST-LINK port. On MCUs without support, the *unsupported* marker still comes out on the debug UART, written directly.

111.1.4 Commands

```
e90 info         lines printed, period, stdout and CDC counters
e90 period N     talker period in ms (5..1000)
e90 stop|start   stops / restarts the talker (to read diagnostic commands)
e90 line N       a line of exactly N characters (1..127): with N=62 and 126 the
                 USB write is 64 and 128 bytes, the empty packet case
cli_stat         CLI state: 'echo dropped' must stay 0
```

`e90 info` print:

```
lines  : 24431
period : 20 ms
stdout : queued 0  dropped 0  echo dropped 0
cdc tx : refused 0
```

- `dropped` — lost strings from stdout: either due to a full queue (with the `stdout: warning queue is full!` marker in the stream) or because the sender has rejected them after `STDOUT_SENDER_RETRIES` attempts (silently).
- `cdc tx refused` — number of times `ca_usb_cdc_write()` has rejected a string because the IN endpoint ring was full. A rejection **is not** a loss: the drain retries the same string one tick later.

111.1.5 How to test

Connect **both** cables: ST-LINK (flash) and USB user. The console is the CDC port (VID `ca01`, for example `/dev/ttyACM1`), not the ST-LINK's VCP.

Human-speed simulated typing with `caos_shell`:

```
CAOS_TTY=/dev/ttyACM1 CAOS_CHAR_MS=120 \
    test/hw_test/build/caos_shell -t 1 -i < commands.txt > run.log
```

Criteria, from the log:

1. every line containing `EX90 seq=` ends with `tick=<n> END`;
2. consecutive `seq` (except for the port opening, see below);
3. one response per command;
4. `echo dropped = 0`.

111.1.6 Results (10/04, NUCLEO-H753ZI, Debug)

Test	Lines from talker	Lines with one character inside	Responses	echo dropped
95 commands, 120 ms/car, talker 20 and 5 ms	18,120	**0**	60/60 `uptime`, 32/32 `e90 info`	0
65 commands, 120 ms/car, talker 5 ms	24,579	**0**	62/62	0
203 commands in burst, talker 5 ms	40,810	**0**	202/202 (*)	0

(*) In 2 responses out of 202, the line `lines : N` is missing from the log but not from the board (`dropped` and `refused` are quiet). `caos_shell` removes the first line from the response if it starts with the typed command; here the echo of the CR arrived **after** the first line of the response (`e90 info + lines : N + \r\n`), so the strip removed also `lines : N`, and instead a blank line remains. The reversed order is a small race in the drain (echo controlled, then ISR + command, then the line): the echo remains **between** the lines.

The echo on CDC behaves like on UART: typed characters appear only at the beginning of lines, never in the middle.

Lost lines: they were from the bench, not the board

At 5 ms (200 lines per second) the first two rounds lost, each time and always on the same command (`e90 period 20`), about 100 bytes: three talker lines and the echo of `2` and `0`. The command arrived intact.

`e90 info` said where: `dropped 5`, `refused 259`, empty queue and no marker. Five strings discarded after 50 attempts, that is, the IN endpoint was stuck: **the PC was not reading**.

The cause is in `serialIface::sendLine()` (`test/common/inc/serialIface.h`): with `CAOS_CHAR_MS` it does `delay()` between one character and the next **without reading the port**. `e90 period 20` is the longest command, 14 characters at 120 ms, so about 1.7 s of PC silence while the board produces ~6 KB/s: the tty fills up, `cdc-acm` stops reading the endpoint and the board, after the attempts, discards. This is the intended behavior for a console that nobody empties: the drain must not hang.

Test: same load with `CAOS_CHAR_MS=0` (command sent in one go, the PC always reads), 200 commands at 5 ms: `dropped` **unchanged**, no lines lost.

Two other bench effects to know:

- **At port opening** `seq` is skipped: the DTR causes the banner to be reprinted and the stdout queue to be cleared (`ca_stdout_flush()`), and the PC can return old lines remaining in its buffer.
- **At port closed the board continues printing.** The bench removes `HUPCL` (on VCP the drop of DTR resets the board), so the DTR stays high even after closing, `ca_usb_cdc_connected()` stays true and the lines are discarded after the attempts: `dropped` grows from one round to the next.

Chapter 112

Kernel Semantics Bench

112.1 Example 91 — Kernel Semantic Testbench

112.1.1 Description

Example 91 tests the **semantics** of kernel primitives: not whether they work under normal conditions, but whether they do the right thing in edge cases. The cases come from reading Zephyr's catalog `tests/kernel` (1009 cases): for every situation that Zephyr thought to test and that caOS's testbench wasn't covering, ex91 has a case.

The example starts idle and prints nothing until it receives a command. Each case is deterministic and judges itself: it prints a line `[e91] <caso> PASS|FAIL <valori misurati>` and the passed case closes with `RUN RESULT : OK|FAIL (n/m)`.

No wiring required. Runs on all boards with at least 16 tasks and the FPU (the `fpu_share` case exists only where there is one).

112.1.2 Why This Example

A green test says that the tested cases pass, not that the function is correct: a conceptual hole remains invisible until someone names the case. Examples ex05-ex20 prove that mutexes, semaphores, condition variables, and timers work in normal flow; nobody asked what happens if the waiter that raised the priority times out, if a timer stops from its own callback, or if an FP task declared actually starts.

Two of these questions found **real bugs** on the first run (05/10):

- **Periodic timer stopped by its own callback**: kept running. The daemon, after the callback, re-armed the periodic (and stopped the one-shot) without checking if the callback had already decided: 12 expirations instead of 3. Now the daemon only decides if the state is still `EXPIRED`.
- **Task** `JOB_FLOAT_POINT`: every FP task declared started with PC=0 and dirtied the neighbor's stack. Two defects summed in `ca_thread_create`: the initial hardware frame was base (8 word) while EXC_RETURN said «extended» (26 word), and `ca_memset_u32` received 64 as count — which is in **word** — zeroing 256 bytes instead of 64, including the PC just written. Latent because no example declared an FP task.

112.1.3 The Mechanism: Actors with a Script

A case is played by up to eight **actors**. Each executes a small script of operations (lock, timed lock, unlock, wait for a gate, turn on a marker, record its own priority, receive from a queue...).

The command task acts as the conductor: it creates the actors, waits for markers, opens gates, and reads priorities. The script makes the order of events explicit and keeps a case in a few lines.

An actor that hasn't exited by the end of the case is blocked in an unexpected wait: it is removed and the case fails with `STUCK`.

Priority inheritance is judged on the **actual `priority` field**, not on who gets the CPU: caOS's scheduler is weight-based (CFS) and a low-priority task continues to run next to a medium one, so the classic «M starving L» doesn't appear.

112.1.4 Configuration os_config.h

Created with `caos_config.py --new 91 --from ex18`, then `--on EN_RWLOCK` and `--off EN_LED --off EN_CLI_LED`. Flags that count:

Flag	Value	Why
`ENABLE_CLI`	1	test cases are launched from CLI
`EN_SW_TIMER`	1	cases `tmr_*`
`EN_RWLOCK`	1	case `rw_excl`
`MAX_TASK`	>= 16	8 actors plus system tasks (F103: example not supported)

112.1.5 Commands

Command	Effect
`e91 list`	lists test cases with one line of description
`e91 start`	runs all test cases, then `RUN RESULT`
`e91 start <caso>`	runs a single test case

Case	What it checks
`pi_basic`	the owner of a mutex boosts to the priority of the waiter, and returns to its own after unlock
`pi_two_mtx`	with two held mutexes, releasing the one that H does not wait for does not remove the boost
`pi_timeout`	the waiter that times out regains the boost: the owner returns low without unlock
`pi_chain`	the boost follows the chain: L holds M1, M holds M0 and waits for M1, H waits for M0 → L boosts to H
`pi_setprio`	`set_priority` on a boosted owner: remains H during the boost, new value after
`pi_kill`	the waiter that raised the owner is removed while waiting: the owner returns to its own priority

Case	What it checks
`pi_hopcap`	chain of 6 owners: the boost stops after `CA_PI_MAX_CHAIN` steps, nothing blocks
`rmutex_cnt`	a recursive mutex is only free to another task when the count reaches zero
`wake_pend`	`ca_os_wake_up_handle` on a task waiting for a semaphore does not grant a count
`reset_wait`	resetting a queue does not let waiting receivers exit with a phantom data
`send_front`	`send_front` bypasses queued elements
`scr_tmo`	8 waiters with timeouts mixed exit in order of expiry, timely within 3 ms
`cv_signal`	a `signal` wakes exactly one waiter
`cv_bcast`	a `broadcast` wakes them all
`cv_relock`	a `timedwait` in timeout returns with the mutex owned
`rw_excl`	no reader sees a partially written block, the writer is not starved
`coop_spin`	the cooperative spinlock does not lose increments (with a yield inside the section)
`tmr_drift`	a 10 ms periodic for 2 s does not drift
`tmr_restart`	`reset` re-arms starting from reset
`tmr_stopcb`	a periodic stopped by its own callback stays stopped
`tmr_rearm`	a one-shot re-armed by its own callback restarts
`tmr_same`	8 armed timers all expire, within 2 ms of each other
`tmr_period`	`set_period` takes effect from the next cycle
`fpu_share`	3 FP preempted tasks for 2 s always give the same bits

caOS has no *scheduler lock*: the corresponding Zephyr case is now `coop_spin`, the cooperative spinlock mutual exclusion.

112.1.6 How to test

```
./do_examples 91 && ./prog.sh -s -e 91
./hw_test.sh -n ex91            # one phase per case
```

or manually from the console: `e91 start`.

112.1.7 Results (05/10, NUCLEO-H753ZI, Debug)

24 cases out of 24. On the first run, the four cases `pi_two_mtx`, `pi_timeout`, `pi_chain` and `pi_setprio` failed: these were the limits of the priority inheritance of that time (one `prio_bkup` per task, boost only on the direct owner, removed only on unlock), as foreseen by the plan before writing the case. Correcting them led to the current PI.

```
[e91] pi_two_mtx  PASS  L boosted=32, after unlock M0 (H still on M1)=32 (want 32), after unlock M1=2 (want 2)
[e91] pi_timeout  PASS  L boosted=32, after H timed out (L still owner)=2 (want 2)
[e91] pi_chain    PASS  M (owner of M0)=32 (want 32), L (owner of M1, M waits)=32 (want 32)
[e91] pi_setprio  PASS  set to 4 while boosted: during=32 (want 32), after unlock=4 (want 4)
[e91] pi_kill     PASS  L boosted=32, after H removed while waiting=2 (want 2)
[e91] pi_hopcap   PASS  chain of 6 owners, cap 4 hops: boosted 5 (want 5) - A0..A5 = 2 32 32 32 32 32
[e91] scr_tmo     PASS  8 timeouts 10..80 ms: early=0 late=0 (worst +0 ms, slack 3) out_of_order=0
[e91] tmr_drift   PASS  10 ms for 2 s: hits=200 (want 200 +-1), span drift=0 ms (max 2)
[e91] fpu_share   PASS  3 FP tasks + 1 integer task for 2000 ms: rounds=4552 wrong=0 (want 0)
RUN RESULT : OK  (24/24)
```

Priority inheritance (Zephyr schema)

- `priority` is the **actual** priority (the weight for the scheduler); `prio_base` is the one assigned at creation or by `ca_os_set_priority_handle`.
- Actual = maximum between `prio_base` and the priority of every task waiting on a mutex owned (`pi_held`, list in the context, `pi_next` in the mutex).
- It is recalculated at every change of the set: a waiter arrives or leaves (lock, timeout, removal), a mutex changes hand (unlock), `prio_base` changes.
- A change proceeds on the owner of the mutex on which the task itself is waiting (`pi_wait`), at most `CA_PI_MAX_CHAIN` steps (default 4, in `sync.h`, overridable): each step switches to masked IRQ, therefore the chain is limited by construction.
- Cost: +8 B per context (180 B), +4 B per mutex. `MAX_TASK` recalculated: 22 on 4 KB TLB (F407, F429, F446, F746), 90 on 16 KB TLB (H753, H747, U575, H563); F767 stays 25 (arena PSP constraint). `ca_scheduler_init()` now stops with a message if `MAX_TASK * sizeof(ca_thread_context_t)` exceeds `_tlb_area_size`.
- The recursive mutex (`ca_rmutex_*`) does not have priority inheritance.

Chapter 113

External SPI NOR Flash on the QSPI

113.1 Example 92 — External SPI NOR Flash on QSPI/OCTOSPI

Drives a W25Qxx-class serial NOR flash via the QSPI driver (QUADSPI on F446/F7/H7, OCTOSPI1 on H5/U5), in **single** and **dual** mode and from the **memory-mapped** window at `0x90000000`. The driver operates via **interrupt**: data on FIFO interrupt, erasure and programming waits on the controller's auto-polling, the task sleeps.

113.1.1 Configuration (os_config.h)

```
#define EN_QSPI      1
#define EN_CLI_QSPI  1     /* the driver's "qspi" command, optional */
```

The example only runs where `MCU_HAS_QSPI` (board objmap) is 1: on F103, F407, and F429 it is declared unsupported.

113.1.2 Hardware — 6-pin module

The module (VCC CS DO GND CLK DI) goes on the Zio QSPI positions, **the same on all Nucleo-144** boards; only the MCU pins behind them change, which come from the driver table (`pinmap` 0):

module	position	F446/F746/F767	H753/H563	U575
1 VCC	CN8-7 (3V3)	–	–	–
2 CS	CN10-13	PB6	PG6	PA2
DI	CN10-23	PD11	PD11	PE12
4 GND	CN10-17	–	–	–
5 CLK	CN10-15	PB2	PB2	PB10
DO	CN10-21	PD12	PD12	PB0

DO/DI are the flash OUTPUT/INPUT data, easy to read as D0/D1: DI goes to IO0, DO to IO1, and `e92 wire` also tests the swap. CN10 does not carry 3V3 (pin 1 is AVDD): power comes from CN8-7. With only DI/DO, the module works in single (1-1-1) or dual output (1-1-2, command `0x3B`), never in quad. WP and HOLD must be pulled to VCC on the module: a floating HOLD freezes the flash.

113.1.3 Commands

At boot, the board is stopped; each test is **one pass** that concludes with a verdict readable by the test bench.

command	what it does	verdict
`e92 wire`	prints the connections of the board under test and reads the JEDEC ID via **simple GPIO** (no QSPI): a FAIL blames the wires, not the driver	`WIRE RESULT`
`e92 start`	everything: id, init, erase, erase verification, write, single and dual readback, and the same data read from the memory-mapped window (0x90000000)	`RUN RESULT`
`e92 write`	erase + pattern write + single readback	`RUN RESULT`
`e92 read`	reads back the pattern (single, dual, memory-mapped) **without writing**: after a power cycle, it tests retention	`RUN RESULT`
`e92 bench`	read speed on 1 MB at the current clock: indirect (interrupt-driven, 512 B calls) versus memory-mapped (memcpy from the window)	`RUN RESULT`
`e92 sweep`	increases the clock (from 7.8 to 125 MHz on H563): for each divider, single write+readback and dual read, with shifting off and on, one line per frequency and the maximum it can handle	`RUN RESULT`
`e92 clk <MHz>`	clock for subsequent tests (default 8 MHz)	–
`e92 shift auto|on|off`	half-cycle sampling shift (auto: on above 40 MHz)	–
`e92 dump [addr]`	64 bytes in single	–
`e92 info`	last ID, prescaler, counters	–

Each step prints `STEP <nome> : OK|FAIL`. The test area is the 4 KB sector at `0x001000`; the pattern (512 B, fixed seed) starts at offset `0x80` so it crosses two page boundaries and also verifies the driver's page splitting. The clock is kept below 8 MHz for the flying wires.

`wire` leaves the pins as GPIO: no need to reboot, the next test reopens the driver and returns them to the alternate function.

Part III

caOS Reference

Chapter 114

Reference API caOS

Funzioni in ordine alfabetico. Per ogni funzione: firma, descrizione, parametri, valore di ritorno, note, esempio.

ca_adc_hw_init_periph

Header: caos/drivers/inc/ca_glue_hw.h:10
GUARD: EN_CA_GLUE_HW

```
1 extern bool ca_adc_hw_init_periph(u8 adc_num, u8 sample_time); /*
     configura il periferico ADC in modalit  polling */
```

Initializes and calibrates the specified ADC hardware peripheral for polling-based operations.

Parametri:

Nome	Tipo	Descrizione
adc_num	u8	The index of the ADC peripheral to initialize (typically 1, 2, or 3 depending on the STM32 model).
sample_time	u8	The sampling time configuration value to be applied to all channels; higher values increase accuracy but decrease conversion speed.

Ritorna:
Returns true if the ADC was successfully initialized and calibrated, false if the hardware failed to respond (e.g., timeout during calibration or power-up).

Note:

- This function is blocking because it performs hardware polling loops (waiting for voltage regulators or calibration cycles to complete). It is NOT thread-safe and must not be called from an Interrupt Service Routine (ISR) due to the potential for long-running loops. Before calling this, ensure the peripheral clock has been enabled via the appropriate clock control function. A common mistake is calling this function multiple times without resetting the peripheral, which may lead to undefined hardware states or calibration errors.

Uso:

- This function is intended to be used during the system startup phase or when a specific ADC peripheral is first requested by the application. It is typically called inside a higher-level driver initialization function (like ca_adc_init) that handles clock gating and configuration validation. It should be paired with subsequent functions that trigger conversions and read data registers, ensuring the hardware is in a ready state before any sampling begins.

Esempio:

```
/* Initialize ADC1 with a sample time of 7 (e.g., 47.5 cycles) */
if (ca_adc_hw_init_periph(1, 7)) {
    /* Hardware is ready, proceed to trigger conversions */
} else {
    /* Handle initialization failure: log error or enter safe state */
    handle_error();
}
```

Q&A — fine-tuning review *7/7 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I call ca_adc_hw_init_periph() in my embedded application?
A: You should call ca_adc_hw_init_periph() once during system initialization, before attempting any ADC conversions. It configures the ADC peripheral for polling mode, sets the sampling time for all channels, and calibrates the ADC. This function is typically called after enabling the ADC clock with ca_clock_hw_adc_init().

Code example conf:0.95 **Q:** Can you show a minimal example of how to use ca_adc_hw_init_periph()?
A:

```
u8 adc_num = 1;
u8 sample_time = 5;
bool success = ca_adc_hw_init_periph(adc_num, sample_time);
/* Use ADC for conversions */
```

Parameters conf:0.95 **Q:** What do the parameters adc_num and sample_time represent in ca_adc_hw_init_periph()?
A: adc_num specifies which ADC peripheral to initialize (1, 2, or 3). sample_time sets the sampling time for all ADC channels, ranging from 0 to 7. Invalid adc_num values (0 or >3) or sample_time values outside 0-7 may cause undefined behavior or incorrect operation.

Return conf:0.95 **Q:** Does ca_adc_hw_init_periph() ever return false?
A: No, ca_adc_hw_init_periph() always returns true. The function is designed not to fail during initialization, although incorrect parameters may lead to malfunctioning ADC behavior.

Error/Edge case conf:0.90 **Q:** What are the most common mistakes when using ca_adc_hw_init_periph()?
A: Common mistakes include calling the function without first enabling the ADC clock using ca_clock_hw_adc_init(), using invalid adc_num values (0 or >3), or using sample_time values outside the valid range (0-7). These can lead to incorrect ADC configuration or initialization failure.

Behavior conf:0.95 **Q:** Is ca_adc_hw_init_periph() blocking or non-blocking, and can it be called from an ISR?
A: It is a blocking function because it waits during the calibration phase using a while loop. It cannot be called from an ISR because it contains blocking code that would prevent proper interrupt handling.

HW differences conf:0.90 **Q:** How does ca_adc_hw_init_periph() differ between STM32F1xx and STM32H7xx families?
A: On F1xx, the function uses ADC_CR2_ADON, ADC_CR2_EXTTRIG, and ADC_CR2_EXTSEL for triggering, and performs calibration by setting ADC_CR2_CAL and waiting for it to clear. On H7xx, it enables the voltage regulator via ADC_CR_ADVREGEN, performs calibration with ADC_CR_ADCAL, and waits for ADC_ISR_ADRDY to be set before enabling the ADC with ADC_CR_ADEN.

`ca_adc_hw_init_periph_isr`

Header: `caos/drivers/inc/ca_glue_hw.h:13`
GUARD: `EN_CA_GLUE_HW`

```
extern bool ca_adc_hw_init_periph_isr(u8 adc_num, u8 sample_time,
    ca_adc_isr_cb_t cb); /* configura ADC in modalit  interrupt con
    callback */
```

Initializes the ADC hardware peripheral and configures it to trigger an interrupt upon conversion completion.

Parametri:

Nome	Tipo	Descrizione
`adc_num`	`u8`	The index of the ADC peripheral (typically 1, 2, or 3 depending on the specific STM32 model). Invalid values return false.
`sample_time`	`u8`	The sampling duration configuration for the ADC channels. Must be a valid value supported by the hardware registers.
`cb`	`ca_adc_isr_cb_t`	A function pointer to the callback function that will be executed inside the Interrupt Service Routine (ISR) when the conversion finishes.

Ritorna:
Returns true if the ADC was successfully initialized and the interrupt was enabled. Returns false if the adc_num is out of range, the underlying hardware initialization fails, or the provided callback is invalid.

Note:

- This function is non-blocking and performs hardware-level configuration, including enabling the End-Of-Conversion (EOC) interrupt and setting the NVIC priority. It is not thread-safe and should be called during the system initialization phase before starting any conversions. It must NOT be called from within an ISR itself, as it modifies NVIC settings and peripheral registers that could lead to race conditions or system instability. A common mistake is passing a NULL pointer as the callback, which will cause the system to crash or jump to an invalid memory address when the interrupt fires.

Uso:

- This function is used when you need to perform non-blocking ADC conversions, allowing the CPU to execute other tasks while waiting for the hardware to finish sampling. It is typically paired with ca_clock_hw_adc_init to ensure the peripheral clock is running, followed by ca_adc_hw_start_isr to trigger the actual conversion process. Once the conversion completes, the hardware automatically jumps to the provided callback function, where you can read the result using a function like ca_adc_get_value.

Esempio:

```
/* Define the callback function to handle the result */
void my_adc_callback(u16 value) {
    /* Process the ADC result here */
}

/* Initialize ADC1 with a specific sample time and the callback */
if (ca_adc_hw_init_periph_isr(1, 15, my_adc_callback)) {
    /* Start the conversion on channel 5 */
    ca_adc_hw_start_isr(1, 5);
} else {
    /* Handle initialization error */
}
```

Q&A — fine-tuning review *7/7 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I call ca_adc_hw_init_periph_isr() in my embedded application?
A: You should call ca_adc_hw_init_periph_isr() when you want to configure an ADC in interrupt mode to handle conversion results asynchronously. This is useful when you need to process ADC data without blocking the main execution flow, such as in real-time systems or when handling multiple sensors.

Code example conf:0.90 **Q:** Can you provide a minimal working example of how to use ca_adc_hw_init_periph
A:

```
u8 adc_num = 1;
u8 sample_time = 13;
ca_adc_isr_cb_t callback = my_adc_callback;
bool success = ca_adc_hw_init_periph_isr(adc_num, sample_time, callback);
if (!success) {
    // Handle error
}
```

Note: my_adc_callback must be defined as a function of type ca_adc_isr_cb_t.

Parameters conf:0.95 **Q:** What are the valid values for the adc_num parameter in ca_adc_hw_init_periph_isr
A: The adc_num parameter must be 1, 2, or 3 depending on the MCU family. For F1xx and H5xx, valid values are 1 and 2. For F4xx, F7xx, and H7xx, valid values are 1, 2, and 3. Values outside this range will cause the function to return false.

Return conf:0.95 **Q:** What does it mean when ca_adc_hw_init_periph_isr() returns false?
A: A return value of false indicates one of the following failures: invalid adc_num (less than 1 or greater than 3), hardware initialization failure via ca_adc_hw_init_periph, or a NULL callback function was passed.

Error/Edge case conf:0.90 **Q:** What are common mistakes when using ca_adc_hw_init_periph_isr()?
A: Common mistakes include passing an invalid adc_num (outside 1-3 range), not properly initializing the ADC pin before calling this function, passing a NULL callback function, or failing to ensure that the ADC clock is enabled and the pin is configured correctly.

Behavior conf:0.95 **Q:** Is ca_adc_hw_init_periph_isr() thread-safe and can it be called from an ISR?
A: No, ca_adc_hw_init_periph_isr() is not thread-safe because it modifies a global variable (s_isr_cb). Additionally, it should not be called from an ISR as it's a hardware initialization function and not meant for interrupt context.

HW differences conf:0.85 **Q:** How does ca_adc_hw_init_periph_isr() differ between H5xx and H7xx MCUs in terms of hardware implementation?
A: On H5xx, only ADC1 is used regardless of the adc_num parameter, and the function uses ADC1_IRQn for ADC1 and ADC2_IRQn for ADC2. On H7xx, the function supports ADC1, ADC2, and ADC3, with ADC3 using ADC3_IRQn and others using ADC_IRQn. H7xx also uses ADC_TypeDef *adc = adc_inst(adc_num) to get the correct ADC instance.

`ca_adc_hw_irq_handler`

Header: `caos/drivers/inc/ca_glue_hw.h:15`
GUARD: `EN_CA_GLUE_HW`

```
extern void ca_adc_hw_irq_handler(u8 adc_num); /* gestore IRQ ADC: legge il risultato e invoca la callback */
```

Hardware-specific interrupt service routine handler for ADC peripheral completion events.

Parametri:

Nome	Tipo	Descrizione
`adc_num`	`u8`	The identifier of the ADC peripheral (e.g., 1, 2, or 3). Must match the hardware configuration limits of the specific STM32 series.

Ritorna:
void. This function does not return a value as it is an interrupt handler.

Note:

- This function is designed to be called exclusively from the hardware interrupt vector table (ISR context). Because it runs in an ISR, it must be extremely fast; performing heavy processing or blocking operations inside the callback will cause system instability or missed interrupts. It is not thread-safe in the sense that it modifies hardware registers directly, but it is re-entrant if the hardware supports multiple ADC instances. A common beginner mistake is to perform long calculations or use blocking RTOS primitives (like mutexes or delays) inside the callback function triggered by this handler, which will crash the system or cause a watchdog reset.

Uso:

- This function is the bridge between the hardware ADC peripheral and your application logic. It is typically invoked by the STM32 vector table when the 'End of Conversion' (EOC) flag is raised by the hardware. You must register a callback function using the appropriate driver initialization function before this handler is triggered, otherwise, the handler will simply exit without notifying your application. It is used in a sequence: initialize the ADC, enable the ADC interrupt in the NVIC, and then this handler will automatically execute every time a conversion finishes.

Esempio:

```c
/* Example of an ISR implementation in the vector table */
void ADC1_2_IRQHandler(void) {
    /* Call the caOS hardware handler for ADC 1 */
    ca_adc_hw_irq_handler(1);
}

/* Example of a callback function registered to handle the data */
void my_adc_callback(u8 adc_num, u16 value) {
    /* Process the 12-bit ADC result here */
    /* Keep this code short and fast! */
}
```

Q&A — fine-tuning review *6/6 pairs · qwen3-coder:latest*

Usage conf:1.00 **Q:** When should ca_adc_hw_irq_handler be called, and why is it important to call it from an ISR?
A: ca_adc_hw_irq_handler should be called from an Interrupt Service Routine (ISR) to handle ADC conversion complete interrupts. It is important because the function reads hardware registers (like DR and SR/ISR) and clears the EOC flag, which must be done in the ISR context to avoid race conditions and ensure correct ADC operation. It must not be called from a task or thread context.

Code example conf:1.00 **Q:** Can you provide a minimal C code example showing how to use ca_adc_hw_irq_handler with caOS types?
A:

```c
u16 adc_callback(u8 adc_num, u16 value) {
    return value;
}

void my_adc_isr(void) {
```

```
6     ca_adc_hw_irq_handler(1);
7 }
```

Parameters conf:1.00 **Q:** What does the adc_num parameter represent, and what are the valid values for it?
A: The adc_num parameter specifies which ADC peripheral to handle. Valid values depend on the MCU family: 1 and 2 for F1xx, 1, 2, and 3 for F4xx and F7xx, 1 and 2 for H5xx, and all ADCs for H7xx. Any other value causes the function to return immediately without effect.

Return conf:1.00 **Q:** Does ca_adc_hw_irq_handler return any value, and what happens if it fails?
A: The function does not return any value. It cannot fail in a strict sense, but it may silently ignore invalid inputs such as an invalid adc_num or be called from a non-ISR context. It always attempts to read the ADC data register and invoke the callback if valid.

Error/Edge case conf:1.00 **Q:** What are the most common mistakes when using ca_adc_hw_irq_handler?
A: Common mistakes include calling the function with an invalid adc_num (outside the valid range for the MCU family), calling it from a task or thread context instead of an ISR, or calling it when the EOC flag is not set. Another mistake is not ensuring that the callback function is properly registered via the s_isr_cb array.

HW differences conf:1.00 **Q:** How does ca_adc_hw_irq_handler differ between H5xx and H7xx MCU families?
A: In H5xx, the function always uses ADC1 regardless of the adc_num parameter, and checks the ADC1->ISR register for EOC. In H7xx, the function uses the adc_inst(adc_num) macro to get the correct ADC register base and checks the ISR flag for that specific ADC. H7xx also supports up to 3 ADCs, while H5xx only supports 2.

`ca_adc_hw_read`

Header: `caos/drivers/inc/ca_glue_hw.h:12`
GUARD: `EN_CA_GLUE_HW`

```
1 extern u16 ca_adc_hw_read(u8 adc_num, u8 channel); /* avvia conversione
    e ritorna il valore grezzo a 12 bit */
```

Triggers a single ADC conversion on a specific channel and returns the 12-bit raw digital value.

Parametri:

Nome	Tipo	Descrizione
`adc_num`	`u8`	The identifier of the ADC peripheral (e.g., 1, 2, or 3). Must correspond to valid hardware instances defined in the BSP.
`channel`	`u8`	The analog input channel index. Must be a valid channel supported by the selected ADC peripheral.

Ritorna:
A 12-bit unsigned integer (0-4095) representing the converted voltage. Note that this function does not return error codes; it assumes valid hardware state.

Note:

- This function is strictly blocking, meaning the CPU will sit in a 'while' loop waiting for the hardware to finish the conversion. Because it uses a busy-wait loop, it is NOT thread-safe

if multiple tasks access the same ADC instance simultaneously, and it must NEVER be called from an Interrupt Service Routine (ISR) as it would cause a system hang. Before calling this, ensure the ADC peripheral has been properly initialized via the system clock and GPIO configuration functions. A common beginner mistake is calling this function at a high frequency in a low-priority task, which can starve other tasks of CPU time due to the blocking nature of the hardware wait.

Uso:

- This function is typically used for polling-based sensor reading where high-speed, non-blocking asynchronous operation is not required. It is usually paired with an initialization function like 'ca_adc_init_isr' or a generic hardware setup routine that configures the GPIO pins to analog mode. In a typical application, you would call this function periodically within a task loop to sample analog data, process the raw 12-bit value, and then perform control logic based on the result.

Esempio:

```
/* Example: Reading a potentiometer value from ADC1, Channel 5 */
u16 raw_value;

/* Ensure ADC is initialized before reading */
if (ca_adc_init_isr(&my_adc_config, my_callback)) {
    /* Blocking read: CPU waits here until conversion completes */
    raw_value = ca_adc_hw_read(1, 5);

    /* Process the 12-bit raw value (0 to 4095) */
    if (raw_value > 2048) {
        /* Perform action if voltage is above threshold */
    }
}
```

Q&A — fine-tuning review *7/7 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I use ca_adc_hw_read() in my caOS project?
A: You should use ca_adc_hw_read() when you need to perform a blocking, non-thread-safe analog-to-digital conversion in a non-critical context. It is intended for use in non-ISR, non-concurrent code where you can tolerate the blocking behavior and don't require thread safety.

Code example conf:0.95 **Q:** Can you show a minimal example of how to read ADC channel 5 from ADC1 using ca_adc_hw_read()?
A: u16 adc_value = ca_adc_hw_read(1, 5);

Parameters conf:0.95 **Q:** What are the valid ranges for adc_num and channel parameters in ca_adc_hw_read()?
A: adc_num must be 1, 2, or 3. channel must be between 0 and 18. Invalid values for either parameter may cause undefined behavior or incorrect readings.

Return conf:0.95 **Q:** What does ca_adc_hw_read() return, and how can I tell if the read was successful?
A: It returns a 12-bit value representing the ADC conversion result. There is no error code returned, so it's impossible to distinguish a valid 0 value from a failed read.

Error/Edge case conf:0.90 **Q:** What are common mistakes when using ca_adc_hw_read()?
A: Common mistakes include calling it from an ISR, calling it from multiple threads simultaneously, not initializing the ADC or configuring the channel beforehand, and assuming that a returned value of 0 indicates an error.

Behavior conf:0.95 **Q:** Is ca_adc_hw_read() thread-safe and ISR-safe?
A: No, ca_adc_hw_read() is neither thread-safe nor ISR-safe. It is a blocking function and should not be called from an ISR or from multiple threads concurrently.

HW differences conf:0.85 **Q:** How does ca_adc_hw_read() differ between STM32H7xx and STM32F4xx families?
A: On STM32F4xx, it uses ADC_CR2_SWSTART to start conversion and ADC_SR_EOC to check completion. On STM32H7xx, it uses ADC_CR_ADSTART and ADC_ISR_EOC, and also sets ADC_PCSEL for channel pre-selection.

---

ca_adc_hw_start_isr

Header: `caos/drivers/inc/ca_glue_hw.h:14`
GUARD: `EN_CA_GLUE_HW`

```
extern void ca_adc_hw_start_isr(u8 adc_num, u8 channel); /* avvia
    conversione asincrona     il risultato arriva via callback */
```

Triggers an asynchronous ADC conversion on a specific channel without blocking the CPU.

Parametri:

Nome	Tipo	Descrizione
`adc_num`	`u8`	The index of the ADC peripheral to use (e.g., 1 for ADC1). Note that some hardware implementations ignore this and always default to ADC1.
`channel`	`u8`	The specific analog input channel to sample. Valid values are typically 0-19 depending on the MCU architecture.

Ritorna:
void. This function does not return a status code; it assumes the hardware is correctly initialized and ready to start.

Note:

- This function is non-blocking and designed to be called from within an Interrupt Service Routine (ISR) or a high-priority task. It is not thread-safe by itself, so ensure that no other process is modifying the ADC registers simultaneously. A common beginner mistake is calling this function before the ADC peripheral has been properly clocked and configured, which will result in a hard fault or silent failure. Because it is asynchronous, the function returns immediately after triggering the hardware; you must rely on a separate interrupt handler or callback mechanism to retrieve the conversion result once the hardware sets the End-Of-Conversion (EOC) flag.

Uso:

- This function is typically used in a continuous sampling loop or a triggered data acquisition system. It is usually paired with an ADC interrupt handler: you call this function to start the conversion, and when the hardware finishes, the ADC interrupt fires, allowing you to read the result and potentially call this function again to start the next conversion. It is essential for high-performance applications where you cannot afford to wait for the ADC to finish (blocking) while the CPU does other work. In a typical sequence, you initialize the ADC, enable the ADC interrupt, and then call this function to kick off the first conversion.

Esempio:

```
/* Example: Triggering a new conversion inside an ADC completion interrupt */
void ADC_IRQHandler(void) {
    /* Check if the conversion is complete */
    if (ADC1->ISR & ADC_ISR_EOC) {
```

```
        u16 result = (u16)ADC1->DR; /* Read the conversion result */

        /* Process the data... */

        /* Trigger the next conversion on the same channel */
        /* Assuming channel 5 was the one being sampled */
        ca_adc_hw_start_isr(1, 5);
    }
}
```

Q&A — fine-tuning review *4/4 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I use ca_adc_hw_start_isr() and what is its main advantage over synchronous ADC conversion?
A: You should use ca_adc_hw_start_isr() when you need non-blocking ADC conversions, especially in real-time applications where blocking the execution is not acceptable. Its main advantage is that it initiates the conversion via ISR and returns immediately, allowing other tasks or ISRs to run while the ADC conversion is in progress. The result is handled through a callback function, making it suitable for time-critical systems.

Code example conf:0.90 **Q:** Can you provide a minimal C code example showing how to call ca_adc_hw_start_isr() with proper caOS types?
A:

```
u8 adc_num = 1;
u8 channel = 5;
ca_adc_hw_start_isr(adc_num, channel);
```

Parameters conf:0.90 **Q:** What are the valid ranges for adc_num and channel parameters in ca_adc_hw_start_isr(), and what happens if invalid values are passed?
A: The adc_num parameter must be 1 or 2; values 0 or greater than 2 are invalid and may cause memory access violations. The channel parameter must be between 0 and 15; values outside this range may result in incorrect channel conversion or undefined behavior. The function does not return an error code, so it's the caller's responsibility to ensure valid inputs.

HW differences conf:0.85 **Q:** How does ca_adc_hw_start_isr() implementation differ across STM32 families like F1, F4, F7, H5, and H7?
A: The F1, F4, and F7 families all use a similar approach by setting the channel in SQR3 and triggering SWSTART in CR2. The H5 family uses ADC1 directly, sets the channel in SQR1, clears EOC in ISR, and starts the ADC. The H7 family additionally sets the PCSEL register to enable the channel before starting the conversion, which is a more complex configuration for its ADC architecture.

`ca_adc_hw_stop`

Header: `caos/drivers/inc/ca_glue_hw.h:93`
GUARD: `EN_CA_GLUE_HW`

```
extern bool ca_adc_hw_stop(u8 adc_num); /* stops conversions and
   disables the ADC (clears ADEN) */
```

Safely stops ADC conversions and powers down the hardware peripheral.

Parametri:

Nome	Tipo	Descrizione
`adc_num`	`u8`	The index of the ADC peripheral to stop (e.g., 1 for ADC1). Note: Current implementations primarily target ADC1, so this parameter is reserved for future multi-ADC support.

Ritorna:
Returns true if the ADC was successfully disabled or was already off. Returns false if the hardware failed to acknowledge the stop command within the internal timeout period.

Note:

- This function is blocking because it performs a busy-wait loop to ensure the hardware registers (like ADEN or ADSTART) have cleared. It is not thread-safe; if multiple tasks share the same ADC, you must wrap this call in a mutex to prevent race conditions. It is generally not safe to call this from an ISR because the blocking loops could stall the system if the hardware hangs. The most common beginner mistake is calling this while a DMA transfer is still active, which can cause the ADC to lock up or leave the DMA in an inconsistent state; always ensure DMA is stopped before calling this.

Uso:

- This function is used to cleanly shut down the ADC peripheral during system power-down, mode switching, or error recovery. It is the mandatory cleanup step after using functions like ca_adc_init or ca_adc_init_isr. In a typical sequence, you would first stop any active DMA or interrupts, call ca_adc_hw_stop to release the hardware, and then potentially re-initialize the peripheral or enter a low-power sleep mode.

Esempio:

```
/* Stop the ADC before reconfiguring or entering sleep */
if (ca_adc_hw_stop(1)) {
    /* ADC is now disabled and analog switches are released */
} else {
    /* Hardware failed to stop; handle as a critical system error */
    /* Log error using available system logging or diagnostic tools */
}
```

Q&A — fine-tuning review *7/7 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** When should I call ca_adc_hw_stop in my caOS application?
A: You should call this function during system shutdown, power-saving transitions, or when you need to reconfigure the ADC for a different mode of operation. It acts as the counterpart to initialization functions like ca_adc_init.

Code example conf:1.00 **Q:** Provide a minimal example of how to safely stop the ADC using caOS types.
A: u8 adc_id = 1; if (!ca_adc_hw_stop(adc_id)) { /* handle hardware failure */ }

Parameters conf:1.00 **Q:** What does the adc_num parameter control, and are there specific values I should use?
A: The adc_num parameter is intended to specify the index of the ADC peripheral (e.g., 1 for ADC1). However, in the current implementation, this parameter is ignored as the driver uses a fixed ADC1 reference.

Return conf:1.00 **Q:** What do the boolean return values of ca_adc_hw_stop indicate?
A: It returns true if the ADC was successfully disabled or was already off. It returns false if the hardware failed to acknowledge the stop command within the internal timeout period.

Error/Edge case conf:1.00 **Q:** What is the most common mistake when calling ca_adc_hw_stop?
A: The most common mistake is calling this function while a DMA transfer is still active, which can lead to incomplete data buffers or unexpected hardware states.

Behavior conf:1.00 **Q:** Is ca_adc_hw_stop thread-safe and safe to call from an ISR?
A: The function is blocking because it waits for hardware status register updates. It is not thread-safe; if multiple tasks access the same ADC, you must use a mutex. It is generally not recommended to call it from an ISR due to the risk of an infinite loop if the hardware fails to respond.

HW differences conf:1.00 **Q:** How does the implementation of ca_adc_hw_stop differ between F1/F4/F7 and H5/H7/U5 families?
A: On F1, F4, and F7 families, the function simply clears the ADON bit in CR2. On H5, H7, and U5 families, the function performs a more complex handshake using ADSTP and ADDIS bits to ensure conversions are stopped before disabling the peripheral, and H7/U5 additionally clear the PCSEL register to release I/O pad switches.

`ca_adc_hw_stop_isr`

Header: `caos/drivers/inc/ca_glue_hw.h:94`
GUARD: `EN_CA_GLUE_HW`

```
extern bool ca_adc_hw_stop_isr(u8 adc_num); /* leaves the ADC on but
   disables its end-of-conversion interrupt */
```

Disables the ADC end-of-conversion interrupt while keeping the peripheral powered and active.

Parametri:

Nome	Tipo	Descrizione
`adc_num`	`u8`	The ADC peripheral index (e.g., 1). Note: current implementation ignores this and defaults to ADC1.

Ritorna:
Always returns true.

Note:

- This function is non-blocking and safe to call from an ISR. It is designed to silence the interrupt mechanism without powering down the ADC hardware, which is critical if you intend to perform polled reads immediately after. If you were to call a full stop function instead, the ADC would lose its configuration and require a complete re-initialization, causing subsequent reads to return zero or invalid data. A common mistake is calling this when you actually want to power down the peripheral; use ca_adc_stop() for that purpose instead.

Uso:

- This function is typically used when transitioning from an interrupt-driven sampling mode to a polled mode, or when cleaning up after an ISR-based acquisition sequence. It is usually paired with ca_adc_isr_done() to signal that the interrupt-driven phase is complete. The typical sequence is: ca_adc_start_isr() to begin sampling, then ca_adc_hw_stop_isr() to silence the hardware interrupt, followed by ca_adc_isr_done() to finalize the driver state.

Esempio:

```
/* Stop the interrupt-driven sampling process */
if (ca_adc_hw_stop_isr(1)) {
    /* Signal the driver that the ISR phase is finished */
    ca_adc_isr_done(1);

    /* Now safe to perform a manual, polled read without ISR interference */
    u32 value = ca_adc_read(1);
    ca_printf("Polled ADC value: %u\n", value);
}
```

Q&A — fine-tuning review *6/6 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** When should I use ca_adc_hw_stop_isr instead of a standard stop function?
A: Use ca_adc_hw_stop_isr when you need to disable the end-of-conversion interrupt while keeping the ADC peripheral powered and active. This is typically done when transitioning from interrupt-driven sampling to polled mode, or when cleaning up after an ISR-based acquisition sequence.

Code example conf:1.00 **Q:** Provide a minimal example of how to use ca_adc_hw_stop_isr in a sequence.
A: u8 adc_idx = 1; ca_adc_start_isr(adc_idx); /* ... perform sampling ... */ ca_adc_hw_stop_isr(ad ca_adc_isr_done(adc_idx);

Parameters conf:1.00 **Q:** What does the u8 adc_num parameter control?
A: The u8 adc_num parameter represents the ADC peripheral index. However, the current implementation ignores this value and defaults to ADC1 across all supported hardware families.

Return conf:1.00 **Q:** What are the possible return values for ca_adc_hw_stop_isr?
A: The function always returns true. There are no failure conditions defined for this operation.

Error/Edge case conf:1.00 **Q:** What is a common mistake when using ca_adc_hw_stop_isr?
A: A common mistake is calling this function when you actually intend to power down the peripheral. If you want to power down the ADC, use ca_adc_stop() instead, as ca_adc_hw_stop_isr keeps the hardware active and configured.

HW differences conf:1.00 **Q:** How does the implementation of ca_adc_hw_stop_isr differ between F1/F4/F7 and H5/H7/U5 families?
A: On F1, F4, and F7 families, the function clears the EOCIE bit in the CR1 register and the EOC bit in the SR register. On H5, H7, and U5 families, it clears the EOCIE bit in the IER register, checks for active conversions in the CR register, performs a stop sequence if necessary, and clears the EOC bit in the ISR register.

`ca_adc_init`

Header: `caos/drivers/inc/adc.h:35`
Source: `caos/drivers/src/adc.c:132:143`
GUARD: `EN_ADC`

```
1 bool ca_adc_init(const ca_adc_config_t *cfg)
```

Initializes the hardware ADC peripheral and configures its sampling parameters.

Parametri:

Nome	Tipo	Descrizione
`cfg`	`const ca_adc_config_t *`	Pointer to a configuration structure containing the ADC index (1-3) and the desired sample time. Passing a NULL pointer or an invalid ADC index (outside 1-3) will cause the function to return false immediately.

Ritorna:
Returns true if the hardware clock and peripheral initialization were successful. Returns false if the input configuration is invalid, the hardware clock fails to initialize, or the peripheral configuration fails.

Note:

- This function is non-blocking and performs direct hardware register manipulation to set up the ADC clock and peripheral registers. It is not thread-safe, so you must ensure that

initialization happens during the system startup phase before any tasks attempt to read from the ADC. It is strictly forbidden to call this from an Interrupt Service Routine (ISR) because it performs hardware setup that may take time and is not re-entrant. A common beginner mistake is to call this function multiple times for the same ADC index without checking if it is already initialized, which can lead to unpredictable hardware states or clock configuration conflicts.

Uso:

- This function is the mandatory first step in the ADC lifecycle. It is typically called during the system initialization sequence, immediately after hardware clocks are enabled but before any pin-specific configuration (like ca_adc_pin_init) or data acquisition occurs. In a typical application, you define a configuration structure, pass it to this function, and then proceed to configure the specific GPIO pins associated with the ADC channels. If you skip this step, subsequent calls to read ADC values will fail or return garbage data because the peripheral clock will be disabled.

Esempio:

```
/* Define the configuration for ADC 1 with a specific sample time */
ca_adc_config_t adc_cfg = { .adc_num = 1, .sample_time = 15 };

/* Initialize the ADC peripheral */
if (ca_adc_init(&adc_cfg)) {
    /* Success: now configure the specific pin for the ADC channel */
    ca_adc_pin_init(1, 10);
} else {
    /* Handle initialization failure: log error or enter safe state */
    while(1);
}
```

Q&A — fine-tuning review *5/5 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I call ca_adc_init() in my caOS application?
A: You should call ca_adc_init() before performing any ADC readings. It must be called once to configure the ADC peripheral with the correct channel number and sampling time. The function is blocking and must be called before any ADC operations.

Code example conf:0.90 **Q:** Can you show a minimal example of how to use ca_adc_init() with caOS types?
A: ca_adc_config_t config = { .adc_num = 1, .sampling_time = 15 }; bool result = ca_adc_init(&config); if (!result) { /* Handle error */ }

Parameters conf:0.90 **Q:** What does the adc_num parameter in ca_adc_config_t represent, and what are valid values?
A: The adc_num parameter specifies which ADC peripheral to initialize. Valid values are 1, 2, or 3. Any value outside this range will cause ca_adc_init() to return false.

Return conf:0.95 **Q:** What does ca_adc_init() return, and what causes it to return false?
A: ca_adc_init() returns true on successful initialization. It returns false if the cfg parameter is NULL or if adc_num is outside the valid range of 1 to 3.

Error/Edge case conf:0.85 **Q:** What are common mistakes when calling ca_adc_init()?
A: Common mistakes include passing a NULL pointer for cfg, or specifying an adc_num outside the valid range (1-3). Additionally, calling ca_adc_init() from an ISR or without enabling the ADC clock beforehand may lead to unexpected behavior, though these are not directly reflected in the return value.

ca_adc_init_isr

Header: caos/drivers/inc/adc.h:49
Source: caos/drivers/src/adc.c:157:162
GUARD: EN_ADC

```
bool ca_adc_init_isr(const ca_adc_config_t *cfg, ca_adc_isr_cb_t cb)
```

Initializes an ADC peripheral in interrupt-driven mode with a user-defined callback function.

Parametri:

Nome	Tipo	Descrizione
cfg	const ca_adc_config_t *	Pointer to a configuration structure containing the ADC number (1-3) and sample time. Must not be NULL.
cb	ca_adc_isr_cb_t	Function pointer to the callback that will be executed when the ADC conversion completes. Must not be NULL.

Ritorna:
Returns true if the ADC peripheral was successfully initialized and the interrupt enabled. Returns false if the configuration pointer is NULL, the ADC number is out of range (1-3), the callback is NULL, or the hardware initialization fails.

Note:

- This function is non-blocking and configures the hardware to trigger an interrupt upon conversion completion. It is not thread-safe by itself, so ensure it is called during system initialization or from a controlled task context. A common beginner mistake is passing a NULL callback or an invalid ADC index, which will cause the function to fail immediately. Before calling this, ensure the system clock for the ADC peripheral is managed correctly by the underlying hardware abstraction layer, as this function relies on ca_clock_hw_adc_init to prepare the peripheral.

Uso:

- This function is typically used when you need to perform non-blocking ADC sampling, allowing the CPU to perform other tasks while waiting for the hardware conversion to finish. It is usually called once during the setup phase of a specific module or via a CLI command to enable diagnostic monitoring. It is almost always paired with ca_adc_start_isr to trigger the actual conversion process after initialization is complete. Once the conversion finishes, the provided callback is executed, where you would typically read the result and potentially trigger the next conversion.

Esempio:

```
ca_adc_config_t my_adc_cfg = { .adc_num = 1, .sample_time = 4 };

// Define the callback function to handle ADC data
void my_adc_callback(u16 value) {
    // Process the ADC result here
}

// Initialize the ADC for interrupt mode
if (ca_adc_init_isr(&my_adc_cfg, my_adc_callback)) {
    // Start the conversion on channel 5
    ca_adc_start_isr(1, 5);
} else {
    // Handle initialization error
}
```

Q&A — fine-tuning review *4/4 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I use ca_adc_init_isr() in my embedded application?
A: You should use ca_adc_init_isr() when you need to perform ADC conversions in the background without blocking the main thread. This function is ideal for acquiring sensor data or other analog signals asynchronously, allowing your application to continue processing other tasks while the ADC conversion is in progress.

Code example conf:0.90 **Q:** Can you show a minimal example of how to use ca_adc_init_isr() with caOS types?
A: ca_adc_config_t config = { .adc_num = 1, .sample_time = 15 }; ca_adc_isr_cb_t callback = my_adc_callback; bool success = ca_adc_init_isr(&config, callback);

Parameters conf:0.90 **Q:** What are the valid values for adc_num in the ca_adc_config_t structure passed to ca_adc_init_isr()?
A: The adc_num field in ca_adc_config_t must be an integer between 1 and 3 inclusive. Values outside this range, such as 0 or 4, are invalid and will cause ca_adc_init_isr() to return false.

Return conf:0.95 **Q:** What does it mean if ca_adc_init_isr() returns false?
A: If ca_adc_init_isr() returns false, it indicates that the initialization failed due to invalid parameters. This can happen if cfg is NULL, adc_num is not between 1 and 3, or cb is NULL.

`ca_adc_irq_handler`

Header: `caos/drivers/inc/adc.h:55`
Source: `caos/drivers/src/adc.c:170:173`
GUARD: `EN_ADC`

```
1 void ca_adc_irq_handler(u8 adc_num)
```

Dispatches the hardware ADC interrupt to the appropriate caOS driver handler for a specific ADC peripheral.

Parametri:

Nome	Tipo	Descrizione
`adc_num`	`u8`	The index of the ADC peripheral (e.g., 1 for ADC1, 2 for ADC2). Must match the hardware peripheral ID defined in your STM32 configuration.

Ritorna:
void

Note:

- This function is strictly intended to be called from within the STM32 hardware interrupt vector table (the ISR). Because it is an ISR handler, it must execute as quickly as possible to avoid blocking other system interrupts or causing timing jitter in the RTOS scheduler. It is not thread-safe in the sense that it should never be called from a standard task; it is the entry point for the hardware signal itself. A common beginner mistake is to perform heavy processing or blocking operations inside the function called by this handler, which will crash the system or cause missed ADC samples. Ensure that the ADC peripheral has been properly initialized via ca_adc_start_isr before this handler is triggered, otherwise, the hardware may trigger an interrupt for an unconfigured peripheral, leading to undefined behavior.

Uso:

- This function is used exclusively in the STM32 startup or HAL interrupt vector files (e.g., stm32f4xx_it.c). You place it inside the specific ADCx_IRQHandler function generated by the IDE. It acts as the bridge between the raw hardware interrupt and the caOS driver logic. It is typically paired with ca_adc_start_isr, which sets up the GPIO pins and triggers the hardware to begin sampling. Once the hardware completes a conversion, it fires the interrupt, which calls this handler to process the data or signal a waiting task.

Esempio:

```
/* Inside stm32f4xx_it.c - The hardware interrupt vector */
void ADC_IRQHandler(void) {
    /* Notify caOS that an ADC interrupt occurred for ADC1 */
    /* This handles the low-level register clearing and data retrieval */
    ca_adc_irq_handler(1);
}

/* Inside your application task */
void start_sampling(void) {
    /* Initialize pins and start the hardware conversion process */
    ca_adc_start_isr(1, 0);
    /* The system will now automatically call ca_adc_irq_handler when data is
    ready */
}
```

Q&A — fine-tuning review *3/3 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I call ca_adc_irq_handler() and why is it important to invoke it from an ISR?
A: You should call ca_adc_irq_handler() from within an ADC interrupt service routine (ISR) that is registered in the interrupt vector table for the ADC peripheral. It is important to invoke it from an ISR because the function is designed to handle ADC interrupts and modifies ADC hardware state. Calling it from a non-ISR context may lead to undefined behavior. The function is used to process ADC conversion results and is typically invoked automatically by the system when an ADC interrupt occurs.

Code example conf:0.90 **Q:** Can you provide a minimal C code example showing how to use ca_adc_irq_handler() with caOS types?
A: void ADC1_IRQHandler(void) { ca_adc_irq_handler(0); }
// This example assumes ADC1 is being used and the interrupt is properly configured.
// The function ca_adc_irq_handler(0) handles the interrupt for ADC1.

Parameters conf:0.90 **Q:** What does the adc_num parameter in ca_adc_irq_handler() represent, and what are the valid values for this parameter?
A: The adc_num parameter in ca_adc_irq_handler() represents the number of the ADC peripheral to be handled, where 0 typically corresponds to ADC1, 1 to ADC2, and so on. Valid values are integers between 0 and the maximum number of ADCs available on the specific STM32 chip. Using invalid values (e.g., greater than the number of ADCs on the chip) can lead to memory access violations or undefined behavior.

`ca_adc_isr_done`

Header: `caos/drivers/inc/adc.h:63`
Source: `caos/drivers/src/adc.c:305:309`
GUARD: `EN_ADC`

```
void ca_adc_isr_done(u8 adc_num)
```

Signals that an ADC interrupt operation is complete, releasing the ADC peripheral for further use.

Parametri:

Nome	Tipo	Descrizione
adc_num	u8	The ADC peripheral index. Valid values are 1, 2, or 3. Values outside this range are ignored.

Ritorna:
void

Note:

- This function is non-blocking and thread-safe because it performs a simple memory write to a status array. It is specifically designed to be called from an Interrupt Service Routine (ISR) context, as it does not use mutexes or any OS primitives that could cause a deadlock or context switch. The most common mistake is passing an invalid ADC index, which results in the function returning immediately without clearing the busy flag, effectively locking the ADC peripheral permanently.

Uso:

- This function is used in the final stage of an asynchronous ADC conversion sequence. It is typically called inside the ADC interrupt handler after the conversion result has been retrieved or stored. It pairs with ca_adc_start_isr, which sets the busy flag, and acts as the 'unlock' mechanism so that subsequent calls to ADC functions from tasks or other interrupts can proceed without being blocked by a stale 'busy' state.

Esempio:

```c
/* Example: Handling an ADC conversion completion in an ISR */
void ADC1_IRQHandler(void) {
    u8 adc_num = 1;
    /* Check if conversion is complete and read the value */
    /* ca_adc_irq_handler(adc_num); // Internal hardware flag clearing */

    /* Signal that the ADC is now free for other tasks */
    ca_adc_isr_done(adc_num);
}

/* Example: Starting a conversion from a task */
void start_adc_task(void) {
    u8 adc_num = 1;
    u8 channel = 0;
    ca_adc_pin_init(adc_num, channel);
    ca_adc_start_isr(adc_num, channel);
    /* The ADC is now busy until the ISR calls ca_adc_isr_done */
}
```

Q&A — fine-tuning review *3/3 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** When should I call ca_adc_isr_done and why is it necessary?
A: You should call ca_adc_isr_done inside the ADC interrupt handler after the conversion result has been retrieved or stored. It is necessary to signal that the ADC operation is complete, acting as an 'unlock' mechanism to clear the busy flag so that subsequent ADC requests from tasks or other interrupts are not blocked by a stale state.

Code example conf:1.00 **Q:** Provide a minimal C example of how to use ca_adc_isr_done within an ISR.
A: void ADC1_IRQHandler(void) { u8 adc_id = 1; /* Retrieve conversion result here */ ca_adc_isr_done(adc_id); }

Parameters conf:1.00 **Q:** What are the valid values for the adc_num parameter, and what happens if I pass an invalid one?
A: The adc_num parameter must be 1, 2, or 3. If you pass a value outside this range, the function ignores it and returns immediately without clearing the busy flag, which will effectively lock the ADC peripheral permanently.

`ca_adc_pin_init`

Header: `caos/drivers/inc/adc.h:40`
Source: `caos/drivers/src/adc.c:145:148`
GUARD: `EN_ADC`

```
void ca_adc_pin_init(u8 adc_num, u8 channel)
```

Configures a specific microcontroller pin to function as an analog input for the ADC peripheral.

Parametri:

Nome	Tipo	Descrizione
`adc_num`	`u8`	The identifier of the ADC peripheral (e.g., 1, 2, or 3). Must match the hardware capabilities of your specific STM32 chip.
`channel`	`u8`	The specific ADC channel index to be mapped to the pin. Ensure this channel is physically connected to the pin you intend to use according to the datasheet.

Ritorna:
void

Note:

- This function is a hardware abstraction layer (HAL) wrapper that configures the GPIO pin mode to 'Analog'. It is non-blocking and executes quickly, but it is not thread-safe; it should be called during the system initialization phase before the ADC is used for sampling. It is not intended to be called from an Interrupt Service Routine (ISR) as it performs hardware register configuration which should be done in a controlled environment. A common beginner mistake is calling this function before initializing the ADC peripheral itself or using an invalid channel/pin combination, which will result in the pin remaining in a digital state or causing unexpected hardware behavior.

Uso:

- This function is typically used during the system startup sequence, immediately after calling ca_adc_init(). The standard workflow is: first, define the ADC configuration structure; second, initialize the ADC peripheral with ca_adc_init(); third, call ca_adc_pin_init() to map the physical pin to the ADC channel; and finally, start reading values using ca_adc_read(). It is essential to pair this with the correct hardware pin mapping found in your STM32 reference manual to avoid reading floating or incorrect voltages.

Esempio:

```
/* Define ADC parameters */
#define ADC_NUM 1
#define ADC_CHANNEL 10

/* Initialize ADC and pin during system setup */
```

```
ca_adc_config_t adc_cfg = { ADC_NUM, ADC_SAMPLE_TIME };
ca_adc_init(&adc_cfg);

/* Configure the physical pin for analog input */
ca_adc_pin_init(ADC_NUM, ADC_CHANNEL);

/* Now it is safe to read the sensor value */
u16 sensor_value = ca_adc_read(ADC_NUM, ADC_CHANNEL);
```

Q&A — fine-tuning review *4/4 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I call ca_adc_pin_init() in my caOS application?
A: You should call ca_adc_pin_init() before attempting to read analog values using ca_adc_read(). This function initializes the GPIO pin corresponding to the specified ADC channel, making it ready for analog input. It must be called once per pin you intend to use, and it's typically called during system initialization or driver setup.

Code example conf:0.90 **Q:** Can you show a minimal C code example using ca_adc_pin_init() with caOS types?
A: u8 adc_num = 1; u8 channel = 5; ca_adc_pin_init(adc_num, channel);

Parameters conf:0.90 **Q:** What are the valid values for the adc_num and channel parameters in ca_adc_pin_init()?
A: The adc_num parameter must be 1, 2, or 3, depending on the STM32 chip's ADC peripherals. A value of 0 or greater than 3 is invalid. The channel parameter must be between 0 and 18, inclusive, based on the ADC channel capabilities of the specific STM32 chip. Values outside this range will cause an error.

Return conf:0.85 **Q:** Does ca_adc_pin_init() return any value, and what can cause it to fail?
A: The function does not return any value. It is non-blocking and not thread-safe. It cannot be called from an ISR. Failures may occur if invalid parameters are passed, such as an adc_num outside the valid range (1-3) or a channel outside the valid range (0-18). It also fails if the underlying GPIO or ADC initialization fails.

`ca_adc_read`

Header: `caos/drivers/inc/adc.h:43`
Source: `caos/drivers/src/adc.c:151:154`
GUARD: `EN_ADC`

```
u16 ca_adc_read(u8 adc_num, u8 channel)
```

Reads the raw digital value from a specific ADC peripheral and channel.

Parametri:

Nome	Tipo	Descrizione
`adc_num`	`u8`	The index of the ADC peripheral (e.g., 1, 2, or 3). Must be within the hardware-supported range defined by the MCU datasheet.
`channel`	`u8`	The specific input channel index to sample. Must correspond to a pin configured for analog input.

Ritorna:
Returns a 16-bit unsigned integer representing the raw ADC conversion result (typically 0 to 4095 for a 12-bit ADC).

Note:

- This function is a synchronous, blocking call that waits for the hardware conversion to complete before returning the value. It is generally not thread-safe if multiple tasks access the same ADC peripheral simultaneously, so ensure you have external synchronization if sharing resources. It is typically safe to call from an ISR if the underlying hardware driver supports it, but be aware that blocking in an ISR is bad practice as it stalls the entire system. A common beginner mistake is calling this function without first initializing the GPIO pins and the ADC peripheral using ca_adc_pin_init, which will result in reading garbage data or potentially triggering a hardware fault.

Uso:

- This function is used to retrieve analog sensor data, such as voltage levels, potentiometers, or temperature sensors. It is typically used in a periodic loop (e.g., inside a task using ca_os_sleep) to monitor environmental changes over time. The standard workflow involves calling ca_adc_pin_init once during system startup to configure the hardware, followed by repeated calls to ca_adc_read to fetch the current state. It is often paired with mathematical scaling logic to convert the raw 12-bit value into meaningful units like millivolts or physical measurements.

Esempio:

```
/* Initialize the pin once before reading */
ca_adc_pin_init(1, 4);

while (1) {
    /* Read raw value from ADC1, channel 4 */
    u16 raw_val = ca_adc_read(1, 4);

    /* Convert 12-bit raw value (0-4095) to millivolts (assuming 3.3V reference)
     */
    u32 mv = ((u32)raw_val * 3300U) / 4095U;

    /* Output the result to the console */
    ca_stdout_printf_n("Voltage: %u.%03u V", (unsigned)(mv / 1000U), (unsigned)(
    mv % 1000U));

    /* Wait 500ms before next sample to avoid flooding the CPU */
    ca_os_sleep(500);
}
```

Q&A — fine-tuning review *4/4 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I use ca_adc_read() in a caOS project?
A: You should use ca_adc_read() when you need to perform a blocking analog-to-digital conversion on a specific ADC channel. It is intended for non-critical contexts where thread safety is not a concern and where you can afford the blocking behavior. It must not be used in ISRs or high-frequency loops due to its blocking nature and lack of thread safety.

Code example conf:0.90 **Q:** Can you provide a minimal C code example using ca_adc_read()?
A: u16 adc_value; ca_adc_pin_init(1, 5); adc_value = ca_adc_read(1, 5); // adc_value now holds the converted value from ADC1 channel 5

Parameters conf:0.90 **Q:** What are the valid ranges for adc_num and channel parameters in ca_adc_read()?
A: The adc_num parameter must be 1, 2, or 3. Any other value will cause an error. The channel parameter must be between 0 and 15 inclusive. Values outside this range will also cause an error. Both parameters are validated at runtime.

Return conf:0.85 **Q:** What does ca_adc_read() return, and what can cause it to fail?
A: ca_adc_read() returns a 12-bit value (0-4095) representing the analog reading from the specified ADC channel. If the function fails, it may return 0 or an invalid value.

Failures can occur if the pin was not initialized with ca_adc_pin_init(), or if invalid adc_num or channel values are passed. The function does not return explicit error codes.

---

ca_adc_start_isr

Header: caos/drivers/inc/adc.h:52
Source: caos/drivers/src/adc.c:164:168
GUARD: EN_ADC

```
void ca_adc_start_isr(u8 adc_num, u8 channel)
```

Initiates an ADC conversion sequence on a specific hardware peripheral and channel using interrupt-driven mode.

Parametri:

Nome	Tipo	Descrizione
adc_num	u8	The hardware ADC unit index (typically 1, 2, or 3). Must correspond to valid hardware peripherals on the STM32 chip.
channel	u8	The specific analog input channel index to be sampled. Must be a valid channel supported by the selected ADC unit.

Ritorna:
void. This function does not provide feedback on success or failure, assuming the hardware configuration is valid.

Note:

- This function is non-blocking, meaning it triggers the hardware and returns immediately while the conversion happens in the background. It is designed to be called after the ADC peripheral has been successfully initialized via ca_adc_init_isr. A common beginner mistake is calling this function before initializing the ADC or the GPIO pins, which will result in undefined behavior or hardware faults. Because it relies on interrupts, ensure that the global interrupt vector table is correctly configured and that the callback provided during initialization is ready to handle the incoming data.

Uso:

- This function is typically used in a setup sequence where you first initialize the ADC peripheral with a callback function, then configure the specific pin, and finally trigger the start. It is often paired with a stop function (not shown here) to manage power consumption or reconfigure the ADC for different channels. In a typical application, you call this once to begin a continuous sampling process or a single-shot conversion that will be processed asynchronously by your ISR callback.

Esempio:

```
/* Ensure the ADC is initialized first with a callback */
if (ca_adc_init_isr(&my_adc_cfg, my_data_ready_callback)) {
    /* Now start the hardware conversion on ADC1, Channel 5 */
    ca_adc_start_isr(1, 5);
} else {
    /* Handle initialization failure */
    log_error("ADC init failed");
}
```

Q&A — fine-tuning review *3/3 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I use ca_adc_start_isr() in a caOS project, and what are its main benefits?
A: You should use ca_adc_start_isr() when you need to initiate a non-blocking ADC conversion on a specific channel. This function is ideal for embedded applications where you want to avoid blocking the execution flow during ADC acquisition. It allows the system to continue executing other tasks while the ADC conversion is in progress, which is particularly useful in real-time systems or when handling multiple peripherals concurrently. The function is designed to be called from a non-ISRs context and assumes that the ADC has already been initialized with an ISR setup.

Code example conf:0.90 **Q:** Can you provide a minimal C code example showing how to use ca_adc_start_isr() with caOS types?
A: u8 adc_num = 1; u8 channel = 5; ca_adc_start_isr(adc_num, channel);

Parameters conf:0.85 **Q:** What are the valid ranges for adc_num and channel parameters in ca_adc_start_isr(), and what happens if invalid values are passed?
A: The adc_num parameter must be 1, 2, or 3. If a value outside this range is passed, the function returns immediately without performing any action. The channel parameter should be a valid ADC channel number for the target STM32 microcontroller (e.g., 0-18 for STM32F4). Invalid channel values may lead to undefined behavior. The function does not validate these parameters internally, so it's the programmer's responsibility to ensure correct values are used.

`ca_adc_stop`

Header: `caos/drivers/inc/adc.h:54`
Source: `caos/drivers/src/adc.c:267:277`
GUARD: `EN_ADC`

```
1 bool ca_adc_stop(u8 adc_num)
```

Safely disables a specific ADC peripheral and releases associated internal resources.

Parametri:

Nome	Tipo	Descrizione
`adc_num`	`u8`	The ADC peripheral index to stop. Valid values are 1, 2, or 3. Values outside this range will cause the function to return false immediately.

Ritorna:
Returns true if the ADC was successfully stopped, or false if the provided adc_num is invalid or the hardware stop operation failed.

Note:

- This function is not thread-safe in isolation and relies on internal state management to prevent deadlocks. It is designed to be called from task context to shut down the ADC hardware, ensuring that any pending ISR-based conversions are cancelled before the peripheral is disabled. A common mistake is calling this function while an ADC conversion is still expected to complete, which can lead to inconsistent state if the hardware is powered down abruptly. It is not intended to be called directly from an ISR, as it performs logic that assumes a stable task environment.

Uso:

- Use this function when you need to power down an ADC peripheral to save energy or reconfigure the pins for a different function (like GPIO or DAC). It is typically paired with ca_adc_init or ca_adc_start_isr during the teardown phase of a driver or application

lifecycle. Always ensure that any tasks waiting on ADC data are notified or have timed out before calling this, as it effectively kills the active conversion process.

Esempio:

```c
/* Example: Safely shutting down ADC1 before reconfiguring pins */
#define ADC_NUM 1

void shutdown_adc_task(void *pvParameters) {
    /* Stop the ADC hardware to prevent further conversions */
    if (ca_adc_stop(ADC_NUM)) {
        /* ADC is now stopped, safe to reconfigure pins if necessary */
        /* ca_gpio_configure(...) would be called here to change pin mode */
    } else {
        /* Handle error: ADC_NUM was likely invalid */
    }
}
```

Q&A — fine-tuning review *5/5 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** When should I call ca_adc_stop and what is its primary purpose?
A: You should call ca_adc_stop when you need to power down an ADC peripheral to save energy or reconfigure its pins for other functions like GPIO or DAC. It is typically used during the teardown phase of a driver or application lifecycle.

Code example conf:1.00 **Q:** Provide a minimal example of how to stop ADC 2 using caOS types.
A: u8 adc_id = 2; if (ca_adc_stop(adc_id)) { /* ADC stopped successfully */ }

Parameters conf:1.00 **Q:** What are the valid values for the adc_num parameter in ca_adc_stop?
A: The adc_num parameter must be a u8 with a value of 1, 2, or 3. Providing any value outside this range will cause the function to return false immediately.

Return conf:1.00 **Q:** What do the boolean return values of ca_adc_stop indicate?
A: The function returns true if the ADC was successfully stopped. It returns false if the provided adc_num is invalid or if the hardware stop operation itself failed.

Error/Edge case conf:1.00 **Q:** What are the risks of calling ca_adc_stop while an ADC conversion is still in progress?
A: Calling this function while an ADC conversion is expected to complete can lead to an inconsistent state because the hardware is powered down abruptly, effectively killing the active conversion process.

`ca_aes_channel_decrypt`

Header: `caos/crypto/inc/aes_channel_service.h:74`
Source: `caos/crypto/src/aes_channel_service.c:164:233`
GUARD: `EN_AES_CHANNEL_SERVICE`

```c
i32 ca_aes_channel_decrypt(ca_aes_channel_t *ch, const u8 *cipher, u32
    cipher_len, u8 **out, u32 *out_len)
```

Decrypts an AES-GCM encrypted buffer using a secure channel context.

Parametri:

Nome	Tipo	Descrizione
ch	ca_aes_channel_t *	Pointer to the initialized AES channel structure. Must not be NULL.
cipher	const u8 *	Pointer to the raw encrypted data buffer, including nonce, length, ciphertext, and tag.
cipher_len	u32	Total length of the input cipher buffer in bytes. Must be greater than AES_CH_OVERHEAD.
out	u8 **	Pointer to a buffer pointer that will be allocated by this function to hold the decrypted data.
out_len	u32 *	Pointer to a variable that will store the length of the decrypted data.

Ritorna:
Returns 0 on success. Returns -1 if any parameter is NULL, if the cipher length is invalid, if memory allocation fails, or if the GCM tag verification fails (indicating data tampering or incorrect key).

Note:

- This function is thread-safe as it uses an internal mutex to protect the cryptographic context during the decryption process. It is a blocking function, meaning the calling task will wait if another task is currently using the same channel. It must NOT be called from an Interrupt Service Routine (ISR) because it performs dynamic memory allocation and mutex locking, both of which are forbidden in ISR context. A common mistake is failing to free the memory returned in the 'out' pointer using ca_aes_channel_free (or the appropriate memory deallocator) after processing the decrypted data, which leads to memory leaks.

Uso:

- This function is typically used in secure communication protocols where data is received over a network or serial interface. The standard workflow involves: 1) Receiving the encrypted packet, 2) Calling ca_aes_channel_decrypt to verify the integrity and decrypt the payload, 3) Processing the decrypted data, and 4) Freeing the allocated output buffer. It is usually paired with ca_aes_channel_free to prevent memory exhaustion in long-running applications.

Esempio:

```
u8 *decrypted_data = NULL;
u32 decrypted_len = 0;

// Attempt to decrypt the received buffer
if (ca_aes_channel_decrypt(&my_channel, rx_buffer, rx_len, &decrypted_data, &
    decrypted_len) == 0) {
    // Success: process the data
    process_data(decrypted_data, decrypted_len);

    // Mandatory: free the buffer allocated by the decryption function
    ca_aes_channel_free(decrypted_data);
} else {
    // Failure: log error or handle authentication failure
    ca_stdout_put_n("Decryption failed or data tampered");
}
```

Q&A — fine-tuning review *6/6 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I use ca_aes_channel_decrypt in a caOS application?
A: You should use ca_aes_channel_decrypt when you need to decrypt an AES-GCM encrypted message using a pre-initialized AES channel. It is typically used in secure

communication protocols or data protection scenarios where you have a cipher buffer containing nonce, tag, and encrypted data, and you want to obtain the plaintext.

Code example conf:0.90 **Q:** Can you show a minimal example of how to call ca_aes_channel_decrypt?
A: u8 *plaintext = NULL; u32 plain_len = 0; ca_aes_channel_t channel; // Assume channel is initialized u8 cipher_data[100]; // Fill cipher_data with valid AES-GCM format data i32 result = ca_aes_channel_decrypt(&channel, cipher_data, 100, &plaintext, &plain_len); if (result == 0) { // Use plaintext and plain_len // Remember to free plaintext after use }

Parameters conf:0.95 **Q:** What are the valid values for the cipher_len parameter in ca_aes_channel_decrypt?
A: The cipher_len must be greater than 30, which is the AES_CH_OVERHEAD. Values less than or equal to 30 will cause the function to return -1. The cipher buffer must contain at least the nonce, tag, and some encrypted data to be valid for decryption.

Return conf:0.95 **Q:** What does a return value of -1 from ca_aes_channel_decrypt indicate?
A: A return value of -1 indicates an error occurred during decryption. This can be due to invalid input parameters, a buffer that is too short, a mismatched authentication tag, or a failure in memory allocation.

Error/Edge case conf:0.90 **Q:** What are common mistakes when using ca_aes_channel_decrypt?
A: Common mistakes include passing NULL pointers for cipher, out, or out_len, providing a cipher buffer shorter than 30 bytes, not allocating memory for *out after the call, or ignoring the return value of the function. Also, calling this function from an ISR is not allowed.

Behavior conf:0.95 **Q:** Is ca_aes_channel_decrypt thread-safe and can it be called from an ISR?
A: Yes, ca_aes_channel_decrypt is thread-safe because it uses a mutex to protect access to the AES channel. However, it is not ISR-safe and must not be called from interrupt service routines because it uses mutex locking and dynamic memory allocation.

`ca_aes_channel_deinit`

Header: `caos/crypto/inc/aes_channel_service.h:93`
Source: `caos/crypto/src/aes_channel_service.c:278:293`
GUARD: `EN_AES_CHANNEL_SERVICE`

```
1 void ca_aes_channel_deinit(ca_aes_channel_t *ch)
```

Safely releases and clears all memory resources associated with an AES cryptographic channel.

Parametri:

Nome	Tipo	Descrizione
`ch`	`ca_aes_channel_t *`	Pointer to the AES channel structure to be deinitialized. Must not be NULL (though the function handles NULL safely).

Ritorna:
void

Note:

- This function is non-blocking and performs memory cleanup by zeroing out sensitive cryptographic contexts before freeing them. It is not thread-safe; you must ensure no other threads are attempting to use the channel while this function is running, typically by holding a mutex or ensuring the task is shutting down. It is strictly forbidden to call this from an ISR because it performs dynamic memory deallocation, which can lead to heap corruption or system crashes. A common beginner mistake is to continue using the

channel pointer after calling this function; always set your local channel reference to NULL immediately after deinit to prevent use-after-free bugs.

Uso:

- This function is used during the teardown phase of a cryptographic service or when a specific secure session is terminated. It is typically called after the channel has been closed and the associated mutex has been released. It is the final step in the lifecycle of an AES channel, following the sequence: initialization (allocation), usage (encryption/decryption), and finally deinitialization to prevent memory leaks and ensure sensitive key material is wiped from RAM.

Esempio:

```
/* Assuming 'my_channel' was previously initialized and used */

// Ensure no other task is accessing the channel
// ca_mutex_lock(&my_channel->mutex);

// Perform cleanup of the AES channel resources
ca_aes_channel_deinit(my_channel);

// Prevent dangling pointer usage
my_channel = NULL;

// Now it is safe to free the channel structure itself if it was dynamically
    allocated
```

Q&A — fine-tuning review *5/5 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I call ca_aes_channel_deinit and why is it important?
A: You should call ca_aes_channel_deinit when you are done using an AES channel and want to free the resources allocated for encryption. It is important to call this function to prevent memory leaks and ensure proper cleanup of the AES context.

Code example conf:0.90 **Q:** Can you show a minimal example of how to use ca_aes_channel_deinit with caOS types?
A: ca_aes_channel_t channel; ca_aes_channel_init(&channel); // ... use the channel ... ca_aes_channel_deinit(&channel);

Parameters conf:0.90 **Q:** What is the significance of the ca_aes_channel_t *ch parameter, and what happens if it is NULL?
A: The parameter 'ch' is a pointer to the AES channel to be deinitialized. If it is NULL, the function does nothing, as it checks for a valid pointer before proceeding.

Error/Edge case conf:0.85 **Q:** What are the common mistakes when using ca_aes_channel_deinit?
A: Common mistakes include calling this function on a channel that has already been deinitialized or passing a NULL pointer. The function does not check if the channel is already deinitialized, so calling it twice on the same channel may lead to undefined behavior.

Behavior conf:0.90 **Q:** Is ca_aes_channel_deinit blocking, ISR-safe, or thread-safe?
A: The function is non-blocking. It is not ISR-safe and should not be called from an ISR. It is also not thread-safe unless called within a protected context using a mutex.

`ca_aes_channel_encrypt`

Header: `caos/crypto/inc/aes_channel_service.h:65`
Source: `caos/crypto/src/aes_channel_service.c:85:162`
GUARD: `EN_AES_CHANNEL_SERVICE`

```
i32 ca_aes_channel_encrypt(ca_aes_channel_t *ch, const u8 *plain, u32
    plain_len, u8 **out, u32 *out_len)
```

Encrypts plaintext data using an AES-GCM channel, returning a dynamically allocated buffer containing the nonce, length, ciphertext, and tag.

Parametri:

Nome	Tipo	Descrizione
ch	ca_aes_channel_t *	Pointer to an initialized AES channel structure. Must not be NULL.
plain	const u8 *	Pointer to the raw plaintext data to be encrypted. Must not be NULL.
plain_len	u32	Length of the plaintext in bytes.
out	u8 **	Pointer to a buffer pointer that will be updated to point to the newly allocated encrypted data. Must not be NULL.
out_len	u32 *	Pointer to a variable that will store the total length of the allocated encrypted buffer. Must not be NULL.

Ritorna:
Returns 0 on success. Returns -1 if any input parameter is NULL, if memory allocation fails, if key loading fails, or if the encryption process encounters an error.

Note:

- This function is blocking because it uses a mutex to ensure thread-safe access to the AES hardware context. It must NOT be called from an Interrupt Service Routine (ISR) because mutex operations are not permitted in ISR context and the function performs dynamic memory allocation. The function allocates memory internally for the output buffer; the caller is responsible for freeing this memory using ca_memory_free once the encrypted data has been processed or transmitted. A common mistake is forgetting to free the returned buffer, which will lead to memory leaks in long-running embedded applications.

Uso:

- This function is typically used in secure communication tasks where data needs to be encrypted before being sent over a queue or network interface. The standard workflow involves initializing the channel with ca_mutex_init, calling ca_aes_channel_encrypt to prepare the packet, sending the packet via a queue (e.g., ca_queue_static_send), and finally freeing the allocated buffer. It is designed to handle padding automatically, making it easier for developers to encrypt arbitrary lengths of data without manually managing 16-byte alignment requirements.

Esempio:

```
/* Assuming s_ch is an initialized ca_aes_channel_t */
u8 *encrypted_data = NULL;
u32 encrypted_len = 0;
const char *message = "Secure Payload";

/* Encrypt the message */
if (ca_aes_channel_encrypt(&s_ch, (const u8 *)message, 14, &encrypted_data, &
    encrypted_len) == 0) {
    /* Send the encrypted packet to a queue */
    aes_pkt_t pkt = { .buf = encrypted_data, .len = encrypted_len };
    if (ca_queue_static_send(q_to_bob, &pkt, 2000)) {
        /* Success: buffer is now owned by the queue receiver */
    } else {
        /* Failed to send: free the buffer to prevent memory leak */
```

```
        ca_memory_free(encrypted_data, NULL, true);
    }
} else {
    /* Handle encryption error */
}
```

Q&A — fine-tuning review *6/6 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I use the ca_aes_channel_encrypt function in a caOS application?
A: You should use ca_aes_channel_encrypt when you need to encrypt data using AES-GCM in a thread-safe, blocking manner. It is ideal for applications requiring secure communication or data protection where you want automatic memory management and mutex handling. It is not suitable for interrupt service routines (ISR) due to its blocking nature.

Code example conf:0.90 **Q:** Can you provide a minimal C code example showing how to use ca_aes_channel_encrypt?
A: ca_aes_channel_t ch; ca_aes_channel_init(&ch); const u8 plaintext[] = "Hello, World!"; u8 *ciphertext; u32 cipher_len; i32 result = ca_aes_channel_encrypt(&ch, plaintext, sizeof(plaintext), &ciphertext, &cipher_len); if (result == 0) { // Use ciphertext and cipher_len ca_free(ciphertext); // Free allocated memory }

Parameters conf:0.90 **Q:** What are the valid and invalid values for the plain parameter in ca_aes_channel_encrypt?
A: The plain parameter must be a valid pointer to a buffer containing the plaintext to encrypt. It cannot be NULL. The plain_len must be greater than 0 and should not cause an overflow in padded_len calculation. If plain is NULL or plain_len is 0, the function will return -1.

Return conf:0.95 **Q:** What does a return value of -1 from ca_aes_channel_encrypt indicate?
A: A return value of -1 indicates that the encryption failed. This can happen due to invalid parameters (e.g., NULL pointers, zero length), memory allocation failure, or a failure in the underlying AES-GCM encryption process. It also occurs if the AES context is not properly initialized.

Error/Edge case conf:0.90 **Q:** What are common error conditions or edge cases when calling ca_aes_channel_encrypt?
A: Common error conditions include passing NULL pointers for plain, out, or out_len, providing a zero or excessively large plain_len that causes overflow, or calling the function before properly initializing the AES channel. Additionally, if the AES context is not initialized, the function will fail and return -1.

Behavior conf:0.95 **Q:** Is ca_aes_channel_encrypt blocking or non-blocking, and is it safe to call from an ISR?
A: ca_aes_channel_encrypt is a blocking function that waits for a mutex lock before proceeding. It is not safe to call from an ISR because it may block and could cause deadlocks or system instability. It is thread-safe due to internal mutex usage, but must be used only from task contexts.

`ca_aes_channel_free`

Header: `caos/crypto/inc/aes_channel_service.h:82`
Source: `caos/crypto/src/aes_channel_service.c:235:238`
GUARD: `EN_AES_CHANNEL_SERVICE`

```
void ca_aes_channel_free(void *p)
```

Deallocates memory previously allocated for an AES channel buffer.

Parametri:

Nome	Tipo	Descrizione
p	void *	A pointer to the memory block to be freed. Must be a pointer previously returned by a caOS memory allocation function. Passing NULL is safe and does nothing.

Ritorna:
void

Note:

- This function is a wrapper around the system memory manager. It is non-blocking and thread-safe, meaning it can be called from different tasks without corrupting the heap. However, it is NOT safe to call from an ISR (Interrupt Service Routine) because heap management operations often require mutexes that cannot be acquired in an interrupt context. The most common beginner mistake is 'double-freeing' memory—calling this function twice on the same pointer—which will lead to heap corruption and likely a system crash or hard fault. Always set your pointer to NULL immediately after calling this function to prevent accidental reuse.

Uso:

- This function is used to clean up dynamic memory buffers that were allocated to hold encrypted or decrypted data packets. It is typically used in error-handling paths where a transmission fails (e.g., if ca_queue_static_send fails, the buffer is no longer needed) or during the teardown phase of a communication session. It is paired with memory allocation functions; once the data has been successfully sent or processed, the buffer must be freed to prevent memory leaks, which would eventually cause the system to run out of RAM.

Esempio:

```
/* Example: Handling a failed transmission */
void *enc_buffer = /* pointer to allocated memory */;
aes_pkt_t pkt = { .buf = enc_buffer, .len = 128 };

/* Attempt to send the packet to a queue */
if (!ca_queue_static_send(q_to_bob, &pkt, 2000)) {
    ca_stdout_put_n("Transmission failed, cleaning up memory");

    /* Free the buffer because the queue failed to take ownership */
    ca_aes_channel_free(enc_buffer);

    /* Prevent dangling pointer usage */
    enc_buffer = NULL;
}
```

Q&A — fine-tuning review *3/3 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I call ca_aes_channel_free() and why is it important?
A: You should call ca_aes_channel_free() after completing AES encryption or decryption operations to free the memory allocated for the AES channel. This prevents memory leaks in your embedded application. It's important because failing to free the memory can lead to memory exhaustion, especially in long-running systems with frequent cryptographic operations.

Code example conf:0.90 **Q:** Can you show a minimal C example using ca_aes_channel_free() with caOS types?
A: void example_aes_free() { void *channel = ca_memory_alloc(sizeof(u32) * 4); if (channel != NULL) { ca_aes_channel_free(channel); } }

Parameters conf:0.90 **Q:** What does the parameter 'p' in ca_aes_channel_free() represent, and what are valid and invalid values?
A: The parameter 'p' is a void pointer to memory previously allocated with ca_memory_alloc() or a similar allocator. Valid values are pointers to memory allocated by the same memory management system. Invalid values include NULL (which the function handles gracefully by doing nothing) and pointers to memory not allocated with ca_memory_alloc(), which will cause crashes or memory corruption.

`ca_aes_channel_init`

Header: `caos/crypto/inc/aes_channel_service.h:53`
Source: `caos/crypto/src/aes_channel_service.c:52:83`
GUARD: `EN_AES_CHANNEL_SERVICE`

```
i32 ca_aes_channel_init(ca_aes_channel_t *ch, ca_aes_mode_t mode,
    ca_aes_keysize_t keysize, void *ks_handle, ca_aes_iv_gen_cb_t iv_cb,
    ca_aes_key_ratchet_cb_t ratchet_cb, void *cb_user)
```

Initializes an AES cryptographic channel structure by allocating internal contexts and setting up synchronization primitives.

Parametri:

Nome	Tipo	Descrizione
`ch`	`ca_aes_channel_t *`	Pointer to the channel structure to initialize. Must be a valid, non-NULL memory address.
`mode`	`ca_aes_mode_t`	The AES mode of operation (e.g., GCM, CBC).
`keysize`	`ca_aes_keysize_t`	The size of the key (e.g., CA_AES_KEY_128, CA_AES_KEY_256).
`ks_handle`	`void *`	Pointer to the key storage handle or key material. Must not be NULL.
`iv_cb`	`ca_aes_iv_gen_cb_t`	Optional callback for IV generation. Pass NULL if not required.
`ratchet_cb`	`ca_aes_key_ratchet_cb_t`	Optional callback for key ratcheting. Pass NULL if not required.
`cb_user`	`void *`	User-defined pointer passed to callbacks.

Ritorna:
Returns 0 on success. Returns -1 if initialization fails, typically due to NULL pointers or memory allocation failure.

Note:

- This function is non-blocking but performs dynamic memory allocation via ca_memory_allocate, meaning it is NOT safe to call from an ISR. It initializes a mutex for thread safety, so it must be called before any other thread attempts to use the channel. A common beginner mistake is failing to check the return value; if memory allocation fails, the channel remains in an uninitialized state, and subsequent operations will cause a system crash or undefined behavior. Ensure the channel structure is not modified by other threads while this function is running.

Uso:

- This function is the mandatory first step in the AES channel lifecycle. It is typically called during system startup or when a new secure communication session is established. It pairs with subsequent encryption/decryption functions and should eventually be followed by a cleanup function (if provided by the API) to free the allocated contexts. It is often used

in conjunction with keystore services to link a specific key handle to a communication channel.

Esempio:

```
ca_aes_channel_t s_ch;
void *s_key_ptr = get_key_from_storage();

// Initialize the channel before any crypto operations
if (ca_aes_channel_init(&s_ch, CA_AES_MODE_GCM, CA_AES_KEY_256, s_key_ptr, NULL,
    NULL, NULL) != 0) {
    // Handle error: allocation failed or invalid parameters
    return;
}

// Now the channel is ready for use in tasks
// ca_aes_encrypt(&s_ch, ...);
```

Q&A — fine-tuning review *6/6 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I call ca_aes_channel_init and what is its purpose in a caOS application?
A: You should call ca_aes_channel_init to initialize an AES channel for encryption or decryption operations. It sets up the channel with a specific mode, key size, and optional callbacks for IV generation and key ratcheting. This function is used when you need to perform AES operations in your application, such as securing data transmission or storage.

Code example conf:0.90 **Q:** Can you provide a minimal working C example using ca_aes_channel_init with caOS types?
A: ca_aes_channel_t ch; ca_aes_keysize_t keysize = CA_AES_KEY_256; ca_aes_mode_t mode = CA_AES_MODE_GCM; void *key_handle = (void *)0x12345678; int result = ca_aes_channel_init(&ch, mode, keysize, key_handle, NULL, NULL, NULL); if (result != 0) { // Handle error }

Parameters conf:0.95 **Q:** What are the valid values for the mode and keysize parameters in ca_aes_channel_init?
A: The mode parameter can be one of: CA_AES_MODE_ECB, CA_AES_MODE_CBC, CA_AES_MODE_CTR, CA_AES_MODE_GCM. The keysize parameter can be one of: CA_AES_KEY_128, CA_AES_KEY_192, CA_AES_KEY_256. These values define the encryption mode and key length used for the AES operations.

Return conf:0.95 **Q:** What does a return value of 0 or -1 indicate in ca_aes_channel_init?
A: A return value of 0 indicates successful initialization of the AES channel. A return value of -1 indicates an error, such as invalid parameters, allocation failure, or a NULL pointer being passed where a valid pointer is required.

Error/Edge case conf:0.90 **Q:** What are common error conditions or edge cases when calling ca_aes_channel_init?
A: Common error conditions include passing NULL to the 'ch' or 'ks_handle' parameters, invalid values for mode or keysize, or insufficient memory for internal allocations. Passing NULL to 'ch' will cause an immediate negative return. The function may also fail if memory is exhausted during internal allocation for AES contexts.

Behavior conf:0.85 **Q:** Is ca_aes_channel_init blocking or non-blocking, and is it safe to call from an ISR or in a multi-threaded context?
A: ca_aes_channel_init is a blocking function and cannot be called from an ISR. It is thread-safe if the underlying context allows it, but the function itself is not ISR-safe. It requires valid pointers and allocates memory for two AES contexts, so it must be called in a context where memory allocation is possible.

ca_aes_channel_rotate

Header: caos/crypto/inc/aes_channel_service.h:88
Source: caos/crypto/src/aes_channel_service.c:240:276
GUARD: EN_AES_CHANNEL_SERVICE

```
i32 ca_aes_channel_rotate(ca_aes_channel_t *ch)
```

Updates an AES channel's cryptographic key by executing a ratchet callback and storing the new key securely.

Parametri:

Nome	Tipo	Descrizione
ch	ca_aes_channel_t *	Pointer to the initialized AES channel structure. Must not be NULL and must have a valid ratchet_cb assigned.

Ritorna:
Returns 0 on success. Returns -1 if the channel pointer is invalid, the ratchet callback fails, the key storage access fails, or if the mutex cannot be acquired.

Note:

- This function is blocking because it uses a mutex to ensure thread safety during the key rotation process. It is NOT safe to call from an ISR (Interrupt Service Routine) because blocking operations are forbidden in ISR context. Before calling this, the channel must be fully initialized with a valid ratchet callback function. A common beginner mistake is failing to check the return value; if the function returns -1, the key was not updated, and the system might be using an outdated or compromised key, which could lead to decryption errors in subsequent operations.

Uso:

- This function is used in secure communication protocols where 'Perfect Forward Secrecy' is required, meaning keys must be rotated periodically. It is typically called after a specific number of messages have been encrypted or after a time interval has elapsed. It is usually paired with an initialization function that sets up the channel and the ratchet callback, and eventually with a cleanup function when the channel is no longer needed. The workflow is: Initialize channel -> Perform encryption/decryption -> Periodically call ca_aes_channel_rotate -> Destroy channel.

Esempio:

```
/* Assuming 'my_channel' is an initialized ca_aes_channel_t */

if (ca_aes_channel_rotate(&my_channel) != 0) {
    /* Handle rotation failure: log error or force re-authentication */
    log_error("Failed to rotate AES key, channel might be compromised");
} else {
    /* Rotation successful, proceed with encrypted communication */
    send_secure_data();
}
```

Q&A — fine-tuning review *6/6 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I call ca_aes_channel_rotate() in a cryptographic application?
A: You should call ca_aes_channel_rotate() when you need to periodically update the encryption key of an AES channel to maintain security, typically as part of a key rotation strategy. This function is used to generate a new key via a callback and update it in protected memory.

Code example conf:0.90 **Q:** Can you show a minimal example of how to use ca_aes_channel_rotate()?
A: ca_aes_channel_t ch; i32 result = ca_aes_channel_rotate(&ch); if (result != 0) { /* handle error */ }

Parameters conf:0.90 **Q:** What does the ch parameter represent, and what are valid values for it?
A: The ch parameter is a pointer to a ca_aes_channel_t structure that must be valid and not NULL. It must have been initialized with a valid ratchet_cb callback. Passing NULL or an uninitialized channel will result in a failure.

Return conf:0.95 **Q:** What do the return values of ca_aes_channel_rotate() indicate?
A: A return value of 0 indicates success: the key was updated successfully. A return value of -1 indicates failure, which can be caused by a NULL pointer, an unset ratchet_cb, or an error during key loading or updating.

Error/Edge case conf:0.85 **Q:** What are common mistakes when using ca_aes_channel_rotate()?
A: Common mistakes include calling the function without initializing the channel, not setting the ratchet_cb callback, or not handling the negative return value, which can lead to unpredictable behavior.

Behavior conf:0.90 **Q:** Is ca_aes_channel_rotate() thread-safe and can it be called from an ISR?
A: Yes, the function is thread-safe due to internal mutex locking. However, it is not ISR-safe and must not be called from interrupt service routines. It is a blocking function that waits for the mutex before proceeding.

`ca_aes_ctx_set_iv`

GUARD: `EN_AES`

```
1 bool ca_aes_ctx_set_iv(ca_aes_ctx_t *ctx, const u8 *iv)
```

Sets the Initialization Vector (IV) for an AES cryptographic context.

Parametri:

Nome	Tipo	Descrizione
`ctx`	`ca_aes_ctx_t *`	Pointer to the AES context structure. Must be initialized and configured before use.
`iv`	`const u8 *`	Pointer to a 16-byte buffer containing the Initialization Vector. Must not be NULL.

Ritorna:
Returns true if the IV was successfully copied into the context, false if the context is invalid, the IV pointer is NULL, or the context has not been configured.

Note:

- This function is non-blocking and thread-safe provided the context is not being accessed by another task simultaneously. It is safe to call from an ISR, but ensure the context pointer is valid. The most common mistake is passing an uninitialized or unconfigured context, which will cause the function to return false immediately. It does not perform any hardware-specific operations; it merely updates the internal software state of the context structure.

Uso:

- This function is used during the setup phase of an AES operation, typically after the context has been initialized via ca_aes_ctx_setup and before calling encryption or decryption

functions like ca_aes_gcm_encrypt. It is essential for maintaining security in modes like GCM or CBC where a unique IV is required for every operation. In a typical sequence, you would enable access to a key slot, set the IV, perform the cryptographic operation, and then lock the slot again.

Esempio:

```
ca_aes_ctx_t *ctx = (ca_aes_ctx_t *)slot;
u8 iv[16] = {0x01, 0x02, 0x03, 0x04, 0x05, 0x06, 0x07, 0x08, 0x09, 0x0A, 0x0B, 0
    x0C, 0x0D, 0x0E, 0x0F, 0x10};

/* Ensure the context is ready for use */
if (ca_keys_store_temp_enable_access(slot, CA_KEYS_STORE_READ_WRITE) == 0) {
    if (ca_aes_ctx_set_iv(ctx, iv)) {
        /* Proceed with encryption using the configured context */
        bool success = ca_aes_gcm_encrypt(ctx, NULL, 0, input_data, output_data,
     len, tag);
    }
    ca_keys_store_lock_completely(slot);
    /* Clear sensitive data from stack */
    ca_memzero(iv, sizeof(iv));
}
```

Q&A — fine-tuning review *4/4 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** At what point in the cryptographic workflow should I call ca_aes_ctx_set_iv?
A: You should call this function during the setup phase of an AES operation, specifically after the context has been initialized via ca_aes_ctx_setup and before executing encryption or decryption functions like ca_aes_gcm_encrypt. It is necessary for modes like GCM or CBC that require a unique IV for each operation.

Code example conf:0.90 **Q:** How do I correctly initialize the IV in a caOS AES context?
A: You must provide a 16-byte buffer for the IV. Example: ca_aes_ctx_t ctx; u8 my_iv[16] = {0x01, 0x02, ...}; if (ca_aes_ctx_set_iv(&ctx, my_iv)) { /* Success */ }

Parameters conf:1.00 **Q:** What are the requirements for the iv parameter in ca_aes_ctx_set_iv?
A: The iv parameter must be a pointer to a 16-byte buffer containing the Initialization Vector. It must not be NULL, as passing a NULL pointer will cause the function to return false.

Return conf:1.00 **Q:** Why might ca_aes_ctx_set_iv return false?
A: The function returns false if the provided context is invalid, the IV pointer is NULL, or the context has not been properly configured via ca_aes_ctx_setup prior to the call.

`ca_aes_ctx_setup`

Header: `caos/drivers/inc/aes.h:51`
Source: `caos/drivers/src/aes.c:30:65`
GUARD: `EN_AES`

```
bool ca_aes_ctx_setup(ca_aes_ctx_t *ctx, ca_aes_mode_t mode,
    ca_aes_keysize_t keysize, const u8 *key, const u8 *iv)
```

Initializes an AES context structure with the specified mode, key, and initialization vector (IV).

Parametri:

Nome	Tipo	Descrizione
`ctx`	`ca_aes_ctx_t *`	Pointer to the AES context structure to be initialized. Must not be NULL.
`mode`	`ca_aes_mode_t`	The AES operation mode (e.g., CA_AES_MODE_ECB, CA_AES_MODE_CBC, CA_AES_MODE_CTR, CA_AES_MODE_GCM).
`keysize`	`ca_aes_keysize_t`	The size of the key (CA_AES_KEY_128, CA_AES_KEY_192, or CA_AES_KEY_256).
`key`	`const u8 *`	Pointer to the raw key buffer. Must not be NULL.
`iv`	`const u8 *`	Pointer to the initialization vector buffer. Required for CBC, CTR, and GCM modes; can be NULL for ECB.

Ritorna:
Returns true if the context was successfully configured, false if parameters are invalid (e.g., NULL pointers, missing IV for required modes, or unsupported key size).

Note:

- This function is non-blocking and performs local memory operations to format the key and IV into the context structure. It is thread-safe in the sense that it only modifies the provided local context object, but it does not interact with the hardware AES peripheral directly. It is safe to call from an ISR, provided the context pointer is valid and not shared with other tasks without proper synchronization. The most common beginner mistake is passing a NULL pointer for the IV when using modes like CBC or GCM, which will cause the function to return false immediately.

Uso:

- This function is the mandatory first step before performing any encryption or decryption operations. It is typically used in a sequence: first, you define a local or heap-allocated ca_aes_ctx_t structure, then you call ca_aes_ctx_setup to populate it with your security parameters, and finally, you pass that context to functions like ca_aes_encrypt or ca_aes_decrypt. It is good practice to zero out the key buffer using ca_memzero immediately after calling this function to prevent sensitive data from lingering in memory.

Esempio:

```
ca_aes_ctx_t my_ctx;
u8 key[32] = { /* 32 bytes of secret key */ };
u8 iv[16] = { /* 16 bytes of IV */ };

// Initialize the context for AES-256-CBC
if (ca_aes_ctx_setup(&my_ctx, CA_AES_MODE_CBC, CA_AES_KEY_256, key, iv)) {
    // Context is ready, proceed to encrypt or decrypt
    // ca_aes_encrypt(&my_ctx, input, output, len);
} else {
    // Handle configuration error
}

// Clear sensitive key material from stack
ca_memzero(key, sizeof(key));
```

Q&A — fine-tuning review *6/6 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I call ca_aes_ctx_setup in a caOS application?
A: You should call ca_aes_ctx_setup before performing any AES encryption or decryption operations to initialize the AES context with the required mode, key size, key, and IV. It is typically called once at the beginning of your application or before starting a new AES operation.

Code example conf:0.95 **Q:** Can you provide a minimal C example using ca_aes_ctx_setup with caOS types?
A: ca_aes_ctx_t ctx; ca_aes_mode_t mode = CA_AES_MODE_CBC; ca_aes_keysize_t keysize = CA_AES_KEY_128; u8 key[16] = {0x00, 0x01, 0x02, 0x03, 0x04, 0x05, 0x06, 0x07, 0x08, 0x09, 0x0A, 0x0B, 0x0C, 0x0D, 0x0E, 0x0F}; u8 iv[16] = {0x10, 0x11, 0x12, 0x13, 0x14, 0x15, 0x16, 0x17, 0x18, 0x19, 0x1A, 0x1B, 0x1C, 0x1D, 0x1E, 0x1F}; bool result = ca_aes_ctx_setup(&ctx, mode, keysize, key, iv);

Parameters conf:0.95 **Q:** What is the meaning of the key parameter in ca_aes_ctx_setup and what are valid values?
A: The key parameter is a pointer to the AES key used for encryption or decryption. It must not be NULL and must contain a valid key of the specified keysize (128, 192, or 256 bits). For example, for CA_AES_KEY_128, the key must be 16 bytes long.

Return conf:0.95 **Q:** What does the return value of ca_aes_ctx_setup indicate and what causes it to return false?
A: The function returns true if the context is successfully initialized. It returns false if any parameter is invalid, such as NULL ctx or key, or if the IV is missing for modes that require it (e.g., CBC, CTR, GCM).

Error/Edge case conf:0.90 **Q:** What are common mistakes or edge cases when using ca_aes_ctx_setup?
A: Common mistakes include passing NULL for ctx or key, not providing an IV for modes that require it (like CBC), or using an invalid keysize or mode. Passing an incorrect key length for the specified keysize also causes failure.

Behavior conf:0.90 **Q:** Is ca_aes_ctx_setup blocking, ISR-safe, or thread-safe?
A: ca_aes_ctx_setup is not blocking but may take some time to copy key and IV data. It is not thread-safe and should be protected by a mutex if used in a multi-threaded environment. It is not recommended to call it from an ISR due to potential non-allowed operations in interrupt contexts.

`ca_aes_decrypt`

Header: `caos/drivers/inc/aes.h:59`
Source: `caos/drivers/src/aes.c:85:101`
GUARD: `EN_AES`

```
1 bool ca_aes_decrypt(ca_aes_ctx_t *ctx, const u8 *in, u8 *out, u32 len)
```

Decrypts a block of data using the hardware AES engine with thread-safe access.

Parametri:

Nome	Tipo	Descrizione
`ctx`	`ca_aes_ctx_t *`	Pointer to the AES context structure. Must be initialized and configured before use; passing NULL or an unconfigured context will cause the function to return false.
`in`	`const u8 *`	Pointer to the encrypted input buffer. Must not be NULL.
`out`	`u8 *`	Pointer to the destination buffer where decrypted data will be stored. Must not be NULL and must have enough allocated space for 'len' bytes.
`len`	`u32`	Length of the data in bytes. Must be greater than 0 and a multiple of 16 (AES block size). If not a multiple of 16, the function returns false.

Ritorna:
Returns true if decryption was successful, false otherwise. A false return indicates invalid parameters, unconfigured context, input length not aligned to 16 bytes, or a hardware setup failure.

Note:

- This function is blocking because it uses a mutex to ensure exclusive access to the hardware AES peripheral. It is NOT safe to call this function from an Interrupt Service Routine (ISR) because the mutex lock operation will cause a system hang or crash. You must ensure the context is properly initialized before calling this function. A common mistake is passing a length that is not a multiple of 16, which will cause the function to fail immediately; always ensure your buffers are padded correctly according to the AES standard.

Uso:

- This function is used when you need to recover original data from an encrypted buffer using the STM32 hardware acceleration. It is typically used in a sequence: first, you initialize the context, then you call this function to perform the decryption, and finally, you verify the output. It is often paired with ca_aes_encrypt to perform round-trip testing or to process incoming secure data packets. Because it uses a mutex, it is designed to be used in multi-threaded environments where multiple tasks might need to access the AES hardware without corrupting each other's operations.

Esempio:

```
ca_aes_ctx_t ctx;
// Assume ctx is already initialized and configured
u8 ciphertext[16] = { /* encrypted data */ };
u8 decrypted[16];

// Attempt to decrypt the 16-byte block
if (ca_aes_decrypt(&ctx, ciphertext, decrypted, 16)) {
    // Decryption successful, proceed with data
} else {
    // Handle error: check if length was multiple of 16 or context was valid
}
```

Q&A — fine-tuning review *6/6 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I call ca_aes_decrypt in a caOS application?
A: You should call ca_aes_decrypt when you need to decrypt AES-encrypted data using a pre-configured AES context. It is typically used after initializing the AES hardware and setting up the decryption key and mode via functions like ca_aes_init(). This function is ideal for handling secure data transmission or storage where AES decryption is required.

Code example conf:0.90 **Q:** Can you provide a minimal C code example using ca_aes_decrypt with caOS types?
A: ca_aes_ctx_t ctx; ca_aes_init(&ctx, AES_MODE_DECRYPT, key, 16); const u8 ciphertext[16] = {0x00}; u8 plaintext[16]; bool result = ca_aes_decrypt(&ctx, ciphertext, plaintext, 16); if (result) { // Decryption successful }

Parameters conf:0.95 **Q:** What are the valid and invalid values for the parameters of ca_aes_decrypt?
A: The ctx parameter must be a valid pointer to a pre-configured AES context; NULL causes an error. The in and out parameters must be valid, non-NULL pointers to memory buffers. The len parameter must be a positive multiple of 16 bytes; otherwise, the function returns false. Passing invalid pointers or incorrect lengths will result in failure.

Return conf:0.95 **Q:** What does ca_aes_decrypt return, and what causes it to return false?
A: ca_aes_decrypt returns true if decryption is successful. It returns false if the context is NULL, input or output buffers are NULL, the length is not a multiple of 16, or if hardware configuration fails. It also returns false if the AES hardware is not properly initialized.

Error/Edge case conf:0.90 **Q:** What are common mistakes or edge cases when using ca_aes_decrypt?
A: Common mistakes include passing NULL pointers for ctx, in, or out; providing a length that is not a multiple of 16; or calling the function without initializing the AES context beforehand. Another frequent error is calling ca_aes_decrypt from an ISR, which is not allowed due to its blocking behavior.

Behavior conf:0.95 **Q:** Is ca_aes_decrypt blocking or non-blocking, and is it safe to call from an ISR?
A: ca_aes_decrypt is a blocking function because it waits for a mutex lock before accessing the AES hardware. It is not safe to call from an ISR because it uses mutex operations that are not ISR-safe. It is thread-safe due to the use of aes_mutex, allowing only one thread to access the AES hardware at a time.

`ca_aes_ecb_selftest`

Header: `caos/crypto/inc/aes.h:92`
Source: `caos/crypto/src/aes.c:751:784`
GUARD: `EN_AES`

```
u32 ca_aes_ecb_selftest(void)
```

Performs a FIPS-197 AES-256-ECB known-answer self-test to validate the cryptographic backend.

Ritorna:
Returns a u32 representing the number of failed tests. A return value of 0 indicates that all tests passed successfully.

Note:

- This function is a diagnostic tool used to verify the integrity of the AES implementation. It is not intended for high-frequency use in production loops, as it performs memory-intensive operations and blocking cryptographic calculations. It is thread-safe assuming the underlying AES hardware/software backend is properly initialized. It must NOT be called from an ISR because it performs blocking operations and uses standard output for reporting. The most common mistake is calling this before the system's cryptographic subsystem or memory management has been fully initialized, which will lead to undefined behavior or system crashes.

Uso:

- This function is typically used during the system boot sequence or as part of a diagnostic CLI command to ensure the hardware acceleration or software library is functioning correctly. It is often paired with other self-test functions like ca_aes_gcm_selftest or ca_sha256_selftest to provide a comprehensive health check of the security module. Developers should invoke this during the initialization phase of the application to catch hardware faults or configuration errors before the system starts processing sensitive data.

Esempio:

```c
/* Example: Running the AES self-test during system initialization */
#include "caos.h"

void run_security_diagnostics(void) {
    u32 failures = 0;

    /* Ensure the AES subsystem is ready before testing */
    ca_aes_init();

    /* Execute the ECB self-test */
    failures = ca_aes_ecb_selftest();

    if (failures > 0) {
        /* Log the failure to the system console */
        ca_stdout_printf_n("Security check failed with %u errors", failures);
        /* Halt or enter a safe state if crypto is broken */
        while(1) { ca_os_yield(); }
    } else {
        ca_stdout_put_n("Security subsystem verified.");
    }
}
```

Q&A — fine-tuning review *5/5 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** When is the appropriate time to call ca_aes_ecb_selftest in my caOS application?
A: It is typically used during the system boot sequence or as part of a diagnostic CLI command. It should be invoked during the initialization phase to ensure the cryptographic subsystem is functioning correctly before the system begins processing sensitive data.

Code example conf:1.00 **Q:** How do I implement a basic check using ca_aes_ecb_selftest?
A: u32 result = ca_aes_ecb_selftest(); if (result != 0) { /* Handle failure */ }

Return conf:1.00 **Q:** What does the u32 return value from ca_aes_ecb_selftest signify?
A: The return value represents the number of failed tests. A return value of 0 indicates that all FIPS-197 AES-256-ECB known-answer tests passed successfully.

Error/Edge case conf:1.00 **Q:** What is the most common mistake developers make when calling ca_aes_ecb_selftest?
A: The most common mistake is calling this function before the system's cryptographic subsystem or memory management has been fully initialized, which will lead to undefined behavior or system crashes.

Behavior conf:1.00 **Q:** Can I call ca_aes_ecb_selftest from an ISR or in a high-frequency loop?
A: No. It must not be called from an ISR because it performs blocking operations and uses standard output. It is also not intended for high-frequency use in production loops due to its memory-intensive nature and blocking cryptographic calculations.

`ca_aes_encrypt`

Header: `caos/drivers/inc/aes.h:56`
Source: `caos/drivers/src/aes.c:67:83`

GUARD: `EN_AES`

```
bool ca_aes_encrypt(ca_aes_ctx_t *ctx, const u8 *in, u8 *out, u32 len)
```

Encrypts a block of data using the hardware AES engine with thread-safe access.

Parametri:

Nome	Tipo	Descrizione
`ctx`	`ca_aes_ctx_t *`	Pointer to the AES context structure. Must be initialized and configured before use.
`in`	`const u8 *`	Pointer to the input plaintext buffer. Must not be NULL.
`out`	`u8 *`	Pointer to the output buffer where ciphertext will be stored. Must not be NULL.
`len`	`u32`	Length of the data in bytes. Must be a non-zero multiple of 16 (AES block size).

Ritorna:
Returns true if encryption was successful, false if parameters are invalid, the context is unconfigured, or the hardware processing failed.

Note:

- This function is blocking because it uses a mutex to ensure exclusive access to the hardware AES peripheral. It is thread-safe, meaning multiple tasks can call it, but they will be queued by the mutex. It must NOT be called from an ISR (Interrupt Service Routine) because mutexes cannot be locked in interrupt context. A common mistake is providing a length that is not a multiple of 16, which will cause the function to return false immediately. Ensure the context is fully initialized before calling this, otherwise the 'configured' check will fail.

Uso:

- This function is used when you need to secure data buffers before transmission or storage. It is typically used in a sequence: first, initialize the context with the key, then call ca_aes_encrypt to process the data, and finally use ca_aes_decrypt to verify or retrieve the original data. It is designed to be used in task-level code where you have enough stack space and can afford to wait for the mutex if another task is currently using the AES hardware.

Esempio:

```
ca_aes_ctx_t ctx;
u8 plaintext[16] = "Hello World 1234";
u8 ciphertext[16];

/* Assume context is initialized with a key elsewhere */
if (ca_aes_encrypt(&ctx, plaintext, ciphertext, 16)) {
    /* Encryption successful, proceed to send ciphertext */
} else {
    /* Handle error: check if length is multiple of 16 or context is valid */
}
```

Q&A — fine-tuning review *6/6 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I use the ca_aes_encrypt function in a caOS project?
A: You should use ca_aes_encrypt when you need to perform AES encryption on data in a thread-safe manner. It is ideal for securing sensitive data before storage or transmission, especially in embedded systems where hardware AES support is available. The function

ensures exclusive access to the AES hardware through a mutex, making it suitable for multi-threaded environments.

Code example conf:0.90 **Q:** Can you provide a minimal working example of how to use ca_aes_encrypt?
A: ca_aes_ctx_t ctx; bool result; u8 input[16] = {0x00, 0x01, 0x02, 0x03, 0x04, 0x05, 0x06, 0x07, 0x08, 0x09, 0x0A, 0x0B, 0x0C, 0x0D, 0x0E, 0x0F}; u8 output[16]; ctx.configured = true; result = ca_aes_encrypt(&ctx, input, output, 16); // Check result for success or failure

Parameters conf:0.90 **Q:** What are the valid values for the input and output buffers in ca_aes_encrypt?
A: The input buffer (in) and output buffer (out) must be valid pointers to memory locations. They must not be NULL. The input buffer should contain the data to be encrypted, and the output buffer must be large enough to hold the encrypted result. Both buffers must be aligned properly for the hardware AES peripheral to access them.

Return conf:0.95 **Q:** What does it mean when ca_aes_encrypt returns false?
A: A return value of false indicates that the encryption failed. This can happen due to invalid parameters such as a NULL buffer, incorrect length (not a multiple of 16), or an unconfigured context. It may also indicate a hardware setup failure or a failure during the encryption process itself.

Error/Edge case conf:0.90 **Q:** What are common mistakes when calling ca_aes_encrypt?
A: Common mistakes include passing NULL pointers for input or output buffers, providing a length that is not a multiple of 16, using an unconfigured context (ctx->configured = false), or calling the function from an ISR. These errors will cause the function to return false and may lead to undefined behavior or system crashes.

Behavior conf:0.95 **Q:** Is ca_aes_encrypt blocking or non-blocking, and can it be called from an ISR?
A: ca_aes_encrypt is a blocking function. It waits for the AES hardware mutex to be available and does not return until the encryption is complete. It is not safe to call from an ISR because it uses mutexes, which could lead to deadlock situations in interrupt contexts.

`ca_aes_gcm_decrypt`

Header: `caos/drivers/inc/aes.h:71`
Source: `caos/drivers/src/aes.c:119:140`
GUARD: `EN_AES`

```
1 bool ca_aes_gcm_decrypt(ca_aes_ctx_t *ctx, const u8 *aad, u32 aad_len,
    const u8 *in, u8 *out, u32 len, const u8 tag[AES_GCM_TAG_SIZE])
```

Decrypts data using AES-GCM and verifies the integrity tag to ensure the data has not been tampered with.

Parametri:

Nome	Tipo	Descrizione
ctx	ca_aes_ctx_t *	Pointer to the initialized AES context. Must be configured before use.
aad	const u8 *	Pointer to Additional Authenticated Data. Can be NULL if no AAD is used.
aad_len	u32	Length of the AAD buffer in bytes.
in	const u8 *	Pointer to the encrypted input data buffer.
out	u8 *	Pointer to the buffer where decrypted data will be stored.
len	u32	Length of the input/output data in bytes.
tag	const u8[AES_GCM_TAG_SIZE]	The 16-byte authentication tag received with ciphertext to verify integrity.

Ritorna:
Returns true if decryption succeeded and the tag matches (integrity verified). Returns false if the context is invalid, pointers are null, or the tag verification fails.

Note:

- This function is blocking because it uses a mutex to ensure thread-safe access to the hardware AES peripheral. It must NOT be called from an ISR (Interrupt Service Routine) because mutexes cannot be acquired in interrupt context. The context must be initialized and configured prior to calling this function, or it will return false immediately. A common mistake is failing to check the return value; if the tag verification fails, the output buffer will contain untrusted data, so you must never process the 'out' buffer if the function returns false.

Uso:

- This function is typically used in secure communication channels or file storage systems where data integrity is as important as confidentiality. It is usually paired with a preceding 'ca_aes_init' and 'ca_aes_ctx_setup' to prepare the context. In a typical workflow, you receive a packet containing the ciphertext and the tag, then call this function to decrypt and verify. If it returns true, the data is safe to use; if false, the system should discard the data and potentially trigger a security alert.

Esempio:

```
ca_aes_ctx_t ctx;
/* Assume ca_aes_init and ca_aes_ctx_setup have been called successfully */

/* Allocate buffer for decrypted data */
u8 *decrypted_buffer = ca_memory_allocate(32);

if (decrypted_buffer && ca_aes_gcm_decrypt(&ctx, aad_buffer, 16, encrypted_data,
    decrypted_buffer, 32, received_tag)) {
    /* Decryption successful and data is authentic */
    ca_printf_n("Decryption successful");
    ca_memory_free(decrypted_buffer, NULL, true);
} else {
    /* Decryption failed or data was tampered with */
    ca_printf_n("Security alert: Tag mismatch or decryption failure");
    if (decrypted_buffer) {
        ca_memory_free(decrypted_buffer, NULL, true);
    }
}
```

Q&A — fine-tuning review *6/6 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I use ca_aes_gcm_decrypt in my embedded application?

A: You should use ca_aes_gcm_decrypt when you need to decrypt data that was encrypted using AES-GCM mode and verify its integrity using the authentication tag. This function is ideal for secure communication protocols or data storage where both confidentiality and authenticity are required.

Code example conf:0.90 **Q:** Can you provide a minimal C code example using ca_aes_gcm_decrypt with caOS types?
A: ca_aes_ctx_t ctx; bool result = ca_aes_gcm_decrypt(&ctx, NULL, 0, ciphertext, plaintext, 16, tag); if (result) { // Decryption successful } else { // Handle decryption failure }

Parameters conf:0.90 **Q:** What are the valid values for the 'aad' parameter in ca_aes_gcm_decrypt?
A: The 'aad' parameter must be a pointer to Additional Authenticated Data. It can be NULL if aad_len is 0. If aad_len > 0, 'aad' must point to valid memory containing the authenticated data. The data must remain valid until the function completes.

Return conf:0.95 **Q:** What does a return value of false from ca_aes_gcm_decrypt indicate?
A: A return value of false indicates that decryption failed. This can happen due to an invalid context, incorrect authentication tag, invalid input/output buffers, incorrect data length (not a multiple of 16), or hardware errors.

Error/Edge case conf:0.85 **Q:** What are common mistakes when calling ca_aes_gcm_decrypt?
A: Common mistakes include passing NULL pointers for input/output buffers when len > 0, providing a data length that is not a multiple of 16, not verifying the return value, or calling the function with an unconfigured AES context (ctx->configured = false).

Behavior conf:0.90 **Q:** Is ca_aes_gcm_decrypt thread-safe and can it be called from an ISR?
A: Yes, ca_aes_gcm_decrypt is thread-safe because it uses a mutex to protect access to the AES hardware. However, it is not ISR-safe and should not be called from an Interrupt Service Routine, as it may block while acquiring the mutex.

`ca_aes_gcm_encrypt`

Header: `caos/drivers/inc/aes.h:66`
Source: `caos/drivers/src/aes.c:105:117`
GUARD: `EN_AES`

```
bool ca_aes_gcm_encrypt(ca_aes_ctx_t *ctx, const u8 *aad, u32 aad_len,
    const u8 *in, u8 *out, u32 len, u8 tag[AES_GCM_TAG_SIZE])
```

Encrypts data using AES-GCM mode and generates an authentication tag.

Parametri:

Nome	Tipo	Descrizione
`ctx`	`ca_aes_ctx_t *`	Pointer to an initialized AES context. Must be configured for GCM mode.
`aad`	`const u8 *`	Pointer to Additional Authenticated Data. Can be NULL if aad_len is 0.
`aad_len`	`u32`	Length of the AAD in bytes.
`in`	`const u8 *`	Pointer to the plaintext buffer. Must be valid if len > 0.
`out`	`u8 *`	Pointer to the output buffer for ciphertext. Must be valid if len > 0.
`len`	`u32`	Length of the plaintext/ciphertext in bytes.
`tag`	`u8[AES_GCM_TAG_SIZE]`	Buffer to store the generated 16-byte authentication tag.

Ritorna:

Returns true if encryption and tag generation succeeded, false otherwise (e.g., invalid context, null pointers, or hardware failure).

Note:

- This function is thread-safe because it uses an internal mutex to protect the hardware AES peripheral. It is a blocking function, meaning the calling task will wait if another task is currently using the AES hardware. You must NEVER call this from an Interrupt Service Routine (ISR) because blocking inside an ISR will cause a system crash or deadlock. Ensure the context is fully initialized via ca_aes_ctx_setup before calling this. A common mistake is passing a NULL pointer for the tag buffer or failing to check the return value, which leads to using uninitialized or corrupted ciphertext.

Uso:

- This function is typically used in secure communication protocols to ensure both data confidentiality and integrity. The standard workflow is: first, initialize the context using ca_aes_ctx_setup with the correct key and nonce; second, call ca_aes_gcm_encrypt to process the data; finally, transmit the ciphertext and the generated tag to the receiver. It is often paired with ca_aes_gcm_decrypt on the receiving end to verify the tag and recover the original plaintext. Always ensure that sensitive buffers are cleared using ca_memzero after the operation is complete to prevent data leakage.

Esempio:

```
ca_aes_ctx_t ctx;
u8 tag[16];
/* Initialize context with GCM mode and key */
if (ca_aes_ctx_setup(&ctx, CA_AES_MODE_GCM, CA_AES_KEY_256, key, nonce)) {
    /* Encrypt plaintext into ciphertext buffer */
    if (ca_aes_gcm_encrypt(&ctx, aad, 16, plaintext, ciphertext, 32, tag)) {
        /* Success: ciphertext and tag are ready for transmission */
    } else {
        /* Handle encryption failure */
    }
    /* Clear sensitive data from memory */
    ca_memzero(key, sizeof(key));
}
```

Q&A — fine-tuning review

5/5 pairs · qwen3-coder:latest

Usage conf:0.95 **Q:** When should I use ca_aes_gcm_encrypt in a caOS project?
A: You should use ca_aes_gcm_encrypt when you need to encrypt data using AES in GCM mode, which provides both confidentiality and authenticity. This is useful in secure communication protocols or when protecting sensitive data where you also need to verify that the data has not been tampered with.

Code example conf:0.90 **Q:** Can you show a minimal example of how to call ca_aes_gcm_encrypt?
A: ca_aes_ctx_t ctx; ca_aes_init(&ctx, CA_AES_KEY_256, (u8*)"example_key_32_bytes_long"); const u8 plaintext[16] = {0x00}; u8 ciphertext[16]; u8 tag[AES_GCM_TAG_SIZE]; bool result = ca_aes_gcm_encrypt(&ctx, NULL, 0, plaintext, ciphertext, 16, tag); // Check result for success or failure

Parameters conf:0.95 **Q:** What are the valid values for the 'len' parameter in ca_aes_gcm_encrypt?
A: The 'len' parameter must be either 0 or a multiple of 16 bytes (128 bits). This is because AES operates on 128-bit blocks, and GCM mode requires data to be processed in these block sizes.

Return conf:0.90 **Q:** What does it mean if ca_aes_gcm_encrypt returns false?
A: A return value of false indicates that the encryption failed due to invalid parameters such as a NULL pointer for ctx, in, out, or tag; or if the input length is not a multiple of 16 bytes. It may also fail if the AES context is not properly initialized.

Error/Edge case conf:0.90 **Q:** What are common mistakes when using ca_aes_gcm_encrypt?
A: Common mistakes include passing NULL pointers for input/output buffers or the tag, failing to ensure the data length is a multiple of 16 bytes, using an uninitialized or improperly configured AES context, and calling this function from an ISR which is not allowed due to mutex acquisition.

`ca_aes_gcm_selftest`

Header: `caos/crypto/inc/aes.h:79`
Source: `caos/crypto/src/aes.c:655:700`
GUARD: `EN_AES`

```
u32 ca_aes_gcm_selftest(void)
```

Performs a self-test of the AES-GCM cryptographic implementation to verify software integrity.

Ritorna:
Returns 0 if all tests pass, or a non-zero integer representing the count of failed test cases if any errors occur.

Note:

- This function is a diagnostic tool used to ensure the cryptographic implementation is functioning correctly. It is not thread-safe and should not be called from an ISR, as it performs multiple operations and potentially heavy calculations that would block the system. A common mistake is to assume it returns a boolean true/false; it actually returns the number of failures, so a return value of 0 is the only indicator of success. Ensure the system has enough stack space before calling this, as it processes several cryptographic vectors.

Uso:

- This function is typically called during the system boot sequence or as part of a diagnostic CLI command to verify the integrity of the crypto library. It is often paired with other self-test functions like ca_sha512_selftest or ca_x25519_selftest to ensure the entire security stack is operational. It is used to validate the environment before the application starts processing real encrypted data, ensuring that the underlying math is correct.

Esempio:

```
/* Run the AES-GCM self-test during system startup */
u32 result;

/* Perform the self-test and check for any failures */
result = ca_aes_gcm_selftest();

if (result == 0) {
    /* All tests passed, proceed with secure operations */
    ca_printf("AES-GCM integrity verified.\n");
} else {
    /* Log the number of failures and halt or enter a safe state */
    ca_printf("AES-GCM self-test failed with %u errors!\n", result);
    /* Perform system reset or enter error loop */
}
```

Q&A — fine-tuning review *5/5 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** When is the appropriate time to execute ca_aes_gcm_selftest in a caOS application?
A: It is typically called during the system boot sequence or as part of a diagnostic CLI command to verify the integrity of the crypto library before the application begins processing real encrypted data.

Code example conf:1.00 **Q:** Provide a minimal C example showing how to check the result of ca_aes_gcm_selftest.
A: u32 result = ca_aes_gcm_selftest(); if (result == 0) { /* Success */ } else { /* Handle result failures */ }

Return conf:1.00 **Q:** How should I interpret the return value of ca_aes_gcm_selftest?
A: The function returns 0 if all tests pass. A non-zero return value represents the count of failed test cases, meaning any value other than 0 indicates an error.

Error/Edge case conf:1.00 **Q:** What is a common mistake developers make when checking the return value of this function?
A: A common mistake is assuming the function returns a boolean true/false. Developers must remember it returns the number of failures, so only a return value of 0 indicates success.

Behavior conf:1.00 **Q:** Can I call ca_aes_gcm_selftest from an ISR or a multi-threaded environment?
A: No. The function is not thread-safe and must not be called from an ISR because it performs heavy calculations that would block the system. Additionally, you must ensure sufficient stack space is available before calling it.

`ca_aes_hw_gcm`

Header: `caos/drivers/inc/ca_glue_hw.h:23`
GUARD: `EN_CA_GLUE_HW`

```
extern bool ca_aes_hw_gcm(ca_aes_ctx_t *ctx, bool encrypt, const u8 *aad
    , u32 aad_len, const u8 *in, u8 *out, u32 len, u8 *tag); /* cifra/
    decifra in modalit  GCM con autenticazione AAD e tag */
```

Performs hardware-accelerated AES-GCM encryption or decryption with authentication tag generation.

Parametri:

Nome	Tipo	Descrizione
`ctx`	`ca_aes_ctx_t *`	Pointer to the initialized AES context structure containing keys and IV.
`encrypt`	`bool`	True for encryption, false for decryption.
`aad`	`const u8 *`	Pointer to Additional Authenticated Data (AAD). Can be NULL if aad_len is 0.
`aad_len`	`u32`	Length of AAD in bytes.
`in`	`const u8 *`	Pointer to input data buffer. Must be valid if len $>$ 0.
`out`	`u8 *`	Pointer to output data buffer. Must be valid if len $>$ 0.
`len`	`u32`	Length of payload data in bytes.
`tag`	`u8 *`	Pointer to a 16-byte buffer where the authentication tag will be stored.

Ritorna:

Returns true if the operation completed successfully, false if a hardware timeout occurred or parameters were invalid.

Note:

- This function is a blocking call that waits for the hardware peripheral to process data. It is NOT thread-safe on its own; it must be protected by a mutex (as seen in the driver layer) to prevent concurrent access to the shared AES hardware registers. It is NOT callable from an ISR because it relies on busy-waiting loops (cryp_wait_busy) which would hang the system if interrupts are disabled or if the hardware is busy. A common mistake is passing unaligned buffers or invalid pointers, which will cause the hardware to hang or the function to return false due to timeout.

Uso:

- This function is used in the high-level AES driver layer to perform authenticated encryption/decryption. It is typically called after the context has been initialized with a key and IV. The standard sequence is: 1) Lock the AES mutex, 2) Call ca_aes_hw_gcm, 3) Unlock the mutex. It is used when data integrity and confidentiality are both required, such as in secure network protocols or encrypted storage.

Esempio:

```
ca_aes_ctx_t my_ctx; /* Assume initialized with key/IV */
u8 tag[16];
u8 input[] = "SecretData";
u8 output[16];

/* Always protect hardware access with a mutex */
ca_mutex_lock(&aes_mutex);

/* Perform GCM encryption */
bool success = ca_aes_hw_gcm(&my_ctx, true, NULL, 0, input, output, sizeof(input), tag);

ca_mutex_unlock(&aes_mutex);

if (!success) {
    /* Handle hardware error or timeout */
}
```

Q&A — fine-tuning review *5/5 pairs · qwen3-coder:latest*

Usage conf:0.90 **Q:** When should I use ca_aes_hw_gcm() function in my caOS project?
A: You should use ca_aes_hw_gcm() when you need to perform AES encryption or decryption in GCM mode with AAD authentication and tag generation using hardware AES acceleration. However, note that all hardware implementations currently return false, making this function non-functional in real deployments.

Code example conf:0.80 **Q:** Can you provide a minimal C code example showing how to call ca_aes_hw_gcm()?
A:

```
ca_aes_ctx_t ctx;
bool result = ca_aes_hw_gcm(&ctx, true, NULL, 0, input_data, output_data, 16, tag);
```

Parameters conf:0.90 **Q:** What are the valid values for the 'encrypt' parameter in ca_aes_hw_gcm()?
A: The 'encrypt' parameter must be either true (to perform encryption) or false (to perform decryption). Any other value is invalid and will lead to undefined behavior.

Return conf:0.95 **Q:** What does it mean when ca_aes_hw_gcm() returns false?

A: A return value of false indicates that the operation failed. This can happen due to invalid parameters, an improperly configured context, or hardware errors. However, since all hardware implementations return false, this function will always fail in practice.

HW differences conf:0.90 **Q:** Are there any differences in how ca_aes_hw_gcm() is implemented across different STM32 families?

A: No, there are no functional differences in the implementation of ca_aes_hw_gcm() across STM32 families (f1xx, f4xx, f7xx, h5xx, h7xx). All implementations simply return false without performing any actual hardware operations, indicating that the function is not functional on any supported hardware.

`ca_aes_hw_init`

Header: `caos/drivers/inc/ca_glue_hw.h:20`
GUARD: `EN_CA_GLUE_HW`

```
extern bool ca_aes_hw_init(void); /* initializes the hardware AES/CRYP
   peripheral */
```

Initializes the hardware AES cryptographic peripheral by enabling its clock in the RCC register.

Ritorna:
Returns true if the hardware peripheral was successfully enabled, or false if the hardware is unsupported, disabled in configuration, or unavailable on the specific MCU model.

Note:

- This function is non-blocking and performs a direct register write to the RCC (Reset and Clock Control) unit. It is thread-safe in the sense that it only modifies a peripheral clock register, but it is not intended to be called repeatedly; it should be executed once during system startup. A common beginner mistake is calling this function multiple times or assuming it configures the AES engine's internal registers (like keys or IVs), which it does not. It must be called before any other AES operations are attempted, as accessing the AES peripheral registers without enabling the clock will cause a hard fault or bus error. It is safe to call from an ISR, though typically unnecessary as it is part of the system boot sequence.

Uso:

- This function is typically called during the system initialization phase, specifically within the higher-level ca_aes_init() function. It acts as the hardware-level prerequisite for the AES driver. You should pair this with other initialization routines to ensure that subsequent cryptographic operations are thread-safe when accessed by multiple tasks. Once initialized, the driver is ready to accept context setups via ca_aes_ctx_setup() and perform encryption or decryption tasks.

Esempio:

```
/* Initialize the AES driver during system startup */
if (ca_aes_init()) {
    /* AES hardware is ready for use */
} else {
    /* Handle error: AES hardware not supported or failed to initialize */
    while(1);
}

/* Later, in a task, setup the context for encryption */
/* Assuming my_ctx is a valid pointer to a structure defined by the driver */
```

```c
if (ca_aes_ctx_setup(my_ctx, 0, 0, key_buffer, iv_buffer)) {
    /* Context is ready, proceed with encryption */
} else {
    /* Handle configuration error */
}
```

Q&A — fine-tuning review *4/4 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should ca_aes_hw_init() be called, and why is it important to call it only once?
A: ca_aes_hw_init() should be called once at system startup before any AES encryption or decryption operations are performed. It initializes the AES hardware peripheral and must be called only once because it is not designed to be re-initialized. Calling it multiple times could lead to undefined behavior or crashes.

Code example conf:0.90 **Q:** Can you provide a minimal C code example showing how to use ca_aes_hw_init() with caOS types?
A: bool result = ca_aes_hw_init(); if (result) { // AES hardware initialized successfully // Proceed with AES operations } else { // Handle initialization failure // AES hardware may be disabled or not functional }

Return conf:0.95 **Q:** What does it mean when ca_aes_hw_init() returns false, and what causes this failure?
A: ca_aes_hw_init() returns false when the AES hardware initialization fails. This can happen if the AES module is disabled in the firmware (EN_AES=0) or if the hardware implementation is not functional. According to the documentation, all current implementations return false, indicating that the function is not currently functional.

HW differences conf:0.85 **Q:** How do the AES hardware implementations differ across STM32 families like F1, F4, F7, H5, and H7?
A: All STM32 families (F1, F4, F7, H5, H7) currently implement ca_aes_hw_init() to return false, meaning none of them have functional AES hardware initialization. The F7 and H7 families have specific notes: F7xx has no CRYP peripheral, and H747 specifically lacks CRYP support. The F1, F4, and H5 families are noted to have AES hardware but are not functional in the current implementation.

`ca_aes_hw_process`

Header: `caos/drivers/inc/ca_glue_hw.h:22`
GUARD: `EN_CA_GLUE_HW`

```c
extern bool ca_aes_hw_process(const u8 *in, u8 *out, u32 len); /* cifra/
   decifra un blocco con la configurazione corrente */
```

Processes a buffer of data through the hardware AES engine using the currently configured key and mode.

Parametri:

Nome	Tipo	Descrizione
`in`	`const u8 *`	Pointer to the input data buffer. Must be aligned to 4-byte boundaries for optimal performance.
`out`	`u8 *`	Pointer to the output buffer where the encrypted/decrypted data will be stored. Must be at least 'len' bytes long.
`len`	`u32`	Length of the data in bytes. Must be a multiple of 16 (AES block size). If not a multiple, the function will fail to process the final partial block.

Ritorna:
Returns true if the entire buffer was processed successfully, or false if a hardware timeout occurred or the input parameters were invalid.

Note:

- This function is a blocking call that waits for the hardware FIFO to become ready for each 128-bit block. It is not thread-safe on its own; it relies on an external mutex (as seen in the usage context) to prevent multiple tasks from accessing the hardware simultaneously. It is not safe to call from an ISR because it uses a polling loop with a timeout, which could cause significant latency or system hangs if the hardware is busy. A common beginner mistake is passing a length that is not a multiple of 16, which will cause the function to process only complete blocks and potentially leave the output buffer partially unwritten or corrupted.

Uso:

- This function is typically used within a higher-level driver wrapper that manages resource locking. The standard sequence is: first, initialize the hardware with 'ca_aes_hw_init', then configure the key and mode using 'ca_aes_hw_setup', acquire a mutex to ensure exclusive access, call 'ca_aes_hw_process' to perform the actual transformation, and finally release the mutex. It is designed to be called repeatedly for large data streams, provided the mutex is held throughout the entire operation to maintain state consistency.

Esempio:

```
/* Assuming aes_mutex is initialized and hardware is configured */
if (ca_mutex_lock(&aes_mutex, 100)) {
    /* Process 32 bytes (2 blocks of 16) */
    if (ca_aes_hw_process(input_buffer, output_buffer, 32)) {
        /* Success: data is now encrypted/decrypted */
    } else {
        /* Handle hardware error or timeout */
    }
    ca_mutex_unlock(&aes_mutex);
} else {
    /* Could not acquire mutex, hardware busy */
}
```

Q&A — fine-tuning review *5/5 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I call ca_aes_hw_process in my embedded application?
A: You should call ca_aes_hw_process when you need to encrypt or decrypt a block of data using the hardware AES peripheral. It is typically used in contexts where high-performance cryptographic operations are required, and it must be called within a mutex-protected section to ensure thread safety.

Code example conf:0.90 **Q:** Can you provide a minimal C code example using ca_aes_hw_process with caOS types?
A:

```
u8 input[16] = {0x00};
u8 output[16];
bool result = ca_aes_hw_process(input, output, 16);
```

Parameters conf:0.90 **Q:** What are the valid values for the length parameter in ca_aes_hw_process?
A: The length parameter must be a multiple of 16 bytes, which corresponds to one AES block. Passing zero or odd-length values can cause errors and undefined behavior. The input and output buffers must also be valid and non-NULL.

Return conf:0.95 **Q:** What does a return value of false from ca_aes_hw_process indicate?
A: A return value of false indicates that the operation failed. This can be caused by invalid parameters such as NULL buffers, incorrect length (not a multiple of 16), or an uninitialized or misconfigured hardware AES peripheral.

HW differences conf:0.80 **Q:** Are there any differences in how ca_aes_hw_process is implemented across different STM32 families?
A: Based on the provided documentation, all hardware implementations (f1xx, f4xx, f7xx, h5xx, h7xx) currently return false for all functions including ca_aes_hw_process, indicating that the actual hardware support is not implemented in these stubs. There are no specific register or peripheral differences mentioned in the stubs.

`ca_aes_hw_setup`

Header: `caos/drivers/inc/ca_glue_hw.h:21`
GUARD: `EN_CA_GLUE_HW`

```
extern bool ca_aes_hw_setup(ca_aes_ctx_t *ctx, bool encrypt); /* carica
    chiave e IV nel periferico per ECB/CBC */
```

Configures the hardware AES peripheral with the provided key, IV, and operational mode.

Parametri:

Nome	Tipo	Descrizione
`ctx`	`ca_aes_ctx_t *`	Pointer to the AES context structure containing the key, IV, and mode settings. Must be initialized before calling this function.
`encrypt`	`bool`	Set to true for encryption, false for decryption. Note that decryption may trigger additional key preparation steps.

Ritorna:
Returns true if the hardware was successfully configured. Returns false if the mode is unsupported (e.g., GCM), if key preparation fails, or if the hardware is not available on the current platform.

Note:

- This function is non-blocking but interacts directly with hardware registers, so it is not thread-safe on its own; it must be protected by a mutex if multiple tasks access the AES peripheral. It is generally not safe to call from an ISR because it may perform complex operations like key preparation. A common beginner mistake is failing to check the return value, which leads to processing data with uninitialized or incorrect hardware settings. Ensure the AES peripheral is powered and initialized before calling this function, as it assumes the hardware is ready to accept configuration.

Uso:

- This function is the mandatory setup step before any data processing occurs. It is typically used within a wrapper function that handles mutual exclusion, ensuring that only one task configures and uses the AES engine at a time. The standard sequence is: lock the mutex, call ca_aes_hw_setup, perform the data processing using ca_aes_hw_process, and finally unlock the mutex. It is never used in isolation; it must always be paired with a processing function to actually perform the cryptographic operation.

Esempio:

```
ca_aes_ctx_t my_aes_ctx;
// ... initialize my_aes_ctx with key and IV ...

ca_mutex_lock(&aes_mutex);

// Configure hardware for encryption
if (ca_aes_hw_setup(&my_aes_ctx, true)) {
    // Proceed to process data if setup succeeded
    bool success = ca_aes_hw_process(input_buffer, output_buffer, data_len);
    if (!success) {
        // Handle processing error
    }
} else {
    // Handle setup failure (e.g., unsupported mode)
}

ca_mutex_unlock(&aes_mutex);
```

Q&A — fine-tuning review *5/5 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I call ca_aes_hw_setup() in my AES encryption/decryption workflow?
A: You should call ca_aes_hw_setup() after initializing the AES context with the key and IV, but before starting actual encryption or decryption operations. It prepares the hardware AES peripheral with the key and IV for ECB/CBC modes. This function is typically called once per encryption/decryption session before processing data.

Code example conf:0.90 **Q:** Can you show a minimal example of how to use ca_aes_hw_setup() with caOS types?
A: ca_aes_ctx_t ctx; ctx.key[0] = 0x12345678; ctx.iv[0] = 0x87654321; bool success = ca_aes_hw_setup(&ctx, true); /* encrypt mode */ if (!success) { /* handle error */ }

Parameters conf:0.95 **Q:** What does the 'encrypt' parameter in ca_aes_hw_setup() control, and what are valid values?
A: The 'encrypt' parameter controls the operation mode: true enables encryption, false enables decryption. Valid values are only true or false. Any other value will result in undefined behavior. The parameter determines whether the hardware AES peripheral will perform encryption or decryption using the loaded key and IV.

Return conf:0.90 **Q:** What does ca_aes_hw_setup() return, and what causes it to return false?
A: It returns true on successful loading of key and IV into the hardware AES peripheral, or false on failure. Common causes of failure include: hardware not available, invalid context pointer, or hardware errors. The function is also not thread-safe and requires external mutex protection.

HW differences conf:0.70 **Q:** How does ca_aes_hw_setup() differ between STM32F1xx and STM32H7xx families in terms of hardware implementation?
A: The implementation is stubbed in all families (F1xx, F4xx, F7xx, H5xx, H7xx) and returns false. There are no functional differences in the API itself, but the underlying hardware peripherals (AES registers, clocking, and DMA support) vary between families.

The F1xx family lacks hardware AES support, while H7xx has full hardware acceleration with advanced features.

---

ca_aes_init

Header: caos/drivers/inc/aes.h:48
Source: caos/drivers/src/aes.c:24:28
GUARD: EN_AES

```
bool ca_aes_init(void)
```

Initializes the AES hardware peripheral and the internal mutex required for thread-safe cryptographic operations.

Ritorna:
Returns true if both the mutex and the AES hardware were initialized successfully; returns false if the hardware initialization failed.

Note:

- This function is not thread-safe and must be called exactly once during the system startup phase, typically before any tasks are created or before any other AES functions are invoked. It is strictly non-blocking and must NOT be called from an Interrupt Service Routine (ISR) because it initializes a mutex, which is a kernel object that requires a running scheduler context. A common mistake is calling this function multiple times or from different tasks; doing so will re-initialize the mutex, potentially causing race conditions or memory corruption if other tasks are already waiting on that mutex.

Uso:

- This function is the mandatory entry point for any application requiring AES encryption or decryption. It is typically called during the system initialization sequence, alongside other hardware drivers like RNG, HASH, or Flash. It must be called before any calls to ca_aes_ctx_setup or actual encryption/decryption functions, as those functions rely on the mutex initialized here to prevent concurrent access to the shared AES hardware peripheral.

Esempio:

```
/* System startup sequence */
void system_init(void) {
    /* Initialize the AES hardware and its internal mutex */
    if (!ca_aes_init()) {
        /* Handle failure: log error or enter safe state */
        CA_SAFE_FAIL("AES init failed");
    }

    /* Now it is safe to use other AES functions */
    ca_aes_ctx_t my_ctx;
    ca_aes_ctx_setup(&my_ctx, CA_AES_MODE_CBC, AES_KEYSIZE_128);
}
```

Q&A — fine-tuning review *3/3 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should ca_aes_init() be called in a caOS application, and why is it important to call it only once?
A: ca_aes_init() should be called once at system startup before any other AES functions are used. It initializes the AES hardware module and creates an internal mutex for thread safety. Calling it more than once or forgetting to initialize it before using other AES

functions will lead to errors. It is a blocking function and must not be called from an ISR.

Code example conf:0.90 **Q:** Can you provide a minimal C code example using ca_aes_init() with caOS types?
A: bool result = ca_aes_init(); if (result) { // AES module initialized successfully } else { // Handle initialization error }

Return conf:0.90 **Q:** What do the return values of ca_aes_init() indicate, and what causes initialization to fail?
A: ca_aes_init() returns true if the AES hardware module was successfully initialized and the mutex was created. It returns false if there was an error during hardware initialization. The most common cause of failure is calling this function more than once or not initializing the mutex before using other AES functions.

`ca_arp_avail`

Header: `caos/net/inc/arp_service.h:74`
Source: `caos/net/src/arp_service.c:231:234`
GUARD: `EN_ARP_SERVICE`

```
bool ca_arp_avail(ca_ipv4_t ip)
```

Checks if a specific IPv4 address has a corresponding MAC address already resolved in the ARP cache.

Parametri:

Nome	Tipo	Descrizione
`ip`	`ca_ipv4_t`	The IPv4 address to search for in the ARP table. Must be a valid 32-bit representation of an IP address.

Ritorna:
Returns true if the IP address exists in the ARP cache and is associated with a valid MAC address; returns false if the IP is not found or the entry has expired.

Note:

- This function is non-blocking and performs a simple lookup in the internal ARP cache memory. It is thread-safe, meaning it can be called from multiple tasks simultaneously without corrupting the cache data. It is safe to call from an ISR (Interrupt Service Routine) because it does not perform any complex operations or wait for hardware responses. The most common mistake is assuming that a 'false' return means the device is offline; it simply means the ARP entry is not currently cached, so you may need to trigger a network request to resolve it.

Uso:

- This function is typically used as a pre-check before attempting to send data to a specific network node to avoid unnecessary ARP resolution delays. It is often paired with ca_arp_find() when you need to retrieve the actual MAC address after confirming its availability. Developers use this in the application layer to verify if a target device is 'known' to the stack before initiating a communication sequence, ensuring that the network stack is ready to transmit packets immediately.

Esempio:

```
ca_ipv4_t target_ip = {192, 168, 1, 50};

```

```c
// Check if we already have the MAC address for this IP
if (ca_arp_avail(target_ip)) {
    // We have the mapping, proceed with sending data
    // ca_mac_t mac;
    // ca_arp_find(target_ip, &mac);
} else {
    // Entry not in cache, we might need to trigger an ARP request
    // or wait for the stack to resolve it automatically.
}
```

Q&A — fine-tuning review *4/4 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I call ca_arp_avail() in my network application?
A: You should call ca_arp_avail() when you need to check if an IPv4 address is already resolved in the ARP cache before attempting to send data to that address. This helps avoid unnecessary ARP requests and improves network efficiency. It's typically used before sending packets to ensure the MAC address is known.

Code example conf:0.90 **Q:** Can you show a minimal example of how to use ca_arp_avail() with caOS types?
A: ca_ipv4_t target_ip = {192, 168, 1, 10}; bool is_resolved = ca_arp_avail(target_ip); if (is_resolved) { // Proceed with sending data } else { // Handle unresolved IP }

Parameters conf:0.90 **Q:** What does the ca_ipv4_t parameter represent in ca_arp_avail() and what are valid values?
A: The ca_ipv4_t parameter represents the IPv4 address to check in the ARP cache. It must be a valid IPv4 address structure with four octets (u8[4]) representing the address. Invalid values include NULL or malformed addresses, which lead to undefined behavior.

Return conf:0.95 **Q:** What do the return values of ca_arp_avail() indicate and what causes it to return false?
A: ca_arp_avail() returns true if the IP address is present in the ARP cache and can be used for communication. It returns false if the IP address is not in the cache, meaning it has not yet been resolved to a MAC address. A return value of false does not indicate an error, but rather that the address is not yet resolved.

`ca_arp_del`

Header: `caos/net/inc/arp_service.h:117`
Source: `caos/net/src/arp_service.c:412:424`
GUARD: `EN_ARP_SERVICE`

```c
bool ca_arp_del(u8 idx)
```

Removes a specific entry from the ARP cache by its index.

Parametri:

Nome	Tipo	Descrizione
`idx`	`u8`	The zero-based index of the active ARP entry to remove. Valid values range from 0 to (ARP_CACHE_SIZE - 1). Providing an index higher than the number of currently active entries will result in a failure.

Ritorna:
Returns true if the entry at the specified index was found and successfully invalidated. Returns false if the index is out of range or if no active entry exists at that position.

Note:

- This function is thread-safe because it uses a mutex to protect the shared ARP cache array from concurrent access. It is a blocking function; if another thread currently holds the mutex, the calling thread will be suspended until the mutex is released. You must NEVER call this function from an Interrupt Service Routine (ISR) because blocking operations are strictly forbidden in ISR context and will cause system instability or hard faults. A common beginner mistake is assuming the index refers to a static memory address rather than the dynamic count of currently active entries.

Uso:

- This function is typically used in command-line interfaces (CLI) or network management tasks where a user or system process needs to clear stale or incorrect ARP mappings. It is usually paired with a display function that lists current entries so the user knows which index to target. The typical sequence is: first, call a function to list or iterate through the cache to identify the target index, then call ca_arp_del(idx) to remove it, and finally verify the result via the return boolean to provide feedback to the user.

Esempio:

```c
/* Example: Deleting an ARP entry based on user input from a CLI */
void handle_arp_delete_command(char *input_idx) {
    u8 idx = (u8)ca_strtol(input_idx, 10);

    /* Attempt to delete the entry at the provided index */
    if (ca_arp_del(idx)) {
        /* Success: entry was found and marked as invalid */
        ca_printf("Successfully deleted ARP entry at index %u\n", idx);
    } else {
        /* Failure: index was invalid or no entry existed at that position */
        ca_printf("Error: Could not delete ARP entry at index %u\n", idx);
    }
}
```

Q&A — fine-tuning review *5/5 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I call ca_arp_del() in a network application?
A: You should call ca_arp_del() when you need to remove a specific entry from the ARP cache, for example, when a device is no longer reachable or when you want to force a refresh of the ARP table. This function is typically used in network services that manage dynamic ARP entries.

Code example conf:0.90 **Q:** Can you show a minimal example of how to use ca_arp_del()?
A: u8 index = 5; bool result = ca_arp_del(index); if (result) { // Entry was successfully deleted } else { // Entry was not found or invalid index }

Parameters conf:0.95 **Q:** What is the significance of the idx parameter in ca_arp_del()?
A: The idx parameter specifies the index of the ARP cache entry to delete. It must be between 0 and ARP_CACHE_SIZE-1. Values outside this range can cause undefined behavior, such as memory access violations, because the function does not validate the input.

Return conf:0.90 **Q:** What does ca_arp_del() return when it fails to delete an ARP entry?
A: The function returns false if no valid entry corresponds to the given index idx. This typically happens when the index is out of bounds or the entry at that index is not currently in use. It returns true only if a valid entry was found and successfully deleted.

Error/Edge case conf:0.85 **Q:** What are common mistakes when using ca_arp_del()?
A: Common mistakes include passing an index outside the valid range [0, ARP_CACHE_SIZE-1], which can lead to memory corruption; not checking the return value, which may cause silent failures; and calling the function from an ISR, which is unsafe due to mutex acquisition and potential deadlocks.

ca_arp_del_ip

Header: caos/net/inc/arp_service.h:123
Source: caos/net/src/arp_service.c:196:209
GUARD: EN_ARP_SERVICE

```
bool ca_arp_del_ip(ca_ipv4_t ip)
```

Removes a specific IPv4 address entry from the internal ARP cache table.

Parametri:

Nome	Tipo	Descrizione
ip	ca_ipv4_t	The IPv4 address structure to search for and remove. Ensure the structure is correctly populated before calling.

Ritorna:
Returns true if the IP address was found and successfully removed from the cache, or false if the IP address did not exist in the cache.

Note:

- This function is thread-safe because it uses a mutex (s_cache_mtx) to protect the shared ARP cache array from concurrent access. It is a blocking function; if another thread currently holds the mutex, the calling thread will wait until it is released. You must NOT call this function from an Interrupt Service Routine (ISR) because blocking operations are strictly forbidden in ISRs and will cause system instability or deadlocks. A common mistake is assuming the cache is updated instantly across all network tasks; always check the return value to confirm if the entry was actually present before assuming it was deleted.

Uso:

- This function is typically used in network management interfaces, such as a Command Line Interface (CLI), to manually clear stale or incorrect ARP entries. It is usually paired with parsing functions like ca_parse_ipv4 to convert user input strings into the required ca_ipv4_t format. In a typical lifecycle, you would use this when a network administrator needs to force a re-discovery of a device's MAC address by clearing its existing ARP mapping, ensuring the system does not use outdated cached information.

Esempio:

```c
ca_ipv4_t target_ip;
// Parse a string input into the ca_ipv4_t structure
if (ca_parse_ipv4("192.168.1.50", &target_ip)) {
    // Attempt to remove the entry from the ARP cache
    if (ca_arp_del_ip(target_ip)) {
        // Successfully removed
        CLI_PRINTF_N("ARP entry deleted successfully.");
    } else {
        // Entry not found in cache
        CLI_PRINTF_N("ARP entry not found.");
    }
}
```

Q&A — fine-tuning review *5/5 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I call ca_arp_del_ip() in a network application?
A: You should call ca_arp_del_ip() when you need to remove a specific IPv4 address from the ARP cache, typically when the corresponding device is no longer reachable or has changed its network configuration. This helps maintain an accurate ARP table and prevents stale entries from causing communication issues.

Code example conf:0.90 **Q:** Can you show a minimal example of how to use ca_arp_del_ip() with caOS types?
A: ca_ipv4_t target_ip = {192, 168, 1, 10}; bool result = ca_arp_del_ip(target_ip); if (result) { // Entry was found and removed } else { // Entry not found in ARP cache }

Parameters conf:0.90 **Q:** What is the significance of the ca_ipv4_t parameter in ca_arp_del_ip() and what values are valid?
A: The ca_ipv4_t parameter represents the IPv4 address to be removed from the ARP cache. It must be a valid IPv4 address; otherwise, the behavior is undefined. Valid values are any 4-byte array representing a valid IPv4 address such as {192, 168, 1, 1}. Invalid values include malformed or out-of-range addresses.

Return conf:0.95 **Q:** What does it mean when ca_arp_del_ip() returns false?
A: When ca_arp_del_ip() returns false, it means that no entry matching the provided IPv4 address was found in the ARP cache. This does not indicate an error in execution, but rather that the specified IP address was not present in the cache.

Error/Edge case conf:0.85 **Q:** What are common mistakes or edge cases when using ca_arp_del_ip()?
A: Common mistakes include calling the function with an uninitialized or invalid IPv4 address, which can lead to undefined behavior. Additionally, calling this function before the ARP cache has been initialized will result in accessing unallocated memory. It's also not recommended to call it from an ISR due to potential mutex blocking and scheduling issues.

`ca_arp_dump`

Header: `caos/net/inc/arp_service.h:106`
Source: `caos/net/src/arp_service.c:372:403`
GUARD: `EN_ARP_SERVICE`

```
1 void ca_arp_dump(void)
```

Prints the current contents of the ARP cache to the system CLI for debugging purposes.

Ritorna:
void

Note:

- This function is a blocking operation because it acquires a mutex (s_cache_mtx) to ensure data consistency while reading the cache. It is NOT safe to call from an Interrupt Service Routine (ISR) because mutexes are designed for thread synchronization and can cause the system to hang or trigger an assertion if locked in an ISR context. The function creates a local snapshot of the cache to minimize the time the mutex is held, which is a good practice to prevent blocking other network tasks for too long. A common beginner mistake is calling this function inside a high-frequency loop or an ISR, which will lead to system instability or deadlocks.

Uso:

- This function is intended for diagnostic use, typically triggered by a user command via the Command Line Interface (CLI). It is usually paired with other maintenance functions like ca_arp_flush() or specific entry deletion functions. Developers use this to verify that the network stack is correctly resolving IP addresses to MAC addresses and to check if entries are expiring as expected. It should be invoked only when the user explicitly requests status information, as it performs significant string formatting and output operations that consume CPU cycles.

Esempio:

```c
/* Example: CLI command handler to display ARP table */
void handle_cli_command(char *cmd) {
    if (ca_strncmp(cmd, "arp info", 8) == 0) {
        /* Safely print the ARP cache to the console */
        ca_arp_dump();
    } else if (ca_strncmp(cmd, "arp flush", 9) == 0) {
        /* Clear the cache if requested */
        ca_arp_flush();
        CLI_PUT_N("Cache cleared.");
    }
}
```

Q&A — fine-tuning review *4/4 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I call ca_arp_dump() in my caOS network application?
A: You should call ca_arp_dump() primarily for debugging and monitoring purposes to inspect the contents of the ARP cache. It is useful when you need to verify ARP table entries or diagnose network connectivity issues. The function is intended for use in non-critical sections of code where blocking is acceptable.

Code example conf:0.90 **Q:** Can you provide a minimal example of how to use ca_arp_dump() in a caOS application?
A: void example_function(void) { ca_arp_dump(); }

Error/Edge case conf:0.85 **Q:** What are the potential issues or edge cases when using ca_arp_dump()?
A: The main edge cases include calling ca_arp_dump() from an ISR, which is not thread-safe and may cause issues. Additionally, if CLI_PUT_N and CLI_PRINTF_N are not implemented or available, the function will not produce any output. If the ARP cache is empty, it will print a specific message indicating this. The function also blocks while acquiring a mutex, so it should not be used in time-critical sections.

Behavior conf:0.90 **Q:** Is ca_arp_dump() blocking or non-blocking, and is it safe to call from an ISR?
A: ca_arp_dump() is a blocking function because it acquires a mutex before reading the ARP cache. It is not safe to call from an ISR as it is not thread-safe in that context. The function must be used in contexts where waiting is acceptable, such as in task-level code, not in interrupt handlers.

`ca_arp_find`

Header: `caos/net/inc/arp_service.h:79`
Source: `caos/net/src/arp_service.c:236:249`
GUARD: `EN_ARP_SERVICE`

```c
bool ca_arp_find(ca_ipv4_t ip, ca_mac_t *mac_out)
```

Searches the local ARP cache for a MAC address associated with a specific IPv4 address.

Parametri:

Nome	Tipo	Descrizione
`ip`	`ca_ipv4_t`	The target IPv4 address to look up in the cache. Must be a valid ca_ipv4_t structure.
`mac_out`	`ca_mac_t *`	A pointer to a ca_mac_t structure where the result will be stored if found. Can be NULL if you only want to check existence.

Ritorna:

Returns true if the IP address exists in the cache and the MAC was successfully copied to mac_out. Returns false if the IP is not found in the cache or if the entry is marked as invalid.

Note:

- This function is blocking because it uses a mutex (ca_mutex_lock) to ensure thread safety while reading the shared ARP cache table. Because it uses a mutex, it must NEVER be called from an Interrupt Service Routine (ISR), as doing so will cause a system deadlock or kernel panic. Before calling this, ensure the network stack and ARP service have been initialized, otherwise the cache will be empty. A common beginner mistake is assuming this function will trigger a network request; it does not. It only checks the local memory table, so if it returns false, you must manually trigger a resolution process like ca_arp_resolve.

Uso:

- This function is typically used as the first step in a network communication sequence to avoid unnecessary ARP broadcast traffic. You call it before sending a packet to check if the destination hardware address is already known. If it returns true, you proceed with the transmission using the retrieved MAC. If it returns false, you typically pair it with ca_arp_resolve to perform a network-level lookup, wait for the response, and then proceed with your communication.

Esempio:

```
ca_ipv4_t target_ip = {{192, 168, 1, 10}}; ca_mac_t target_mac;

// Check if we already know the MAC address
if (ca_arp_find(target_ip, &target_mac)) {
    // MAC found, proceed to send data
    // send_packet(target_mac, data);
} else {
    // MAC not in cache, attempt to resolve it via network
    // Wait up to 1000ms for the ARP reply
    if (ca_arp_resolve(target_ip, &target_mac, 1000U)) {
        // Resolution successful, now we can send
    } else {
        // Handle error: host unreachable
    }
}
```

Q&A — fine-tuning review *5/5 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I use ca_arp_find to look up an IP address in the ARP cache?
A: You should use ca_arp_find when you need to resolve an IPv4 address to its corresponding MAC address from the local ARP cache. This is typically done before sending an Ethernet frame to ensure the correct destination MAC address is used. It is not used for dynamic ARP resolution; it only checks pre-populated cache entries.

Code example conf:0.90 **Q:** Can you show a minimal example of how to use ca_arp_find in C with caOS types?
A: ca_ipv4_t ip = {192, 168, 1, 10}; mac_t mac; bool found = ca_arp_find(ip, &mac); if (found) { // Use mac here }

Parameters conf:0.90 **Q:** What is the significance of the mac_out parameter in ca_arp_find, and what happens if it's NULL?
A: The mac_out parameter is a pointer to a buffer where the MAC address will be copied if the IP is found in the ARP cache. If mac_out is NULL, the function still returns true if the IP is found, but no MAC address is copied. This is a valid usage, but the caller must be aware that no result will be returned.

Return conf:0.95 **Q:** What does it mean when ca_arp_find returns false?
A: When ca_arp_find returns false, it means the specified IPv4 address was not found in the ARP cache. This does not indicate an error in the function itself, but rather that

no mapping exists for the given IP at that time. It is up to the caller to handle this case, possibly by initiating an ARP request.

Error/Edge case conf:0.85 **Q:** What are common mistakes when calling ca_arp_find?

A: Common mistakes include passing a NULL pointer for mac_out when expecting to retrieve the MAC address, which leads to no data being copied despite a successful lookup. Another mistake is calling ca_arp_find from an ISR, which is not allowed due to potential mutex deadlock issues. Also, calling the function before the ARP cache has been initialized or populated may lead to unexpected behavior.

---

ca_arp_flush

Header: `caos/net/inc/arp_service.h:111`
Source: `caos/net/src/arp_service.c:405:410`
GUARD: `EN_ARP_SERVICE`

```
void ca_arp_flush(void)
```

Clears all entries in the ARP cache by marking them as invalid.

Ritorna:
This function returns void and does not provide a status code.

Note:

- This function is thread-safe because it uses a mutex (s_cache_mtx) to protect the shared ARP cache array during the clearing process. It is a blocking function, meaning if another thread currently holds the mutex, the calling thread will be suspended until the mutex is released. You must NOT call this function from an Interrupt Service Routine (ISR) because blocking operations are strictly forbidden in ISRs and will cause system instability or hard faults. A common mistake is assuming this function resets the hardware network interface; it only clears the software-level mapping table, so the device will need to re-resolve IP-to-MAC addresses via ARP requests after this call.

Uso:

- This function is typically used during network stack resets, interface re-initialization, or when a user explicitly requests a cache clear via a CLI command to resolve connectivity issues caused by stale ARP entries. It is often paired with ca_arp_dump() to verify the state of the cache before and after the flush. In a typical lifecycle, it is called when the network link status changes or when the system detects a potential IP address conflict that requires forcing a fresh ARP discovery cycle.

Esempio:

```
/* Example: Clearing the ARP cache via a CLI command handler */
void handle_network_command(const char *cmd) {
    if (ca_strncmp(cmd, "flush", 5) == 0) {
        /* Clear the cache to force re-discovery of all network neighbors */
        ca_arp_flush();

        /* Notify the user that the operation is complete */
        CLI_PUT_N("ARP cache has been cleared successfully.");
    }
}
```

Q&A — fine-tuning review *2/2 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I call ca_arp_flush() and what is the intended use case for it?
A: You should call ca_arp_flush() when you need to invalidate all entries in the ARP cache, typically to force a renewal of network connections. This function is useful in scenarios where network topology changes or when you want to ensure that all MAC addresses are re-learned. It is a blocking function that acquires a mutex before clearing the cache, so it should be used carefully in high-frequency contexts to avoid temporary communication slowdowns.

Code example conf:0.90 **Q:** Can you provide a minimal C code example using ca_arp_flush() with caOS types?
A: void example_arp_flush(void) { ca_arp_flush(); }

`ca_arp_resolve`

Header: `caos/net/inc/arp_service.h:87`
Source: `caos/net/src/arp_service.c:294:331`
GUARD: `EN_ARP_SERVICE`

```
1 bool ca_arp_resolve(ca_ipv4_t ip, ca_mac_t *mac_out, u32 timeout_ms)
```

Resolves an IPv4 address to a MAC address using the ARP protocol with a blocking timeout.

Parametri:

Nome	Tipo	Descrizione
`ip`	`ca_ipv4_t`	The target IPv4 address to resolve.
`mac_out`	`ca_mac_t *`	Pointer to a buffer where the resolved MAC address will be stored. Must be a valid memory address.
`timeout_ms`	`u32`	Maximum time in milliseconds to wait for the ARP response. Must be greater than the internal ARP retry cycle to avoid race conditions.

Ritorna:
Returns true if the MAC address was successfully resolved and copied to mac_out. Returns false if the resolution failed, the timeout expired, or if no internal ARP slots were available.

Note:

- This function is blocking; it will suspend the calling thread until the ARP process completes or the timeout is reached. It is NOT safe to call from an ISR (Interrupt Service Routine) because it uses mutexes and semaphores that require thread context. A common mistake is providing a timeout that is too short; if the timeout is shorter than the time required for the ARP request/retry cycle, the function will return false even if the device is reachable. Ensure the system network stack is initialized before calling this, as it relies on an internal ARP task to process the request queue.

Uso:

- This function is typically used when preparing to send an Ethernet frame to a specific IP address. It is often paired with routing functions, such as checking a routing table to find the next hop IP, and then calling this function to resolve that IP into a hardware MAC address. In a typical application flow, you would call this before attempting to transmit data, ensuring the destination hardware address is known. If it returns false, the application should handle the failure by dropping the packet or notifying the user, as communication with that IP is currently impossible.

Esempio:

```
ca_ipv4_t target_ip = {{192, 168, 1, 10}}; ca_mac_t target_mac; // Buffer for
    result

// Attempt to resolve with a 2000ms timeout
// We use a generous timeout to allow for ARP retries
if (ca_arp_resolve(target_ip, &target_mac, 2000U)) {
    // Success: target_mac is now populated
    // Proceed to send Ethernet frame using target_mac
} else {
    // Failure: log error or inform the user that the host is unreachable
    // Do not attempt to send data using an uninitialized ca_mac_t
}
```

Q&A — fine-tuning review *6/6 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I use ca_arp_resolve to resolve an IP address to a MAC address?

A: You should use ca_arp_resolve when you need to send an Ethernet frame to a specific IPv4 address and you don't already have its corresponding MAC address. This is typically required in network protocols like IP routing or when building an Ethernet driver that needs to resolve addresses before transmission.

Code example conf:0.90 **Q:** Can you show a minimal C code example using ca_arp_resolve with caOS types?

A: ca_ipv4_t target_ip = {192, 168, 1, 10}; mac_t resolved_mac; bool success = ca_arp_resolve(target_ip, &resolved_mac, 1000); if (success) { // Use resolved_mac to send Ethernet frame }

Parameters conf:0.90 **Q:** What are the valid and invalid values for the ip parameter in ca_arp_resolve?

A: The ip parameter must be a valid ca_ipv4_t structure representing an IPv4 address. Invalid values include any structure that does not represent a valid IPv4 address, such as all zeros or an address outside the valid range. Passing an invalid IP will cause the function to return false.

Return conf:0.95 **Q:** What does it mean when ca_arp_resolve returns false?

A: ca_arp_resolve returns false when the ARP resolution fails. This can happen due to a timeout, no free ARP slots available, or an internal error during the resolution process. The MAC address buffer is not modified in this case.

Error/Edge case conf:0.90 **Q:** What are common mistakes when calling ca_arp_resolve?

A: Common mistakes include calling the function from an ISR (which is not allowed), passing a timeout value less than ARP_RETRY_N * ARP_RETRY_MS (causing premature timeouts), passing a NULL pointer for mac_out, or using an invalid IPv4 address in the ip parameter.

Behavior conf:0.95 **Q:** Is ca_arp_resolve blocking or non-blocking, and can it be called from an ISR?

A: ca_arp_resolve is a blocking function. It suspends the calling task until either the MAC address is resolved or the timeout expires. It cannot be called from an ISR because it uses blocking operations like ca_sem_timedwait, and must be called from a task context.

`ca_arp_send_garp`

Header: `caos/net/inc/arp_service.h:131`
Source: `caos/net/src/arp_service.c:437:453`
GUARD: `EN_ARP_SERVICE`

```
bool ca_arp_send_garp(void)
```

Sends a Gratuitous ARP (GARP) packet to announce the device's IP address on the network.

Ritorna:
Returns true if the GARP packet was successfully queued for transmission, false if the IP is not set, buffer allocation failed, or the packet construction failed.

Note:

- This function is non-blocking and thread-safe, as it relies on the internal network buffer management system. It is not intended to be called from an ISR because it performs memory allocation via ca_net_buf_alloc. A common beginner mistake is calling this function before the network stack is fully initialized or before the link is confirmed to be up, which will result in the function returning false or the packet being dropped by the hardware. Ensure that the local IP address has been assigned (either via static configuration or DHCP) before calling this, otherwise, the function will immediately return false.

Uso:

- This function is typically used during the network initialization sequence to announce the device's presence to other nodes on the local network segment. It is often paired with ca_net_proto_init to set up the stack and ca_eth_link_poll to ensure the physical link is active. Developers call this after the IP address is assigned to prevent IP conflicts and to update the ARP tables of other devices on the network. It is also used when a DHCP lease is renewed or when the network interface is reset to ensure the network topology remains consistent.

Esempio:

```
/* Initialize the network stack first */
ca_net_proto_init(&net_cfg);

/* Wait for the link to stabilize */
ca_os_sleep(500);
ca_eth_link_poll();

/* Announce our IP to the network */
if (ca_arp_send_garp()) {
    ca_stdout_printf_n("GARP sent successfully");
} else {
    ca_stdout_printf_n("Failed to send GARP: check IP assignment or buffer
    availability");
}
```

Q&A — fine-tuning review *5/5 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I call ca_arp_send_garp() and why is it important for network stability?
A: You should call ca_arp_send_garp() whenever the local IP address changes on the network interface. This function sends a Gratuitous ARP (GARP) packet to notify other nodes in the network about the new IP address. This ensures that the ARP tables of neighboring devices are updated correctly and prevents communication issues due to stale IP-to-MAC mappings.

Code example conf:0.90 **Q:** Can you show a minimal example of how to use ca_arp_send_garp() in a caOS application?
A: u32 ip_addr = 0xC0A80101; // 192.168.1.1 // Assume IP is configured here if (ca_arp_send_garp()) { // GARP packet initialized for sending } else { // Failed to send GARP, check IP configuration or buffer availability }

Return conf:0.95 **Q:** What does it mean when ca_arp_send_garp() returns false?
A: A return value of false indicates that the GARP packet could not be initialized for sending. This typically happens if the local IP address has not been configured yet or if

there is no available buffer to construct the packet. It's a failure condition that should be handled by checking IP setup or resource availability.

Error/Edge case conf:0.85 **Q:** What are common mistakes or edge cases when using ca_arp_send_garp()?
A: Common mistakes include calling ca_arp_send_garp() before the local IP address is properly configured, which leads to a false return. Another mistake is calling it from an ISR or a high-priority context without proper synchronization, which can lead to race conditions or system instability. Also, not ensuring sufficient network buffers are available may cause the function to fail.

Behavior conf:0.90 **Q:** Is ca_arp_send_garp() blocking or non-blocking, and is it safe to use in an ISR?
A: ca_arp_send_garp() is a non-blocking function. It does not wait for the packet to be transmitted but prepares it for sending. It is NOT safe to call from an ISR or high-priority context unless proper synchronization mechanisms are in place. It must be called from a thread context and is not thread-safe unless protected by appropriate locking.

`ca_arp_service_init`

Header: `caos/net/inc/arp_service.h:63`
Source: `caos/net/src/arp_service.c:211:229`
GUARD: `EN_ARP_SERVICE`

```
1 void ca_arp_service_init(ca_mac_t local_mac, ca_ipv4_t local_ip)
```

Initializes the ARP service internal structures, mutexes, and semaphores required for network address resolution.

Parametri:

Nome	Tipo	Descrizione
`local_mac`	`ca_mac_t`	The 6-byte hardware MAC address assigned to the device interface. Must be a valid, unique MAC address.
`local_ip`	`ca_ipv4_t`	The initial IPv4 address for the interface. Can be set to 0.0.0.0 if using DHCP to obtain an address later.

Ritorna:
void

Note:

- This function is not thread-safe and must be called exactly once during the system initialization phase, typically before the RTOS scheduler starts or before any network tasks are spawned. It performs critical setup of mutexes and semaphores; calling it while the network stack is already active will corrupt the internal state, leading to unpredictable behavior or system crashes. It is strictly forbidden to call this function from an Interrupt Service Routine (ISR) because it performs blocking-style initialization operations that are not ISR-safe. A common mistake is to call this function multiple times or after the network stack has already begun processing packets, which will reset the ARP cache and cause active connections to drop.

Uso:

- This function is the mandatory entry point for the ARP subsystem. It is typically called within the main initialization sequence, often immediately after the Ethernet hardware driver is initialized and the network interface is registered via ca_net_init. It is frequently paired with ca_arp_service_start, which enables the background processing of

ARP requests. In dynamic network environments, it is common to initialize the service with a zeroed IP address (0.0.0.0) and later update the IP configuration once a DHCP server provides a valid lease.

Esempio:

```c
/* Typical initialization sequence in ca_os_main */
void ca_os_main(void) {
    ca_mac_t my_mac = { .addr = {0x00, 0x11, 0x22, 0x33, 0x44, 0x55} };
    ca_ipv4_t my_ip = { .addr = 0x00000000 }; // Will be updated via DHCP later

    // 1. Initialize hardware and network interface
    eth_gpio_init();
    ca_net_init(ca_eth_iface_get(&eth_cfg));

    // 2. Initialize ARP service before starting network tasks
    ca_arp_service_init(my_mac, my_ip);

    // 3. Start the service and background tasks
    ca_arp_service_start();

    // 4. Proceed to spawn application tasks
    ca_os_job("net", CA_TH_LEVEL2, task_net, 0, STACK_SMALL, CA_JOB_STD,
    CA_FAULT_RESTART_THREAD);
}
```

Q&A — fine-tuning review *5/5 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I call ca_arp_service_init() in my caOS project?
A: You should call ca_arp_service_init() early in your application, before using any other ARP-related functions. It initializes the ARP cache and semaphores needed for handling ARP requests and replies. It must be called once before any ARP operations, typically during system initialization.

Code example conf:0.90 **Q:** Can you show a minimal example of how to use ca_arp_service_init() with caOS types?
A: u8 local_mac[6] = {0x00, 0x08, 0x9B, 0x00, 0x00, 0x01}; ipv4_t local_ip = 0x01020304; ca_arp_service_init(local_mac, local_ip);

Parameters conf:0.90 **Q:** What are the valid values for local_mac and local_ip in ca_arp_service_init()?
A: The local_mac must be a valid 6-byte MAC address. It cannot be NULL or invalid, as it's used to build ARP packets. The local_ip must be a valid IPv4 address. If set to 0.0.0.0, it indicates that the IP has not yet been assigned to the device.

Error/Edge case conf:0.85 **Q:** What can go wrong when calling ca_arp_service_init()?
A: If invalid parameters are passed, such as a NULL mac address or an invalid IP, the function may cause communication errors. Additionally, calling this function multiple times without resetting previous state may overwrite existing data. If the internal mutex or semaphore initialization fails, the function may not behave correctly, though it does not return an error code directly.

Behavior conf:0.90 **Q:** Is ca_arp_service_init() blocking or non-blocking, and is it safe to call from an ISR?
A: ca_arp_service_init() is a non-blocking function. It is not safe to call from an ISR, as it may attempt to use system resources like mutexes or semaphores that are not ISR-safe. It is thread-safe if called with valid parameters, but concurrent calls from multiple threads without external protection are not recommended.

ca_arp_service_start

Header: caos/net/inc/arp_service.h:69
Source: caos/net/src/arp_service.c:431:435
GUARD: EN_ARP_SERVICE

```
void ca_arp_service_start(void)
```

Initializes and launches the background ARP service task within the caOS scheduler.

Ritorna:
void

Note:

- This function is non-blocking; it simply registers a new job with the caOS scheduler and returns immediately. It is not thread-safe to call this from an ISR, as it interacts with the OS task management system. You must ensure that the ARP service has been properly initialized (e.g., via ca_arp_service_init) before calling this, otherwise the task may attempt to operate on uninitialized memory or invalid network configurations. A common beginner mistake is calling this function multiple times; doing so will attempt to spawn multiple instances of the ARP task, which will lead to unpredictable network behavior and potential system instability.

Uso:

- This function is typically called once during the system startup phase inside ca_os_main, alongside other network service starters like DHCP or UDP servers. It acts as the 'enable' switch for the ARP protocol stack, allowing the device to resolve IP addresses to MAC addresses. It is almost always preceded by a configuration step where the local IP and MAC addresses are set, ensuring the ARP service has the necessary identity to communicate on the network. Once started, the ARP service runs as a background task, handling incoming ARP requests and maintaining the ARP cache automatically.

Esempio:

```
void ca_os_main(void) {
    // 1. Configure the network identity first
    // Assuming s_mac and s_ip are defined globally
    ca_arp_service_init(s_mac, s_ip);

    // 2. Start the ARP service task
    // This registers the task with the scheduler
    ca_arp_service_start();

    // 3. Start other dependent services
    ca_udp_server_start(&srv_cfg);

    // 4. Proceed to launch other application tasks
    ca_os_job("app_task", CA_TH_LEVEL5, my_app_task, 0, STACK_SMALL, CA_JOB_STD,
     CA_FAULT_RESTART_THREAD);
}
```

Q&A — fine-tuning review *2/2 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I call ca_arp_service_start() and what is its purpose in a caOS network application?
A: You should call ca_arp_service_start() after initializing the ARP service to begin handling ARP requests and responses in the network. This function starts a task that manages ARP operations, which is essential for IP address resolution in Ethernet networks. It is non-blocking and must be called from a main task context, not from an ISR.

The function is not thread-safe and should not be called multiple times without stopping the previous task first.

Code example conf:0.85 **Q:** Can you provide a minimal C example using caOS types that demonstrates how to start the ARP service?
A: u8 result = ca_arp_service_start(); if (result != 0) { // Handle error return; } // ARP service is now running

---

`ca_arp_service_update_local_ip`

Header: `caos/net/inc/arp_service.h:101`
Source: `caos/net/src/arp_service.c:426:429`
GUARD: `EN_ARP_SERVICE`

```
void ca_arp_service_update_local_ip(ca_ipv4_t local_ip)
```

Updates the local IPv4 address used by the ARP service to resolve hardware addresses.

Parametri:

Nome	Tipo	Descrizione
`local_ip`	`ca_ipv4_t`	A structure containing the 4-byte representation of the new local IP address. Must be a valid IPv4 address; passing an uninitialized or zeroed structure may cause ARP resolution failures.

Ritorna:
void

Note:

- This function is non-blocking and executes immediately as it performs a simple memory assignment. It is thread-safe in the sense that it performs an atomic write to a static variable, but it does not use mutexes, meaning it should be called when the network configuration is stable to avoid race conditions during packet processing. It is safe to call from an ISR, though this is rarely necessary. The most common beginner mistake is calling this function before the ARP service has been initialized or while the network stack is actively processing traffic, which could lead to a momentary inconsistency in ARP replies.

Uso:

- This function is typically used during the network initialization phase or when a DHCP client receives a new IP address lease. It is part of a sequence where the application sets the local IP across multiple layers: first in the core network protocol stack, then in the UDP/TCP server modules, and finally in the ARP service to ensure that outgoing ARP requests use the correct source IP. It is usually paired with functions that configure the network interface to ensure the entire stack is synchronized with the new network identity.

Esempio:

```
ca_ipv4_t new_ip = {{192, 168, 1, 50}};

/* Update the core network stack first using internal network protocol functions */
/* ca_net_proto_set_local_ip(new_ip); */

/* Update the ARP service so it knows which IP to claim in ARP requests */
#if EN_ARP_SERVICE
    ca_arp_service_update_local_ip(new_ip);
```

```
#endif

/* Verify the change via console output */
ca_stdout_printf_n("ARP service updated to: %u.%u.%u.%u",
                   new_ip.v[0], new_ip.v[1], new_ip.v[2], new_ip.v[3]);
```

Q&A — fine-tuning review *3/3 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I call ca_arp_service_update_local_ip() and why is it important for network operations?
A: You should call ca_arp_service_update_local_ip() when you need to update or reset the local IPv4 address used by the ARP service. This function is important for maintaining correct ARP table entries and ensuring proper network communication. It can be called from any context, including ISRs, and is typically used when the local IP changes (e.g., after DHCP assignment or manual configuration).

Code example conf:0.90 **Q:** Can you provide a minimal C code example showing how to use ca_arp_service_update_local_ip() with caOS types?
A: ca_ipv4_t local_ip = 0xC0A80164; // 192.168.1.100 in network byte order ca_arp_service_update_ // To reset the IP: ca_arp_service_update_local_ip(0);

Parameters conf:0.90 **Q:** What does the local_ip parameter represent in ca_arp_service_update_local_ip(), and what are valid and invalid values?
A: The local_ip parameter represents the IPv4 address to be set as the local IP for ARP service operations. A valid value is any IPv4 address in network byte order (e.g., 0xC0A80164 for 192.168.1.100). If 0 is passed, the IP is reset. The function does not validate the IP address, so passing an invalid or malformed value may cause communication issues, but no error is returned.

`ca_arp_set`

Header: `caos/net/inc/arp_service.h:95`
Source: `caos/net/src/arp_service.c:251:288`
GUARD: `EN_ARP_SERVICE`

```
void ca_arp_set(ca_ipv4_t ip, ca_mac_t mac)
```

Updates or adds an entry in the ARP cache and notifies any tasks waiting for that specific IP address.

Parametri:

Nome	Tipo	Descrizione
`ip`	`ca_ipv4_t`	The IPv4 address structure to associate with the MAC address. Must be a valid IPv4 representation.
`mac`	`ca_mac_t`	The 6-byte MAC address structure to store in the cache.

Ritorna:
void

Note:

- This function is thread-safe as it uses a mutex to protect the internal cache array. It is a blocking operation because it acquires a mutex; therefore, it must NEVER be called from an Interrupt Service Routine (ISR), as this could lead to system deadlocks or crashes. The function implements an LRU (Least Recently Used) replacement policy: if the cache is full and the IP is not found, it overwrites the oldest entry. A common mistake is calling this

function from a high-priority interrupt context when processing incoming network packets; ensure that the network stack architecture offloads this to a task context if necessary.

Uso:

- This function is the primary mechanism for the network stack to 'learn' the mapping between IP and MAC addresses. It is typically called when an ARP reply is received or when a manual entry is added via a CLI command. It is often paired with ca_sem_post to wake up tasks that were blocked waiting for an ARP resolution to complete. In the network stack lifecycle, it is used during the packet parsing phase to ensure the ARP table remains current, allowing subsequent outgoing packets to be routed correctly without repeated ARP requests.

Esempio:

```
/* Example: Manually updating the ARP cache from a configuration task */
ipv4_t target_ip = {{192, 168, 1, 50}};
mac_t target_mac = {{0x00, 0x11, 0x22, 0x33, 0x44, 0x55}};

/* Update the cache with the new mapping */
ca_arp_set(target_ip, target_mac);

/* The function handles internal mutex locking and notifies any tasks
   waiting on this IP via semaphores automatically. */
```

Q&A — fine-tuning review *5/5 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I call ca_arp_set() in a network application?
A: You should call ca_arp_set() when you need to update or insert an entry in the ARP cache, typically after receiving an ARP reply or when you have resolved an IP address to a MAC address. It is commonly used in network protocol implementations to maintain up-to-date address resolution tables.

Code example conf:0.90 **Q:** Can you show a minimal example of how to use ca_arp_set() with caOS types?
A: u8 ip_addr[4] = {192, 168, 1, 10}; u8 mac_addr[6] = {0x00, 0x11, 0x22, 0x33, 0x44, 0x55}; ca_arp_set(ip_addr, mac_addr);

Parameters conf:0.90 **Q:** What are the valid values for the ip and mac parameters in ca_arp_set()?
A: The ip parameter must be a valid IPv4 address represented as a 4-byte array. The mac parameter must be a valid MAC address represented as a 6-byte array. Passing invalid or NULL values leads to undefined behavior.

Error/Edge case conf:0.85 **Q:** What are common mistakes or edge cases when using ca_arp_set()?
A: Common mistakes include calling ca_arp_set() with NULL or invalid parameters, which leads to undefined behavior. Additionally, calling it from an ISR is not thread-safe and may cause issues due to mutex usage. If the ARP cache is full, the function may silently ignore the operation.

Behavior conf:0.90 **Q:** Is ca_arp_set() blocking or non-blocking, and is it safe to call from an ISR?
A: ca_arp_set() is blocking if the internal mutex is already acquired by another thread, which can lead to deadlock if not handled properly. It is not safe to call from an ISR because it uses mutexes and is not ISR-safe. It is also not thread-safe if called from multiple threads without proper synchronization.

`ca_barrier_init`

Header: `caos/inc/sync.h:367`
Source: `caos/src/sync.c:838:844`

GUARD: `EN_SYNC`

```
void ca_barrier_init(ca_barrier_t *b, u32 count)
```

Initializes a synchronization barrier object that forces a specific number of threads to wait until all have reached a common point.

Parametri:

Nome	Tipo	Descrizione
`b`	`ca_barrier_t *`	Pointer to the barrier structure to be initialized. Must be allocated in memory accessible by the RTOS.
`count`	`u32`	The number of threads that must call the wait function before any are allowed to proceed. Must be greater than 0.

Ritorna:
void

Note:

- This function is non-blocking and performs the setup of internal structures like the wait queue and spinlock. It is not thread-safe if called while other threads are actively using the same barrier, so it must be called during the system initialization phase before any worker threads are spawned. It is not intended to be called from an ISR. A common beginner mistake is to initialize the barrier with a count of 0 or to re-initialize it while threads are already blocked on it, which will lead to undefined behavior or system deadlocks.

Uso:

- The barrier is typically used in parallel processing scenarios where multiple worker threads must synchronize their progress before moving to the next phase of a task. You initialize the barrier once during the system setup phase, then pass the pointer to the worker threads. It is usually paired with ca_barrier_wait that threads call to pause execution until the 'count' threshold is met. After the barrier is no longer needed, ensure no threads are still waiting on it before deallocating the memory.

Esempio:

```
ca_barrier_t bar;
#define N_WORKERS 3

void system_init(void) {
    /* Initialize the barrier for 3 workers before starting tasks */
    ca_barrier_init(&bar, N_WORKERS);

    /* Now it is safe to spawn threads that will use this barrier */
    ca_os_job("worker1", CA_TH_LEVEL2, worker_task, NULL, STACK_SMALL,
    CA_JOB_STD, CA_FAULT_ASSERT);
    ca_os_job("worker2", CA_TH_LEVEL2, worker_task, NULL, STACK_SMALL,
    CA_JOB_STD, CA_FAULT_ASSERT);
    ca_os_job("worker3", CA_TH_LEVEL2, worker_task, NULL, STACK_SMALL,
    CA_JOB_STD, CA_FAULT_ASSERT);
}

void worker_task(void *arg) {
    /* Each worker performs work and then waits for others */
    /* Call the barrier wait function to synchronize with other threads */
    ca_barrier_wait(&bar);
}
```

Q&A — fine-tuning review *3/3 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I call ca_barrier_init and what is its purpose in a multi-threaded caOS application?
A: You should call ca_barrier_init to initialize a synchronization barrier before any threads attempt to use it. The purpose of the barrier is to synchronize a fixed number of threads, ensuring they all reach the same point in execution before any of them can proceed further. This is useful for coordinating tasks in a multi-threaded environment where certain operations must complete before others begin.

Code example conf:0.90 **Q:** Can you provide a minimal C code example using ca_barrier_init with caOS types?
A: ca_barrier_t my_barrier; ca_barrier_init(&my_barrier, 3); // The barrier is now initialized to wait for 3 threads before allowing them to proceed.

Parameters conf:0.90 **Q:** What is the significance of the 'count' parameter in ca_barrier_init, and what happens if it is set to zero?
A: The 'count' parameter specifies how many threads must reach the barrier before all threads can proceed. If count is set to zero, the barrier will not function correctly because it requires at least one thread to participate in the synchronization. The parameter must be greater than zero, otherwise the behavior is undefined and may cause the barrier to never release any threads.

`ca_barrier_wait`

Header: `caos/inc/sync.h:374`
Source: `caos/src/sync.c:846:872`
GUARD: `EN_SYNC`

```
bool ca_barrier_wait(ca_barrier_t *b)
```

Synchronizes multiple threads at a specific point by blocking them until a predefined number of threads have arrived.

Parametri:

Nome	Tipo	Descrizione
`b`	`ca_barrier_t *`	Pointer to an initialized ca_barrier_t structure. Must be properly allocated and initialized via ca_barrier_init before use.

Ritorna:
Returns true only for the last thread that reaches the barrier (the one that triggers the release). Returns false for all other threads that arrive earlier and are subsequently blocked.

Note:

- This function is blocking; threads that arrive before the count is met will be suspended and removed from the CPU scheduler until the barrier is released. It is NOT safe to call this function from an Interrupt Service Routine (ISR) because it performs thread context switching and blocking operations. The function uses an internal spinlock to ensure thread safety during the increment of the arrival counter. A common beginner mistake is to assume all threads continue execution simultaneously; in reality, the threads are woken up by the scheduler, and their order of resumption depends on the scheduler's priority policy. Ensure the barrier count is correctly set during initialization, otherwise, threads may block indefinitely if the count is never reached.

Uso:

- The barrier is typically used in parallel processing scenarios where multiple worker threads must complete a specific stage of computation before moving to the next phase. The typical sequence is: initialize the barrier with a specific count using ca_barrier_init, spawn worker threads, have each worker perform its task, and then call ca_barrier_wait. The thread that receives 'true' is often designated as the 'coordinator' to perform cleanup, log progress, or signal a main control thread that the phase is complete. After the barrier is released, all threads proceed to the next block of code, effectively synchronizing the execution flow across the system.

Esempio:

```c
/* Example: Synchronizing 3 worker threads */
ca_barrier_t bar;

void worker_task(void *arg) {
    /* Perform some work */
    ca_os_sleep(50u);

    /* Wait for all 3 workers to reach this point */
    bool is_last = ca_barrier_wait(&bar);

    if (is_last) {
        /* Only the last thread executes this cleanup */
        ca_stdout_printf_n("All workers finished, proceeding to next phase.");
    }

    /* All threads continue here after the barrier is released */
    /* Proceed to next processing stage */
}
```

Q&A — fine-tuning review *6/6 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I use ca_barrier_wait() in a caOS application?
A: You should use ca_barrier_wait() when you need to synchronize multiple tasks at a specific point in your code, ensuring that all tasks reach that point before any of them proceed. This is useful for coordinating parallel execution paths, such as in multi-core or multi-threaded applications where certain operations must complete before others begin.

Code example conf:0.90 **Q:** Can you show a minimal example of how to use ca_barrier_wait() with caOS types?
A: ca_barrier_t barrier; ca_barrier_init(&barrier, 2); // Task 1 if (ca_barrier_wait(&barrier)) { // Only one task reaches here // Proceed with post-barrier logic } // Task 2 if (ca_barrier_wait(&barrier)) { // Only one task reaches here // Proceed with post-barrier logic }

Parameters conf:0.95 **Q:** What does the 'b' parameter in ca_barrier_wait() represent and what are valid values?
A: The 'b' parameter is a pointer to a pre-initialized ca_barrier_t structure. It must not be NULL and must point to a valid barrier that has been initialized with ca_barrier_init(). Passing a NULL pointer or an uninitialized barrier will result in undefined behavior or a crash.

Return conf:0.90 **Q:** What do the return values of ca_barrier_wait() indicate?
A: The function returns true if the calling task is the last one to reach the barrier, indicating that all other tasks have also arrived and synchronization is complete. It returns false for all other tasks, which will block until the last task arrives and returns true.

Error/Edge case conf:0.90 **Q:** What are common mistakes or error conditions when using ca_barrier_wait()?
A: Common errors include calling ca_barrier_wait() without first initializing the barrier

with ca_barrier_init(), passing a NULL pointer, or using an uninitialized or corrupted barrier structure. These conditions can lead to undefined behavior or system crashes.

Behavior conf:0.90 **Q:** Is ca_barrier_wait() thread-safe, ISR-safe, and blocking?

A: Yes, ca_barrier_wait() is thread-safe, using a spinlock to protect critical sections. It is also blocking for all tasks except the last one, which returns true. It is not safe to call from an ISR because it blocks and may cause deadlocks or undefined behavior.

---

ca_bkp_count

Header: `caos/drivers/inc/bkp.h:22`
Source: `caos/drivers/src/bkp.c:14:17`
GUARD: `EN_BKP`

```c
u32 ca_bkp_count(void); /* registers available on this part */
```

Returns the total number of available hardware backup registers on the current device.

Ritorna:
A u32 value representing the count of available backup registers. Returns 0 if the hardware abstraction layer is not initialized or if the device lacks backup register support.

Note:

- This function is non-blocking and thread-safe, as it typically performs a simple read of a hardware-defined constant or register. It is safe to call from an ISR (Interrupt Service Routine) because it does not involve complex OS primitives or blocking operations. The most common beginner mistake is assuming the returned count is zero-indexed; if the function returns 16, the valid register indices are 0 through 15. Always ensure the system hardware abstraction layer is initialized before relying on this value.

Uso:

- This function is used to determine the bounds for data storage in non-volatile backup registers, which persist across system resets. It is typically paired with ca_bkp_write and ca_bkp_read to implement a safe indexing strategy. Developers use it to prevent 'out-of-bounds' access errors when writing status flags or error codes that must survive a reboot. It is often called during system initialization or within an emergency callback (like a watchdog reset handler) to log diagnostic information.

Esempio:

```c
/* Example: Safely writing a status marker to the last available backup register */
#include "caos.h"

void log_system_status(u32 status_code) {
    u32 count = ca_bkp_count();

    /* Ensure we have at least one register to avoid underflow */
    if (count > 0) {
        /* Use the last register index (zero-based) */
        u32 last_idx = count - 1U;

        /* Write the status code to the hardware backup register */
        ca_bkp_write(last_idx, status_code);
    } else {
        /* Handle case where no backup registers are available */
        ca_printf("Error: No backup registers available to log status.\n");
    }
}
```

Q&A — fine-tuning review *3/3 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** When should I call ca_bkp_count and what is its primary purpose?
A: You should call ca_bkp_count during system initialization or within emergency callbacks like watchdog reset handlers. Its primary purpose is to determine the bounds for non-volatile storage in backup registers, allowing you to implement safe indexing strategies for data that must persist across system resets.

Code example conf:1.00 **Q:** How do I safely iterate through all available backup registers using caOS types?
A: You can determine the limit using ca_bkp_count and iterate using a u32 index. Example: u32 count = ca_bkp_count(); for(u32 i = 0; i < count; i++) { /* perform operations with index i */ }

Return conf:1.00 **Q:** What does the return value of ca_bkp_count represent, and what causes it to return 0?
A: The return value is a u32 representing the total count of available hardware backup registers. It returns 0 if the hardware abstraction layer is not initialized or if the device lacks backup register support. Note that the count is not zero-indexed; if it returns 16, valid indices are 0 through 15.

`ca_bkp_hw_count`

Header: `caos/drivers/inc/ca_glue_hw.h:362`
GUARD: `EN_CA_GLUE_HW`

```
extern u32 ca_bkp_hw_count(void); /* backup registers on this part */
```

Returns the total number of hardware backup registers available on the current STM32 microcontroller.

Ritorna:
An unsigned 32-bit integer representing the count of available backup registers (e.g., 10, 20, or 32 depending on the specific STM32 series).

Note:

- This function is a hardware abstraction layer (HAL) utility that provides the limit for backup register indexing. It is non-blocking, thread-safe, and safe to call from an ISR because it simply returns a constant value defined at compile-time for the specific target hardware. The most common mistake is assuming a fixed number of registers across different STM32 families; always use this function to determine the limit dynamically rather than hardcoding values like 10 or 32, which will cause out-of-bounds access on different chips.

Uso:

- This function is typically used as a boundary check before performing read or write operations on backup registers. It is usually paired with ca_bkp_read and ca_bkp_write to ensure that the index provided by the application logic does not exceed the physical hardware capacity. By using this function, your code remains portable across different STM32 series (e.g., F1, F4, H7) without requiring manual adjustments to array bounds or loop limits.

Esempio:

```
/* Example: Safely reading all available backup registers */
#include "caos.h"

```

```c
void dump_backup_registers(void) {
    u32 total_regs = ca_bkp_count();

    for (u32 i = 0; i < total_regs; i++) {
        u32 val = ca_bkp_read(i);
        /* Use ca_printf to output the register value */
        ca_printf("BKP[%lu] = 0x%08lX\n", i, val);
    }
}
```

Q&A — fine-tuning review *4/4 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** When should I call ca_bkp_hw_count in my caOS application?
A: You should call ca_bkp_hw_count as a boundary check before performing any read or write operations on backup registers. It is used to ensure that the index provided by your application logic does not exceed the physical hardware capacity, preventing out-of-bounds access.

Code example conf:0.90 **Q:** How do I safely write to a backup register using ca_bkp_hw_count?
A: You should use the function to validate the index before calling the write function: u32 index = 5; if (index < ca_bkp_hw_count()) { ca_bkp_write(index, 0xDEADBEEF); }

Return conf:1.00 **Q:** What does the return value of ca_bkp_hw_count represent and can it fail?
A: The function returns an unsigned 32-bit integer representing the total number of hardware backup registers available on the specific STM32 microcontroller. It cannot fail, as it is a non-blocking, thread-safe utility that returns a constant value defined at compile-time for the target hardware.

HW differences conf:1.00 **Q:** How does the number of backup registers differ across STM32 families in caOS?
A: The number of registers is hardware-dependent: STM32F1xx provides 10 registers, STM32F4xx provides 20 registers, and the F7xx, H5xx, H7xx, and U5xx families provide 32 registers. You must use ca_bkp_hw_count to determine the limit dynamically rather than hardcoding values to ensure portability.

`ca_bkp_hw_read`

Header: `caos/drivers/inc/ca_glue_hw.h:363`
GUARD: `EN_CA_GLUE_HW`

```c
extern u32 ca_bkp_hw_read(u32 idx); /* backup register idx (in range,
    checked by the caller) */
```

Reads a 32-bit value directly from a hardware backup register at the specified index.

Parametri:

Nome	Tipo	Descrizione
`idx`	`u32`	The index of the backup register to read. Must be less than the value returned by ca_bkp_count().

Ritorna:
The 32-bit value stored in the specified hardware backup register. If the index is out of bounds, the behavior is undefined (typically resulting in a memory access fault).

Note:

- This function is a low-level hardware abstraction layer (HAL) call and does not perform any bounds checking; it is intended to be called by the higher-level ca_bkp_read() function. It

is non-blocking and executes in constant time, making it safe to call from ISRs or critical sections. Because it accesses hardware registers directly, ensure the backup domain is properly initialized and powered before use. A common beginner mistake is calling this function directly instead of using the safer ca_bkp_read() wrapper, which handles index validation.

Uso:

- This function is used to retrieve persistent data stored in the STM32 backup domain, which survives system resets. It is typically used in a sequence where the application first checks the number of available registers using ca_bkp_count(), then reads specific indices to restore system state or configuration flags after a reboot. It is paired with ca_bkp_write() for data persistence and is often used during the system initialization phase to check for 'magic numbers' that indicate if the device has been previously configured.

Esempio:

```c
/* Example: Restoring a system configuration flag from backup memory */
#include "caos.h"

void restore_system_state(void) {
    u32 magic_idx = 0U;
    u32 expected_magic = 0xDEADBEEFU;

    /* Always check bounds using the safe wrapper before accessing hardware */
    if (magic_idx < ca_bkp_count()) {
        u32 current_val = ca_bkp_read(magic_idx);

        if (current_val == expected_magic) {
            /* Configuration is valid, proceed with system boot */
        } else {
            /* Backup data is invalid or uninitialized, perform factory reset */
            ca_bkp_write(magic_idx, expected_magic);
        }
    }
}
```

Q&A — fine-tuning review *5/5 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** When should I use ca_bkp_hw_read() instead of ca_bkp_read()?
A: You should generally avoid calling ca_bkp_hw_read() directly. It is a low-level function intended for use by the higher-level ca_bkp_read() wrapper. The wrapper provides necessary index validation, whereas ca_bkp_hw_read() performs no bounds checking and can lead to undefined behavior or memory access faults if the index is invalid.

Code example conf:0.90 **Q:** How do I safely read a value from a backup register using caOS types?
A: To safely read a value, first verify the index is within bounds using ca_bkp_count(), then perform the read: u32 idx = 0; if (idx < ca_bkp_count()) { u32 val = ca_bkp_hw_read(idx); }

Parameters conf:1.00 **Q:** What are the constraints for the 'idx' parameter in ca_bkp_hw_read?
A: The 'idx' parameter represents the index of the hardware backup register. It must be a u32 value strictly less than the total number of available registers returned by ca_bkp_count(). Providing an index outside this range results in undefined behavior, typically a memory access fault.

Return conf:1.00 **Q:** What does the return value of ca_bkp_hw_read represent, and what happens if it fails?
A: The function returns the 32-bit value stored in the specified hardware backup register. If the function 'fails' due to an out-of-bounds index, the behavior is undefined, which

typically manifests as a memory access fault rather than a specific error return code.

HW differences conf:1.00 **Q:** Are there differences in how ca_bkp_hw_read is implemented across STM32 families like F1xx, F4xx, or H7xx?
A: Based on the provided implementation files for F1xx, F4xx, F7xx, H5xx, H7xx, and U5xx, the implementation is identical across all these families. Each version simply returns the value at the index provided by the bkp_regs() accessor function.

---

ca_bkp_hw_sram_open

Header: `caos/drivers/inc/ca_glue_hw.h:377`
GUARD: `EN_CA_GLUE_HW`

```
extern u8 *ca_bkp_hw_sram_open(void); /* clock + backup domain write
    access on, returns the base */
```

Initializes the hardware backup SRAM domain and returns a pointer to its base address.

Ritorna:
Returns a pointer (u8 *) to the start of the Backup SRAM memory region on success. Returns NULL if the hardware platform does not support Backup SRAM (e.g., F1xx series).

Note:

- This function is not thread-safe and should be called during system initialization before any tasks attempt to access the backup memory. It performs low-level register manipulation to enable the power and clock domains required for the SRAM to persist data across resets. It is not intended to be called from an ISR, as it performs hardware configuration that should be done in a controlled, synchronous manner. A common mistake is assuming the memory is ready immediately after power-on without calling this function; failing to call it will result in a hard fault or bus error when attempting to access the memory address.

Uso:

- This function is typically used by the internal backup driver to lazily initialize the memory region upon the first request. It is paired with ca_bkp_sram_read and ca_bkp_sram_write to manage persistent data. Developers should check the return value against NULL before dereferencing the pointer to ensure the current hardware target actually supports this feature.

Esempio:

```
u8 *sram_ptr;

/* Check if the hardware supports backup SRAM before attempting to use it */
if (ca_bkp_sram_size() > 0U) {
    /* Initialize the hardware domain and get the base address */
    sram_ptr = ca_bkp_hw_sram_open();

    if (sram_ptr != NULL) {
        /* Perform a write operation to the first byte of backup SRAM */
        sram_ptr[0] = 0xAA;
    } else {
        /* Handle error: hardware initialization failed */
    }
} else {
    /* Backup SRAM is not available on this device */
}
```

Q&A — fine-tuning review *4/4 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** When should I call ca_bkp_hw_sram_open in my caOS application?
A: You should call it during system initialization, before any tasks attempt to access the backup memory. It is not thread-safe and should not be called from an ISR. It is required to enable the power and clock domains for the SRAM to persist data across resets; failing to call it will result in a hard fault or bus error.

Code example conf:1.00 **Q:** Provide a minimal C example for initializing the backup SRAM.
A: u8 *bkp_ptr = ca_bkp_hw_sram_open(); if (bkp_ptr != NULL) { /* Safe to access backup memory */ }

Return conf:1.00 **Q:** What does the return value of ca_bkp_hw_sram_open indicate?
A: It returns a pointer (u8 *) to the base address of the Backup SRAM on success. It returns NULL if the hardware platform does not support Backup SRAM, such as on the F1xx series. You must check for NULL before dereferencing the pointer to avoid errors.

HW differences conf:1.00 **Q:** How does the implementation of ca_bkp_hw_sram_open differ across STM32 families?
A: Implementations vary by register access and peripheral clocking. F4xx and F7xx use RCC_APB1ENR_PWREN and RCC_AHB1ENR_BKPSRAMEN, while H5xx uses RCC_AHB1ENR_BKPRAMEN and H7xx uses RCC_AHB4ENR_BKPRAMEN. U5xx requires enabling RCC_AHB3ENR_PWREN. Additionally, the base address returned differs, such as D3_BKPSRAM_BASE for H7xx versus BKPSRAM_BASE for others. F1xx does not support this and returns NULL.

`ca_bkp_hw_sram_retain`

Header: `caos/drivers/inc/ca_glue_hw.h:378`
GUARD: `EN_CA_GLUE_HW`

```
1 extern bool ca_bkp_hw_sram_retain(void); /* backup regulator on (Standby
     /VBAT retention), false if not possible */
```

Enables the backup regulator to maintain power to the Backup SRAM during low-power modes (Standby/VBAT).

Ritorna:
Returns true if the backup regulator is successfully enabled and ready, false if the hardware does not support it or if the regulator failed to stabilize within the timeout period.

Note:

- This function is non-blocking in some architectures (U5) but uses a busy-wait loop in others (H7, H5, F4, F7) to verify the regulator's readiness. It is generally thread-safe as it performs atomic register modifications, but it should be called during system initialization before entering low-power states. A common beginner mistake is assuming that calling this function automatically preserves all RAM; it only preserves the specific Backup SRAM region. If the hardware does not support Backup SRAM (like F1), this function will always return false, so always check the return value before assuming data persistence.

Uso:

- This function is typically used during the system power-up sequence or before entering a deep sleep mode where the main power rail is cut. It is usually paired with ca_bkp_sram_write to store critical data before sleep and ca_bkp_sram_read to retrieve it after a wake-up event. Developers should call this early in the application lifecycle to ensure the hardware state is prepared for potential power loss scenarios.

Esempio:

```c
/* Check if Backup SRAM is available and enable retention */
if (ca_bkp_sram_retain()) {
    /* Backup regulator is active, safe to write critical data */
    uint32_t data = 0xDEADBEEF;
    ca_bkp_sram_write(0, (uint8_t *)&data, sizeof(data));
} else {
    /* Retention not possible, handle error or log warning */
    ca_printf("Backup SRAM retention failed!\n");
}
```

Q&A — fine-tuning review *4/4 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** When should I call ca_bkp_hw_sram_retain in my caOS application?
A: You should call this function during the system initialization sequence, ideally before entering low-power modes like Standby or VBAT. It is intended to prepare the hardware to maintain power to the Backup SRAM, and it is typically paired with ca_bkp_sram_write and ca_bkp_sram_read to manage critical data persistence across power cycles.

Code example conf:1.00 **Q:** Provide a minimal example of how to initialize Backup SRAM retention in caOS.
A: void init_backup_storage(void) { if (ca_bkp_hw_sram_retain()) { /* Backup SRAM is ready for use */ } else { /* Handle failure or lack of hardware support */ } }

Return conf:1.00 **Q:** What does the boolean return value of ca_bkp_hw_sram_retain indicate?
A: A return value of true indicates the backup regulator is successfully enabled and ready. A return value of false indicates that the hardware does not support Backup SRAM (e.g., F1 series), the regulator failed to stabilize within the timeout period, or the initialization failed.

HW differences conf:1.00 **Q:** How does the implementation of ca_bkp_hw_sram_retain differ across STM32 families?
A: Implementations vary significantly: F1 returns false as it lacks support. F4 and F7 use the PWR->CSR/CSR1 registers with a busy-wait loop. H5 and H7 use PWR->BDCR/CR2 registers and check ready flags (BRRDY/BRRDH). The U5 implementation is non-blocking, checks the LDO status via PWR->SVMSR, and does not use a ready flag.

`ca_bkp_hw_sram_size`

Header: `caos/drivers/inc/ca_glue_hw.h:376`
GUARD: `EN_CA_GLUE_HW`

```c
extern u32 ca_bkp_hw_sram_size(void); /* backup SRAM bytes, 0 = none */
```

Returns the total size in bytes of the hardware-specific Backup SRAM available on the current MCU.

Ritorna:
Returns a u32 representing the size in bytes. A return value of 0 indicates that the specific MCU model does not have Backup SRAM hardware support.

Note:

- This function is a hardware abstraction layer (HAL) utility that provides compile-time or platform-specific information about the available non-volatile memory region. It is non-blocking, thread-safe, and safe to call from an ISR because it simply returns a constant value defined by the hardware configuration. The most common mistake is assuming that all STM32 variants have the same amount of Backup SRAM; always check the return value

before attempting to allocate or access memory buffers to avoid out-of-bounds access or null pointer dereferences.

Uso:

- This function is typically used during the initialization phase of a driver or a persistent data storage module to determine if the Backup SRAM is available for use. It is often paired with memory management functions to verify if the system can support persistent data retention across resets. Developers use this to dynamically size buffers or to decide whether to fallback to other storage mechanisms like internal Flash or external EEPROM if the returned size is 0.

Esempio:

```c
/* Check if Backup SRAM is available before initializing a persistent storage buffer */
u32 bkp_size = ca_bkp_hw_sram_size();

if (bkp_size > 0U) {
    /* Backup SRAM is present, proceed to use it for critical data */
    /* ca_bkp_sram_write(offset, data, length); */
} else {
    /* No Backup SRAM available, log an error or use alternative storage */
    ca_printf("Warning: No Backup SRAM detected on this hardware.\n");
}
```

Q&A — fine-tuning review *4/4 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** When should I call ca_bkp_hw_sram_size in my caOS application?
A: You should call this function during the initialization phase of a driver or persistent data storage module. It is used to determine if Backup SRAM is available so you can decide whether to use it for data retention across resets or to fallback to other storage mechanisms like internal Flash or external EEPROM if the returned size is 0.

Code example conf:1.00 **Q:** How do I check for Backup SRAM availability and store a value in C?
A: You should check the return value before accessing memory. Example: u32 size = ca_bkp_hw_sram_size(); if (size > 0) { /* Proceed with memory operations */ } else { /* Fallback to alternative storage */ }

Return conf:1.00 **Q:** What does a return value of 0 from ca_bkp_hw_sram_size signify?
A: A return value of 0 indicates that the specific MCU model does not have Backup SRAM hardware support. It does not indicate an error, but rather a lack of hardware capability for that specific platform.

HW differences conf:1.00 **Q:** How does the Backup SRAM capacity vary across different STM32 families in caOS?
A: Capacity varies by family: F1xx has 0 bytes, F4xx, F7xx, and H7xx provide 4096 bytes, U5xx provides 2048 bytes, and H5xx returns a value defined by the BKPSRAM_SIZE constant. Memory locations also differ, such as 0x40024000 for F4xx/F7xx versus 0x38800000 for H7xx.

`ca_bkp_hw_write`

Header: `caos/drivers/inc/ca_glue_hw.h:364`
GUARD: `EN_CA_GLUE_HW`

```c
extern void ca_bkp_hw_write(u32 idx, u32 value); /* unlocks the backup domain (DBP) and writes register idx */
```

Unlocks the hardware backup domain and writes a value to a specific backup register index.

Parametri:

Nome	Tipo	Descrizione
`idx`	`u32`	The index of the backup register to write. Must be within the valid range defined by the hardware (check ca_bkp_count()).
`value`	`u32`	The 32-bit data value to be stored in the register.

Ritorna:
void

Note:

- This function is a low-level hardware access routine. It performs a 'write-unlock' sequence on the Power Control (PWR) register to allow modification of the backup domain, which is protected by default to prevent accidental corruption. It is not thread-safe; if multiple tasks attempt to write to backup registers simultaneously, you must wrap this call in a mutex or scheduler lock. It is generally safe to call from an ISR, but be aware that it performs a direct register write which is blocking in terms of CPU cycles. The most common mistake is passing an index that exceeds the hardware's available register count, which can lead to memory corruption or hard faults.

Uso:

- This function is typically used to persist small amounts of configuration data or state across system resets. It is usually paired with ca_bkp_read() to retrieve the data after a reboot. In a typical application, you would first verify the index using ca_bkp_count(), then use ca_bkp_write() to save your data. Because the backup domain is battery-backed, this is the standard way to store 'non-volatile' flags that must survive a power cycle without writing to the main Flash memory.

Esempio:

```c
/* Example: Saving a system state flag to the first backup register */
#include "caos.h"

void save_system_state(u32 state_flag) {
    /* Check if the index is valid before writing */
    if (ca_bkp_count() > 0) {
        /* Lock the scheduler to ensure atomic access to the backup domain */
        ca_os_sched_lock();

        /* Write the state to the first backup register (index 0) */
        ca_bkp_write(0, state_flag);

        ca_os_sched_unlock();
    } else {
        /* Handle error: no backup registers available */
    }
}
```

Q&A — fine-tuning review *4/4 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** When should I use ca_bkp_hw_write in my caOS application?
A: You should use ca_bkp_hw_write to persist small amounts of configuration data or state that must survive a system reset. Since the backup domain is battery-backed, this function provides a way to store non-volatile flags without writing to main Flash memory. It is typically paired with ca_bkp_read() to retrieve the data after a reboot.

Code example conf:1.00 **Q:** How do I safely write a value to a backup register using caOS types?
A: You should first verify the index using ca_bkp_count() to avoid memory corruption, then call ca_bkp_hw_write. Example: u32 idx = 0; u32 val = 0xDEADBEEF; if (idx < ca_bkp_count()) { ca_bkp_hw_write(idx, val); }

Parameters conf:1.00 **Q:** What are the constraints on the 'idx' parameter for ca_bkp_hw_write?
A: The 'idx' parameter represents the index of the backup register to write. It must be within the valid range defined by the hardware, which you should verify by calling ca_bkp_count() before the write operation. Passing an index that exceeds the available register count can lead to memory corruption or hard faults.

HW differences conf:1.00 **Q:** How does the implementation of ca_bkp_hw_write differ across STM32 families?
A: The function handles the backup domain protection (DBP) differently based on the MCU family's Power Control (PWR) register structure. For example, f1xx and f4xx use PWR->CR, f7xx and h7xx use PWR->CR1, h5xx uses PWR->DBPCR, and u5xx uses PWR->DBPR to unlock the backup domain.

`ca_bkp_read`

Header: `caos/drivers/inc/bkp.h:23`
Source: `caos/drivers/src/bkp.c:19:22`
GUARD: `EN_BKP`

```
u32 ca_bkp_read(u32 idx); /* 0 when idx is out of range */
```

Reads a 32-bit value from the non-volatile backup register at the specified index.

Parametri:

Nome	Tipo	Descrizione
`idx`	`u32`	The index of the backup register to read. Must be less than the value returned by ca_bkp_count().

Ritorna:
The 32-bit value stored in the backup register if the index is valid; returns 0 if the index is out of range.

Note:

- This function is non-blocking and thread-safe, as it performs a direct hardware read. It is safe to call from an ISR because it does not involve complex OS primitives or waiting. The most common mistake is assuming that a return value of 0 means the register contains 0; since 0 is also returned for invalid indices, you must ensure your index is always within the bounds provided by ca_bkp_count() before calling this function.

Uso:

- This function is typically used to persist system state across device resets, such as boot flags, error codes, or trial status markers. It is often paired with ca_bkp_write() to update the state and ca_bkp_count() to verify index bounds. In a typical lifecycle, you read the value during system initialization to decide the boot path, and update it during runtime when a state transition occurs (e.g., confirming a firmware update).

Esempio:

```
/* Check if the system is in a trial state using a backup register */
#include "caos.h"

```

```c
void check_system_status(void) {
    u32 count = ca_bkp_count();
    u32 target_idx = 0; /* Assume index 0 is used for system state */

    if (target_idx < count) {
        u32 state = ca_bkp_read(target_idx);
        if (state == 0xDEADBEEF) {
            /* Perform recovery or specific logic for this state */
        }
    } else {
        /* Handle error: index out of range */
    }
}
```

Q&A — fine-tuning review *4/4 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** When should I use ca_bkp_read in my application lifecycle?
A: You should use ca_bkp_read during system initialization to retrieve persisted state, such as boot flags or error codes, to determine the appropriate boot path. It is also used during runtime to check state markers, often in conjunction with ca_bkp_write to update system status across device resets.

Code example conf:1.00 **Q:** How do I safely read a backup register value using caOS types?
A: You must verify the index against ca_bkp_count() before reading. Example: u32 idx = 0; if (idx < ca_bkp_count()) { u32 val = ca_bkp_read(idx); }

Parameters conf:1.00 **Q:** What are the constraints for the idx parameter in ca_bkp_read?
A: The idx parameter represents the index of the non-volatile backup register. It must be a u32 value that is strictly less than the total count returned by ca_bkp_count(). Providing an index outside this range is considered invalid.

Return conf:1.00 **Q:** Does a return value of 0 always indicate that the backup register contains the value 0?
A: No. A return value of 0 is ambiguous because it is returned both when the register contains 0 and when the provided index is out of range. You must validate the index using ca_bkp_count() before calling the function to ensure the returned 0 is a valid data value.

`ca_bkp_sram_read`

Header: `caos/drivers/inc/bkp.h:32`
Source: `caos/drivers/src/bkp.c:45:53`
GUARD: `EN_BKP`

```c
bool ca_bkp_sram_read(u32 off, void *dst, u32 len); /* false when out of range */
```

Reads a block of data from the Backup SRAM memory area.

Parametri:

Nome	Tipo	Descrizione
`off`	`u32`	The starting byte offset within the Backup SRAM to begin reading from.
`dst`	`void *`	Pointer to the destination buffer where the read data will be stored. Must not be NULL.
`len`	`u32`	The number of bytes to read. The sum of off and len must not exceed the total Backup SRAM size.

Ritorna:
Returns true if the read operation was successful. Returns false if the parameters are invalid (e.g., NULL pointer, out-of-bounds access, or if the requested length exceeds the available memory).

Note:

- This function is a synchronous, blocking operation that copies data directly from the hardware Backup SRAM to your provided buffer. It is thread-safe in the sense that it performs a simple memory copy, but it does not implement internal locking for concurrent access to the same memory region; if multiple tasks access the same Backup SRAM offsets, you must manage synchronization externally. It is safe to call from an ISR, as it performs no blocking OS primitives, but keep in mind that large read operations will consume CPU cycles and increase interrupt latency. The most common mistake is failing to check the return value, which leads to processing uninitialized or garbage data when the read fails due to an out-of-bounds offset.

Uso:

- This function is typically used to retrieve persistent configuration data, state flags, or diagnostic logs that must survive a system reset. It is often paired with ca_bkp_sram_size to determine the memory boundaries before reading, and ca_bkp_sram_write to save data. In a typical lifecycle, you would call ca_bkp_sram_size to verify the hardware is available, then perform one or more ca_bkp_sram_read calls to restore the application state during the system initialization phase.

Esempio:

```c
/* Example: Restoring a configuration structure from Backup SRAM */
#include "caos.h"

void restore_system_state(void) {
    u32 bkp_size = ca_bkp_sram_size();
    u32 config_buffer[16]; /* Buffer for 64 bytes of data */

    /* Check if Backup SRAM is available and large enough */
    if (bkp_size >= sizeof(config_buffer)) {
        /* Attempt to read the configuration from the start of Backup SRAM */
        if (ca_bkp_sram_read(0U, config_buffer, sizeof(config_buffer))) {
            /* Data read successfully, proceed to use config_buffer */
        } else {
            /* Handle read failure: log error or use default values */
            ca_printf_n("Failed to read Backup SRAM");
        }
    }
}
```

Q&A — fine-tuning review *4/4 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** When should I use ca_bkp_sram_read in my application?
A: You should use this function during system initialization to restore persistent configuration data, state flags, or diagnostic logs that need to survive a system reset. It is typically used after calling ca_bkp_sram_size to verify memory boundaries.

Code example conf:1.00 **Q:** How do I read 16 bytes from the start of the Backup SRAM into a buffer?
A: u8 buffer[16]; if (ca_bkp_sram_read(0, buffer, 16)) { /* Data read successfully */ }

Parameters conf:1.00 **Q:** What are the constraints on the 'off' and 'len' parameters?
A: The 'off' parameter is the starting byte offset. The sum of 'off' and 'len' must not exceed the total Backup SRAM size. If this sum exceeds the available memory, the function will return false.

Return conf:1.00 **Q:** What causes ca_bkp_sram_read to return false?
A: The function returns false if the parameters are invalid, which includes passing a NULL pointer for the destination, requesting an out-of-bounds offset, or requesting a length that exceeds the available Backup SRAM capacity.

---

ca_bkp_sram_retain

Header: caos/drivers/inc/bkp.h:34
Source: caos/drivers/src/bkp.c:85:89
GUARD: EN_BKP

```
bool ca_bkp_sram_retain(void); /* backup regulator on: kept in Standby/
    VBAT */
```

Checks if the Backup SRAM is configured to retain data during low-power Standby or VBAT modes.

Ritorna:
Returns true if the hardware supports and is configured for SRAM retention, false if the regulator is off or the hardware does not support this feature.

Note:

- This function is non-blocking and thread-safe. It does not require complex initialization, but it relies on the underlying hardware support for Backup SRAM. It is safe to call from any context, including ISRs, as it performs a simple register check. A common mistake is assuming that data in Backup SRAM is automatically preserved across all power states; you must verify this function returns true to ensure your data will survive a transition to Standby mode.

Uso:

- Use this function when your application needs to store critical state information that must persist even if the main power supply is removed or the device enters a deep sleep state. It is typically used in a diagnostic or initialization sequence, often paired with ca_bkp_sram_size to determine how much space is available, and ca_bkp_sram_write or ca_bkp_sram_read to manage the actual data storage.

Esempio:

```
if (ca_bkp_sram_retain()) {
    /* Backup SRAM is active, safe to store critical system state */
    unsigned char data[] = "SYSTEM_OK";
    ca_bkp_sram_write(0, data, 9);
} else {
    /* Retention not available, log error or use alternative storage */
    ca_printf_n("Warning: Backup SRAM retention is disabled!");
}
```

Q&A — fine-tuning review *3/3 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** When should I use ca_bkp_sram_retain in my application?
A: You should call this function when your application needs to store critical state information that must persist through deep sleep or power loss. It is typically used during initialization or diagnostic sequences to verify that the hardware is correctly configured to keep data in Backup SRAM before attempting to store persistent data.

Code example conf:1.00 **Q:** How do I check if Backup SRAM is ready for data storage using caOS types?

A: You can verify the retention status using a simple conditional check as shown: if (ca_bkp_sram_retain()) { /* Safe to proceed with data operations */ } else { /* Handle error: retention not supported or regulator off */ }

Return conf:1.00 **Q:** What do the return values of ca_bkp_sram_retain indicate?

A: The function returns true if the hardware supports and is configured for Backup SRAM retention, ensuring data will survive a transition to Standby mode. It returns false if the backup regulator is off or if the specific hardware does not support the retention feature.

---

ca_bkp_sram_size

Header: `caos/drivers/inc/bkp.h:31`
Source: `caos/drivers/src/bkp.c:40:43`
GUARD: `EN_BKP`

```
u32 ca_bkp_sram_size(void); /* bytes, 0 = none */
```

Returns the total size in bytes of the available Backup SRAM memory.

Ritorna:
Returns a u32 representing the size in bytes. Returns 0 if no Backup SRAM is available or if the hardware feature is disabled.

Note:

- This function is thread-safe and non-blocking. It can be safely called from an ISR, as it simply queries the hardware configuration or a cached size value. The most common mistake is assuming that a non-zero return value guarantees that the memory is currently writable; you must still ensure the Backup SRAM domain is powered and unlocked (via hardware-specific registers) before attempting write operations. It does not perform any initialization itself, but it is often used as a guard condition before calling ca_bkp_sram_write.

Uso:

- Use this function to determine the memory capacity before performing bulk operations like saving system state, logs, or calibration data to the Backup SRAM. It is typically used in a sequence: first check the size with ca_bkp_sram_size, then allocate a buffer if necessary, and finally use ca_bkp_sram_write to commit data. It is essential for writing robust code that adapts to different STM32 variants, some of which may have different Backup SRAM sizes or none at all.

Esempio:

```
#include "caos.h"

void save_system_state(u32 *data, u32 len) {
    /* Check if Backup SRAM is available on this hardware */
    u32 bkp_size = ca_bkp_sram_size();

    if (bkp_size >= len) {
        /* Write data to Backup SRAM if it fits */
        (void)ca_bkp_sram_write(0U, data, len);
    } else {
        /* Handle case where memory is too small or unavailable */
        ca_printf("Backup SRAM too small or missing: %u bytes available\n",
    bkp_size);
    }
}
```

Q&A — fine-tuning review *3/3 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** When should I call ca_bkp_sram_size and why is it important for my application?
A: You should call ca_bkp_sram_size before performing bulk operations like saving system state, logs, or calibration data. It is important because it allows your code to adapt to different STM32 variants that may have varying Backup SRAM sizes or none at all, serving as a guard condition before attempting write operations.

Code example conf:1.00 **Q:** How do I check if Backup SRAM is available before proceeding with a write operation?
A: You can use the following pattern: u32 size = ca_bkp_sram_size(); if (size > 0) { /* Proceed with memory operations */ }

Return conf:1.00 **Q:** What does the return value of ca_bkp_sram_size indicate, and does a non-zero value guarantee I can write to the memory?
A: The function returns a u32 representing the size in bytes. A return value of 0 indicates that no Backup SRAM is available or the feature is disabled. A non-zero return value does not guarantee the memory is writable; you must still ensure the Backup SRAM domain is powered and unlocked via hardware-specific registers before attempting writes.

`ca_bkp_sram_write`

Header: `caos/drivers/inc/bkp.h:33`
Source: `caos/drivers/src/bkp.c:59:83`
GUARD: `EN_BKP`

```
1 bool ca_bkp_sram_write(u32 off, const void *src, u32 len)
```

Writes data to the Backup SRAM, handling word-alignment and ECC requirements automatically.

Parametri:

Nome	Tipo	Descrizione
`off`	`u32`	The byte offset within the Backup SRAM where writing begins. Must be within [0, ca_bkp_sram_size() - 1].
`src`	`const void *`	Pointer to the source buffer containing the data to be written. Must not be NULL.
`len`	`u32`	Number of bytes to write. The sum of off + len must not exceed the total Backup SRAM size.

Ritorna:
Returns true if the write operation was successful. Returns false if parameters are invalid (e.g., NULL pointer, out-of-bounds access, or if Backup SRAM is unavailable).

Note:

- This function is not thread-safe and should not be called from an ISR. It performs a read-modify-write operation to handle unaligned access, which is critical because Backup SRAM on many STM32 chips (like the H7) uses ECC logic that requires full 32-bit word writes to maintain data integrity. If you attempt to write partial words without this function, a system reset could corrupt the surrounding bytes in the same word. The function is blocking, meaning it will not return until the entire memory copy is complete.

Uso:

- Use this function when you need to persist small amounts of configuration data or state across system resets. It is typically used in conjunction with ca_bkp_sram_size() to verify memory bounds before writing. In a typical lifecycle, you would initialize your data, call ca_bkp_sram_write() to save it, and later use ca_bkp_sram_read() to retrieve it after a reboot. Always ensure the offset and length are validated against the total size to prevent memory corruption.

Esempio:

```c
/* Example: Saving a system configuration structure to Backup SRAM */
#include "caos.h"

void save_system_state(const u32 *data, u32 count) {
    u32 size = ca_bkp_sram_size();
    u32 bytes_to_write = count * sizeof(u32);

    /* Ensure we do not overflow the Backup SRAM */
    if (size >= bytes_to_write) {
        /* Write the data starting at offset 0 */
        if (!ca_bkp_sram_write(0, data, bytes_to_write)) {
            /* Handle write error: log or trigger recovery */
        }
    }
}
```

Q&A — fine-tuning review *6/6 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** When should I use ca_bkp_sram_write in my caOS application?
A: You should use this function when you need to persist small amounts of configuration data or system state across system resets. It is typically used to save data that you intend to retrieve later using ca_bkp_sram_read after a reboot.

Code example conf:0.90 **Q:** Provide a minimal C example of how to write a u32 value to the Backup SRAM.
A: u32 my_data = 0xDEADBEEF; if (ca_bkp_sram_write(0, &my_data, sizeof(u32))) { /* Success */ }

Parameters conf:1.00 **Q:** What are the constraints on the 'off' and 'len' parameters for ca_bkp_sram_write?
A: The 'off' parameter must be within [0, ca_bkp_sram_size() - 1]. The sum of 'off' and 'len' must not exceed the total Backup SRAM size to prevent out-of-bounds access.

Return conf:1.00 **Q:** What does a return value of false indicate when calling ca_bkp_sram_write?
A: A return value of false indicates that the operation failed. This occurs if parameters are invalid, such as passing a NULL pointer, requesting an out-of-bounds memory access, or if the Backup SRAM is currently unavailable.

Error/Edge case conf:1.00 **Q:** What happens if I try to write partial words to the Backup SRAM without using this function?
A: On STM32 chips like the H7, the Backup SRAM uses ECC logic that requires full 32-bit word writes. Attempting to write partial words without this function could lead to a system reset or corruption of surrounding bytes within the same word.

Behavior conf:1.00 **Q:** Is ca_bkp_sram_write safe to call from an interrupt service routine (ISR) or in a multi-threaded environment?
A: No, this function is not thread-safe and must not be called from an ISR. Additionally, it is a blocking function, meaning it will not return until the entire memory copy operation is complete.

---

ca_bkp_write

Header: caos/drivers/inc/bkp.h:24
Source: caos/drivers/src/bkp.c:24:29
GUARD: EN_BKP

```
bool ca_bkp_write(u32 idx, u32 value); /* false when idx is out of range
    */
```

Writes a 32-bit value to a specific index in the non-volatile backup memory.

Parametri:

Nome	Tipo	Descrizione
idx	u32	The index of the backup register to write. Must be less than the value returned by ca_bkp_count().
value	u32	The 32-bit data to store in the backup register.

Ritorna:
Returns true if the write operation was successful (index was valid). Returns false if the index is out of range, indicating the write was ignored.

Note:

- This function is a wrapper for hardware-specific backup registers, which are typically preserved across system resets. It is not thread-safe by default, so ensure that multiple tasks do not attempt to write to the same index simultaneously without external synchronization. It is generally safe to call from an ISR if the underlying hardware access is atomic, but you should verify your specific hardware implementation. The most common mistake is passing an index that exceeds the hardware limit, which silently fails; always validate your index or use constants defined by the system.

Uso:

- This function is primarily used to persist system state, boot flags, or diagnostic markers that must survive a reboot. It is often paired with ca_bkp_read() to retrieve the stored value upon system startup. In bootloader scenarios, it is used to confirm successful image updates or to signal state transitions between the application and the bootloader. Always check the return value if your application logic depends on the persistence of the data.

Esempio:

```
/* Example: Persisting a boot state marker */
#define MY_BKP_INDEX 0U

void update_system_status(u32 new_status) {
    /* Attempt to write the status to backup memory */
    if (ca_bkp_write(MY_BKP_INDEX, new_status)) {
        /* Success: status is now in non-volatile storage */
    } else {
        /* Error: index was invalid, handle accordingly */
        ca_printf("Failed to write to backup register!\n");
    }
}

/* Example: Reading back the value later */
void check_status(void) {
    u32 status = ca_bkp_read(MY_BKP_INDEX);
    ca_printf("Current status: %u\n", status);
}
```

Q&A — fine-tuning review *4/4 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** When should I use ca_bkp_write in my caOS application?
A: You should use ca_bkp_write to persist system state, boot flags, or diagnostic markers that need to survive a system reset. It is commonly used to signal state transitions between an application and a bootloader or to confirm successful image updates.

Code example conf:1.00 **Q:** How do I write a value to the first backup register using caOS types?
A: u32 index = 0; u32 data = 0xDEADBEEF; if (ca_bkp_write(index, data)) { /* Success */ }

Parameters conf:1.00 **Q:** What are the constraints for the idx parameter in ca_bkp_write?
A: The idx parameter represents the index of the backup register to write. It must be a u32 value that is strictly less than the value returned by ca_bkp_count(). Passing an index that exceeds this hardware limit will cause the function to fail silently.

Return conf:1.00 **Q:** What does the boolean return value of ca_bkp_write indicate?
A: The function returns true if the write operation was successful, meaning the provided index was valid. It returns false if the index is out of range, which indicates that the write operation was ignored.

`ca_block_alloc`

Header: `caos/inc/block_pool.h:64`
Source: `caos/src/block_pool.c:39:50`
GUARD: `EN_BLOCK_POOL`

```
1 void *ca_block_alloc(ca_block_pool_t *bp)
```

Allocates a fixed-size memory block from a pre-allocated memory pool.

Parametri:

Nome	Tipo	Descrizione
`bp`	`ca_block_pool_t *`	Pointer to the initialized block pool structure. Must not be NULL and must have been initialized via the appropriate pool creation function.

Ritorna:
Returns a pointer to the allocated memory block if successful, or NULL if the pool is empty (no free blocks available).

Note:

- This function is thread-safe because it uses a spinlock to protect the free list during the allocation process. It is safe to call from an Interrupt Service Routine (ISR) because it uses a spinlock with interrupt disabling (ca_spinlock_lock_irq). The function is non-blocking; it returns immediately with NULL if no memory is available, rather than waiting for a block to be freed. A common beginner mistake is failing to check if the returned pointer is NULL before dereferencing it, which will cause a hard fault or undefined behavior if the pool is exhausted.

Uso:

- This function is used in scenarios where dynamic memory allocation (like standard malloc) is discouraged due to fragmentation or non-deterministic timing. It is typically used in a producer-consumer pattern where a task requests a block, fills it with data, and then passes it to a queue or another task. It is usually paired with ca_block_free, which returns the block to the pool once the task is finished with it. Before calling this, the pool must be fully initialized to ensure the free list pointers are correctly linked.

Esempio:

```
/* Assuming block_pool is globally initialized */
DataBlock *blk = (DataBlock *)ca_block_alloc(&block_pool);

if (blk != NULL) {
    /* Successfully allocated, safe to write data */
    blk->seq = 123;
    /* ... process data ... */

    /* Always return the block to the pool when done */
    /* ca_block_free(&block_pool, blk); */
} else {
    /* Handle allocation failure: log error or retry later */
    handle_alloc_error();
}
```

Q&A — fine-tuning review *5/5 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I use ca_block_alloc() in a real-time embedded system?
A: You should use ca_block_alloc() when you need to dynamically allocate fixed-size memory blocks from a pre-defined pool, typically for managing data structures or buffers in a deterministic way. It's ideal for scenarios where you want to avoid heap fragmentation and ensure predictable allocation times.

Code example conf:0.90 **Q:** Can you show a minimal example of how to use ca_block_alloc() with caOS types?
A: ca_block_pool_t pool; ca_block_pool_init(&pool, 10, sizeof(u32)); void *block = ca_block_alloc(&pool); if (block != NULL) { *(u32*)block = 0x12345678; }

Parameters conf:0.95 **Q:** What is the significance of the ca_block_pool_t pointer passed to ca_block_alloc()?
A: The ca_block_pool_t pointer must point to a valid and properly initialized pool. It defines the memory pool from which the block is allocated. If the pool is not initialized using ca_block_pool_init(), the behavior is undefined and may cause crashes or corruption.

Return conf:0.90 **Q:** What does it mean if ca_block_alloc() returns NULL?
A: If ca_block_alloc() returns NULL, it means the pool is exhausted and no more blocks are available for allocation. This is not an error condition per se, but the caller must handle this case, for example by retrying later or using a fallback mechanism.

Error/Edge case conf:0.90 **Q:** What are common mistakes when using ca_block_alloc()?
A: Common mistakes include not checking the return value for NULL, which can lead to accessing unallocated memory; and calling ca_block_free() on memory not allocated via ca_block_alloc(). Additionally, calling ca_block_alloc() without prior initialization of the pool leads to undefined behavior.

`ca_block_free`

Header: `caos/inc/block_pool.h:70`
Source: `caos/src/block_pool.c:52:64`
GUARD: `EN_BLOCK_POOL`

```
void ca_block_free(ca_block_pool_t *bp, void *ptr)
```

Returns a previously allocated memory block back to the specified block pool for future reuse.

Parametri:

Nome	Tipo	Descrizione
bp	ca_block_pool_t *	Pointer to the initialized block pool structure. Must not be NULL.
ptr	void *	Pointer to the memory block to be freed. If NULL, the function safely returns without action.

Ritorna:
This function returns void; it does not provide a status code because it is designed to always succeed as long as the pointer belongs to the pool.

Note:

- This function is thread-safe because it uses a spinlock to protect the internal free list from concurrent access by multiple tasks or interrupts. It is safe to call from an ISR because it uses the 'irq' variant of the spinlock, which disables local interrupts to prevent deadlocks. A common beginner mistake is passing a pointer that was not originally allocated from this specific pool, which will corrupt the free list and cause the system to crash or behave unpredictably during the next allocation. Always ensure the block pool has been properly initialized before calling this function, as using an uninitialized pool will lead to a hard fault.

Uso:

- This function is used to recycle memory blocks once a task has finished processing data, preventing memory leaks in long-running embedded applications. It is typically paired with a block allocation function (like ca_block_alloc) in a cycle: allocate a block, fill it with data, send it to a queue for processing, and then call ca_block_free once the consumer task is done with the data. It is also used as a fallback mechanism when a message queue is full, allowing the producer to release the memory back to the pool instead of losing the block.

Esempio:

```c
/* Assuming block_pool is initialized and blk is a pointer to a block */
void process_data(void *blk) {
    if (blk == NULL) return;

    /* Perform operations on the block */
    // ... data processing logic ...

    /* Return the block to the pool so it can be reused by other tasks */
    ca_block_free(&block_pool, blk);
}
```

Q&A — fine-tuning review *5/5 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I call ca_block_free and why is it important for memory management in caOS?
A: You should call ca_block_free when you are done using a memory block that was previously allocated from a ca_block_pool_t. It is important because it returns the block to the pool's free list, making it available for future allocations. This ensures efficient reuse of memory and prevents memory leaks in a bare-metal environment where manual memory management is required.

Code example conf:0.90 **Q:** Can you provide a minimal C example using ca_block_free with caOS types?
A: ca_block_pool_t pool; void *block = ca_block_alloc(&pool, 32); if (block != NULL) { // Use the block ca_block_free(&pool, block); }

Parameters conf:0.90 **Q:** What is the significance of the 'bp' parameter in ca_block_free, and what happens if it's invalid?
A: The 'bp' parameter is a pointer to the ca_block_pool_t from which the memory block was originally allocated. It must be a valid and initialized pool structure. If it is invalid or uninitialized, calling ca_block_free will likely cause a crash because the function relies on the pool's internal structures to manage the free list.

Return conf:0.95 **Q:** Does ca_block_free return any value, and what does it mean if it does not fail?
A: ca_block_free does not return any value. It is a void function. It cannot fail in the traditional sense, but it may silently ignore invalid inputs such as a NULL pointer. The function is designed to be robust and will not crash even if given invalid parameters, though incorrect usage can still lead to memory corruption.

Error/Edge case conf:0.85 **Q:** What are common mistakes or edge cases when using ca_block_free that could lead to memory corruption?
A: Common mistakes include calling ca_block_free with a pointer that was not allocated from the specified pool, or calling it with a pointer that has been modified after allocation. Additionally, calling ca_block_free with a NULL pointer is safe but does nothing. Using the same block pointer more than once or freeing memory allocated by malloc or another system will corrupt the free list and lead to unpredictable behavior.

`ca_block_pool_free_count`

Header: `caos/inc/block_pool.h:75`
Source: `caos/src/block_pool.c:66:68`
GUARD: `EN_BLOCK_POOL`

```
1 u32 ca_block_pool_free_count(ca_block_pool_t *bp)
```

Returns the current number of available (free) memory blocks in a specific block pool.

Parametri:

Nome	Tipo	Descrizione
`bp`	`ca_block_pool_t *`	A pointer to the initialized block pool structure. Must not be NULL.

Ritorna:
Returns an unsigned 32-bit integer representing the count of currently free blocks. If the pool is empty, it returns 0.

Note:

- This function is non-blocking and executes in constant time, making it safe to call from both tasks and Interrupt Service Routines (ISRs). It is thread-safe in the sense that it performs a simple read of a variable, but note that the value returned is a 'snapshot'—it may change immediately after the function returns if another task allocates or frees a block. A common mistake is assuming this value remains constant for subsequent logic; always re-read the count if you need to make decisions based on the current availability of memory. Ensure the block pool pointer is valid and initialized before calling, as passing a NULL or uninitialized pointer will cause a hard fault.

Uso:

- This function is primarily used for system monitoring, diagnostics, and debugging purposes rather than for flow control. It is typically paired with 'ca_block_pool_total' to calculate the percentage of memory usage or to log system health statistics to a console or telemetry

interface. Developers use it in background tasks or periodic reporting threads to detect memory exhaustion trends before they lead to critical allocation failures in time-sensitive tasks.

Esempio:

```c
/* Example: Monitoring block pool health */
#include "caos.h"

void monitor_task(void *arg) {
    while (1) {
        /* Get current status of the pool */
        u32 free_blocks = ca_block_pool_free_count(&block_pool);
        u32 total_blocks = ca_block_pool_total(&block_pool);

        /* Log status if memory is running low */
        if (free_blocks < 5) {
            ca_stdout_printf_n("Warning: Low memory! Free: %u/%u", free_blocks,
    total_blocks);
        }

        /* Wait before next check */
        ca_os_sleep(1000);
    }
}
```

Q&A — fine-tuning review *4/4 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should a developer call ca_block_pool_free_count() and why is it useful?
A: A developer should call ca_block_pool_free_count() to monitor memory usage in a block pool, which is useful for debugging and ensuring sufficient free memory is available. It returns the number of free blocks in the pool, allowing developers to track memory consumption and prevent potential memory exhaustion issues.

Code example conf:0.90 **Q:** Can you provide a minimal C example using ca_block_pool_free_count() with caOS types?
A: ca_block_pool_t my_pool; ca_status_t status = ca_block_pool_create(&my_pool, 10, sizeof(u32)); if (status == CA_SUCCESS) { u32 free_count = ca_block_pool_free_count(&my_po // Use free_count for monitoring or debugging }

Parameters conf:0.95 **Q:** What does the 'bp' parameter represent in ca_block_pool_free_count() and what are valid/invalid values?
A: The 'bp' parameter is a pointer to a ca_block_pool_t structure that must be valid and properly initialized. If passed a NULL pointer or a pointer to an uninitialized pool, the behavior is undefined and will likely cause a crash. Only a valid, initialized ca_block_pool_t pointer should be passed.

Return conf:0.90 **Q:** What does ca_block_pool_free_count() return and what causes failures in its execution?
A: The function returns a u32 representing the number of free blocks in the pool. It does not return error codes; failures occur only due to invalid input parameters like NULL pointer or uninitialized pool, which cause undefined behavior and potential crashes. The function itself is not designed to signal errors.

`ca_block_pool_init`

Header: `caos/inc/block_pool.h:58`
Source: `caos/src/block_pool.c:16:37`
GUARD: `EN_BLOCK_POOL`

```
void ca_block_pool_init(ca_block_pool_t *bp, void *buf, u32 buf_size,
    u32 block_size)
```

Initializes a memory pool to manage fixed-size memory blocks for efficient, deterministic allocation.

Parametri:

Nome	Tipo	Descrizione
bp	ca_block_pool_t *	Pointer to the block pool control structure. Must be allocated in static memory or global scope.
buf	void *	Pointer to the raw memory buffer used for the pool. Must be aligned to 4 bytes for optimal performance.
buf_size	u32	Total size of the buffer in bytes. Determines the maximum number of blocks available.
block_size	u32	Size of each individual block. If smaller than 4 bytes, it is automatically padded to 4 bytes.

Ritorna:
void. This function does not return a status code; it assumes valid pointers are provided.

Note:

- This function is non-blocking and thread-safe as it initializes the internal spinlock. It is safe to call from an ISR, provided the buffer memory is already accessible. The function performs 'in-place' initialization, meaning it writes pointers into the provided buffer to link free blocks together; therefore, the buffer must not be used by other parts of the application before this initialization is complete. A common mistake is providing a buffer that is too small to hold even one block, or failing to ensure the buffer is properly aligned, which can lead to hard faults on some ARM Cortex-M architectures.

Uso:

- This function is typically called during the system startup phase or within a task initialization routine before any memory allocation requests are made. It is the mandatory first step in the lifecycle of a block pool, followed by calls to ca_block_alloc and ca_block_free. It is often paired with static buffer definitions to ensure memory is reserved at compile-time. Once initialized, the pool is ready to be used by other tasks to safely manage fixed-size data structures without the fragmentation risks associated with standard heap allocators.

Esempio:

```
/* Define a structure and a static buffer for the pool */
typedef struct { u32 id; u32 value; } DataBlock;
static u8 pool_buf[128];
static ca_block_pool_t my_pool;

void system_init(void) {
    /* Initialize the pool with the buffer and block size */
    ca_block_pool_init(&my_pool, pool_buf, sizeof(pool_buf), sizeof(DataBlock));

    /* Now the pool is ready for use with other caOS functions */
    /* void *ptr = ca_block_alloc(&my_pool); */
    /* if (ptr != NULL) { ca_block_free(&my_pool, ptr); } */
}
```

Q&A — fine-tuning review *6/6 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I use ca_block_pool_init() in a caOS project?
A: You should call ca_block_pool_init() when you need to set up a fixed-size memory pool for efficient allocation and deallocation of blocks of memory. This is useful for managing resources like task stacks, message buffers, or any scenario where you repeatedly allocate and free fixed-size objects.

Code example conf:0.90 **Q:** Can you show a minimal example of how to use ca_block_pool_init() with caOS types?
A: ca_block_pool_t pool; static u8 buffer[1024]; ca_block_pool_init(&pool, buffer, 1024, 32);

Parameters conf:0.85 **Q:** What are the valid ranges for block_size and buf_size in ca_block_pool_init()?
A: The block_size must be greater than or equal to sizeof(void*) and must be aligned to 4-byte boundaries. The buf_size must be at least as large as block_size and should be sufficient to hold multiple blocks of block_size.

Return conf:0.90 **Q:** Does ca_block_pool_init() return any value, and what does it indicate?
A: The function does not return any value. It initializes the ca_block_pool_t structure in-place and prepares the memory pool for use. Failures are not indicated through return values but may manifest as incorrect behavior if parameters are invalid.

Error/Edge case conf:0.80 **Q:** What are common mistakes or edge cases when calling ca_block_pool_init()?
A: Common mistakes include passing an unaligned buffer, using a block_size smaller than sizeof(void*), or providing a buf_size that is too small to accommodate even one block. Additionally, calling this function from an ISR or without proper alignment can lead to undefined behavior.

Behavior conf:0.90 **Q:** Is ca_block_pool_init() thread-safe or ISR-safe, and does it block?
A: The function is blocking and not inherently thread-safe unless an external lock is used. It is also not safe to call from an ISR, as it is designed for use in task contexts where it can safely manage memory without interruption.

`ca_block_pool_total`

Header: `caos/inc/block_pool.h:80`
Source: `caos/src/block_pool.c:70:72`
GUARD: `EN_BLOCK_POOL`

```
u32 ca_block_pool_total(ca_block_pool_t *bp)
```

Returns the total number of memory blocks available in a specific block pool.

Parametri:

Nome	Tipo	Descrizione
`bp`	`ca_block_pool_t *`	A pointer to the initialized block pool structure. Must not be NULL; passing a NULL pointer will cause a hard fault or undefined behavior.

Ritorna:
Returns a u32 value representing the total capacity of the pool (the number of blocks defined at creation time). This value is constant after the pool is initialized.

Note:

- This function is non-blocking and executes in constant time, making it extremely lightweight. It is thread-safe because it only performs a read operation on a structure member that does not change after initialization. It is safe to call from an Interrupt Service Routine (ISR) or any task context. The most common mistake is passing an uninitialized or NULL pointer to the function, which will lead to a memory access violation. Ensure the block pool has been successfully created before calling this function.

Uso:

- This function is primarily used for system monitoring, diagnostics, and telemetry. It is typically paired with ca_block_pool_free_count to calculate the percentage of memory usage or to detect potential memory leaks in the application. Developers use it inside logging tasks or status reporting loops to provide visibility into the system's resource consumption. It is usually called after the system initialization phase, once the block pool has been allocated and is ready for use.

Esempio:

```c
/* Assuming block_pool is a global or accessible ca_block_pool_t instance */
caBlockPool block_pool;

void monitor_task(void *p) {
    while (1) {
        /* Get total capacity and current free blocks */
        u32 total = ca_block_pool_total(&block_pool);
        u32 free = ca_block_pool_free_count(&block_pool);

        /* Calculate usage percentage */
        u32 used = total - free;
        ca_stdout_printf_n("Pool Usage: %u/%u blocks", used, total);

        /* Wait before next update */
        ca_os_sleep(1000);
    }
}
```

Q&A — fine-tuning review *4/4 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I call ca_block_pool_total, and what is its purpose in memory monitoring?
A: You should call ca_block_pool_total to monitor the total number of blocks available in a block pool, which helps in assessing memory utilization. It is useful for debugging memory leaks or ensuring sufficient memory is available for allocation. The function is non-blocking and returns immediately, making it suitable for real-time systems.

Code example conf:0.90 **Q:** Can you provide a minimal C example using ca_block_pool_total with caOS types?
A: ca_block_pool_t my_pool; ca_status status = ca_block_pool_create(&my_pool, 10, sizeof(u32)); if (status == CA_SUCCESS) { u32 total_blocks = ca_block_pool_total(&my_pool); // Use total_blocks for monitoring }

Parameters conf:0.95 **Q:** What does the 'bp' parameter represent, and what happens if it is NULL or invalid?
A: The 'bp' parameter is a pointer to a valid and initialized ca_block_pool_t structure. If bp is NULL or points to an uninitialized structure, the behavior is undefined and may cause a crash. It is essential to ensure the pool is properly initialized before calling this function.

Return conf:0.90 **Q:** What does ca_block_pool_total return, and what causes it to fail?
A: ca_block_pool_total returns a u32 representing the total number of blocks in the block pool. It does not have failure modes in itself; however, calling it with a NULL or invalid pointer results in undefined behavior, which may lead to a crash or incorrect data.

`ca_boot_confirm`

Header: `caos/inc/boot_image.h:80`
Source: `caos/src/boot_image.c:60:66`

GUARD: `EN_BOOT_IMAGE`

```
void ca_boot_confirm(void)
```

Marks the current firmware image as successfully booted and stable in the bootloader's configuration.

Ritorna:
This function returns void and does not provide a status code.

Note:

- This function is used to finalize a 'trial' boot process. If the system is not currently in a trial state (checked via ca_boot_is_trial), the function returns immediately without doing anything. It is not thread-safe in the sense that it should only be called once the application has verified its own health (e.g., network connectivity, sensor initialization). It is not intended to be called from an ISR. The most common mistake is calling this too early, before the application has actually verified that it can perform its primary tasks, which could lead to 'bricking' the device if the new firmware is faulty but marked as confirmed.

Uso:

- This function is typically used in the main application loop or an initialization task after the system has successfully performed a self-test. It is usually paired with ca_boot_is_trial to ensure the confirmation logic only runs when a new update is being tested. Once ca_boot_confirm is called, the bootloader will consider this image as the 'golden' image and will not attempt to revert to the previous version on the next power cycle.

Esempio:

```
/* Check if we are running in a trial mode after an update */
if (ca_boot_is_trial()) {
    /* Perform critical system health checks */
    bool system_healthy = true; /* Logic to verify hardware/network */

    if (system_healthy) {
        /* Confirm the image so the bootloader keeps it permanently */
        ca_boot_confirm();
        ca_printf("Firmware confirmed successfully.\n");
    } else {
        /* If unhealthy, we do not confirm. On next reboot, the bootloader
           will detect the lack of confirmation and revert to the old image. */
        ca_printf("System unhealthy, not confirming image.\n");
    }
}
```

Q&A — fine-tuning review *2/2 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** When is the appropriate time to call ca_boot_confirm in my application?
A: You should call ca_boot_confirm only after the application has verified its own health, such as confirming network connectivity or successful sensor initialization. It is typically called in the main application loop or an initialization task after a successful self-test. Calling it too early before verifying primary tasks can lead to 'bricking' the device if the firmware is faulty.

Code example conf:0.90 **Q:** How do I implement a check to confirm the firmware update using caOS types?
A: You should check the trial status before confirming the boot. Example: if (ca_boot_is_trial()) { /* Perform self-test logic here */ ca_boot_confirm(); }

ca_boot_image_slot

Header: caos/inc/boot_image.h:72
Source: caos/src/boot_image.c:18:26
GUARD: EN_BOOT_IMAGE

```
char ca_boot_image_slot(void)
```

Returns the identifier ('A' or 'B') of the memory slot from which the current application is executing.

Ritorna:
'A' if running from slot A, 'B' if running from slot B, or 0 if the execution context does not match a known boot slot.

Note:

- This function is non-blocking and thread-safe as it performs a simple read of the SCB->VTOR register. It is safe to call from an ISR because it does not involve any OS primitives, locks, or complex logic. The function relies on the bootloader correctly setting the Vector Table Offset Register (VTOR) before jumping to the application. If the application is started via a debugger or a non-standard bootloader that does not configure VTOR as expected, this function will return 0, which may cause logic errors in applications that assume they are always running from a valid slot.

Uso:

- This function is typically used during application initialization to determine the current execution context, allowing the firmware to distinguish between slot A and slot B. It is frequently paired with ca_boot_is_trial to verify if the current image is a 'trial' version or a confirmed production image. Developers use it to dynamically locate headers, verify versioning, or decide which backup registers to read for state management.

Esempio:

```
void check_my_slot(void) {
    char slot = ca_boot_image_slot();
    if (slot == 'A') {
        ca_printf("Running from Slot A\n");
    } else if (slot == 'B') {
        ca_printf("Running from Slot B\n");
    } else {
        ca_printf("Unknown execution slot!\n");
        return;
    }

    // Check if this is a trial image using the slot identifier
    if (ca_boot_is_trial()) {
        ca_printf("This is a trial image in slot %c\n", slot);
    }
}
```

Q&A — fine-tuning review *3/3 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** When should I call ca_boot_image_slot in my application?
A: You should call it during application initialization. It is used to determine the current execution context, allowing the firmware to distinguish between slot A and slot B, which helps in dynamically locating headers, verifying versioning, or managing state via backup registers.

Code example conf:1.00 **Q:** How do I implement a check for the current boot slot using caOS types?
A: You can store the result in a u8 variable as shown: u8 slot = ca_boot_image_slot(); if (slot == 'A') { /* Logic for slot A */ } else if (slot == 'B') { /* Logic for slot B */ }.

Return conf:1.00 **Q:** What does it mean if ca_boot_image_slot returns 0?
A: A return value of 0 indicates that the execution context does not match a known boot slot. This typically happens if the application is started via a debugger or a non-standard bootloader that fails to correctly configure the SCB->VTOR register before jumping to the application.

`ca_boot_image_start`

Header: `caos/inc/boot_image.h:78`
Source: `caos/src/boot_image.c:50:58`
GUARD: `EN_BOOT_IMAGE`

```
void ca_boot_image_start(void)
```

Initializes the watchdog and starts a background task to monitor system health during trial mode.

Ritorna:
This function returns void and does not provide a status code.

Note:

- This function is intended to be called during the system startup sequence. It checks if the device is in 'trial' mode; if so, it initializes the Independent Watchdog (IWDG) and spawns a background thread to periodically feed it. It is not thread-safe in the sense that it should only be called once during initialization, typically within ca_os_main. A common mistake is calling this function multiple times, which could lead to multiple watchdog-feeding threads competing for resources or re-initializing hardware peripherals incorrectly.

Uso:

- This function is used in the early stages of the application lifecycle, specifically inside ca_os_main, to ensure the system remains responsive during trial periods. It is typically paired with other service startup functions like ca_arp_service_start or ca_dhcp_service_start. By spawning a dedicated job, it ensures that even if the main application logic hangs, the watchdog is serviced, preventing an unwanted system reset while the trial logic is active.

Esempio:

```
void ca_os_main(void) {
    /* Initialize system watchdog and trial monitoring */
    ca_boot_image_start();

    /* Start network services */
    ca_arp_service_start();
    ca_dhcp_service_start();

    /* Start main application task */
    if (ca_os_job("app", CA_TH_LEVEL3, task_app, NULL, STACK_MEDIUM, CA_JOB_STD,
     CA_FAULT_RESTART_THREAD) == 0) {
        /* Handle error: job creation failed */
    }

    /* Enter the OS scheduler */
    ca_os_run();
```

```
}
```

Q&A — fine-tuning review *2/2 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** When should I call ca_boot_image_start and what is its primary purpose?
A: You should call ca_boot_image_start during the early system startup sequence, specifically within ca_os_main. Its purpose is to initialize the Independent Watchdog (IWDG) and spawn a background thread to feed it if the device is in 'trial' mode, ensuring the system remains responsive even if the main application logic hangs.

Code example conf:0.95 **Q:** How do I correctly implement ca_boot_image_start in my ca_os_main function?
A: It should be called once during initialization. Example: void ca_os_main(void) { ca_boot_image_start(); /* Other service startups like ca_arp_service_start() */ }

`ca_boot_is_trial`

Header: `caos/inc/boot_image.h:74`
Source: `caos/src/boot_image.c:28:34`
GUARD: `EN_BOOT_IMAGE`

```
bool ca_boot_is_trial(void)
```

Checks if the current firmware is running in a temporary 'trial' state, typically after an update.

Ritorna:
Returns true (1) if the system is currently running in a trial mode (waiting for confirmation), and false (0) otherwise.

Note:

- This function is thread-safe and reads from the system's backup registers to determine the boot state. It is non-blocking and can be safely called from any task or ISR. The function relies on the bootloader having correctly set the magic numbers in the backup registers during the boot process. A common mistake is to assume that a 'false' return means the firmware is invalid; it simply means the system is not in a trial state (it is either fully confirmed or not using the trial mechanism).

Uso:

- This function is primarily used by the application to decide whether to initialize safety mechanisms like the Independent Watchdog (IWDG). In a typical workflow, the application calls ca_boot_is_trial() at startup; if true, it initializes the watchdog and starts a feeder task. If the application fails to call ca_boot_confirm() before the watchdog expires, the system will reset, allowing the bootloader to revert to the previous stable firmware slot. It is often paired with ca_boot_image_start() to manage the transition from the bootloader to the main application.

Esempio:

```
void app_init_check(void) {
    /* Check if we are in a trial period after an update */
    if (ca_boot_is_trial()) {
        /* Initialize watchdog to ensure we confirm the update */
        if (ca_wdt_init(5000, 1, 0)) {
            ca_wdt_enable();
        }
        /* Log the status to the system console */
```

```
        ca_printf_n("System running in TRIAL mode. Confirm update soon.");
    } else {
        ca_printf_n("System running in NORMAL mode.");
    }
}
```

Q&A — fine-tuning review *3/3 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** When should I call ca_boot_is_trial() and what is its primary purpose in my application?
A: You should call ca_boot_is_trial() at application startup. Its primary purpose is to determine if the system is in a temporary 'trial' state after an update. If it returns true, you should initialize safety mechanisms like the Independent Watchdog (IWDG) and start a feeder task to ensure the system can revert to a stable firmware slot if the application fails to confirm the boot.

Code example conf:0.90 **Q:** Provide a minimal C example showing how to check the trial state and conditionally initialize the watchdog.
A: bool is_trial = ca_boot_is_trial(); if (is_trial) { iwdg_init(); iwdg_start_feeder(); }

Return conf:1.00 **Q:** What do the return values of ca_boot_is_trial() signify, and does a false return indicate a firmware error?
A: A return of true (1) indicates the system is in a trial mode waiting for confirmation. A return of false (0) means the system is not in a trial state; it does not imply the firmware is invalid, only that the system is either fully confirmed or not utilizing the trial mechanism. The function reads this state from the system's backup registers.

`ca_boot_receive_update`

Header: `caos/inc/boot_image.h:87`
Source: `caos/src/boot_image.c:120:143`
GUARD: `EN_BOOT_IMAGE`

```
bool ca_boot_receive_update(ca_mac_t local_mac, u32 wait_ms)
```

Downloads a firmware update via TFTP into the inactive flash slot and triggers a system reset to apply it.

Parametri:

Nome	Tipo	Descrizione
`local_mac`	`ca_mac_t`	The MAC address to assign to the TFTP service for receiving the update.
`wait_ms`	`u32`	Timeout in milliseconds to wait for the TFTP transfer to complete. Use CA_WAIT_FOREVER to block indefinitely.

Ritorna:
Returns true if the update was successfully received, verified, and the boot request was queued. Returns false if the device is in a trial state, the TFTP transfer failed, the image header is invalid, or the boot request could not be initiated.

Note:

- This function is a blocking call that manages the entire lifecycle of a firmware update, including network reception and flash writing. It is not thread-safe and must be called from a task context, never from an ISR. Before calling this, ensure the system is not in an unconfirmed trial state, as the function will explicitly refuse to overwrite the current image.

A common mistake is calling this function without sufficient free flash space or while the network stack is not yet initialized, which will cause the underlying TFTP service to fail immediately.

Uso:

- This function is typically used in a dedicated background task responsible for system maintenance or remote updates. It is often paired with a loop that checks for updates periodically. Once the function returns true, the system will automatically reset into the bootloader to finalize the installation. It is the high-level entry point for the 'A/B' slot update mechanism, abstracting the complexity of TFTP, flash memory management, and bootloader communication.

Esempio:

```c
/* Example: Background task to handle remote firmware updates */
void update_task(void *pvParameters) {
    ca_mac_t my_mac = {0x00, 0x11, 0x22, 0x33, 0x44, 0x55};

    while (1) {
        /* Attempt to receive update; blocks until transfer finishes or timeout */
        if (ca_boot_receive_update(my_mac, 60000)) {
            /* If successful, the system will reset into the bootloader */
            ca_printf("Update received, rebooting...\n");
        } else {
            /* Log failure and wait before retrying */
            ca_printf("Update failed or timed out, retrying in 5s...\n");
            ca_os_sleep(5000);
        }
    }
}
```

Q&A — fine-tuning review *6/6 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** When should I call ca_boot_receive_update in my application?
A: It should be called from a dedicated background task responsible for system maintenance or remote updates, typically within a loop that checks for updates periodically. It serves as the high-level entry point for the A/B slot update mechanism.

Code example conf:1.00 **Q:** Provide a minimal C example of how to invoke the update function.
A: ca_mac_t my_mac = {0x00, 0x11, 0x22, 0x33, 0x44, 0x55}; u32 timeout = 5000; bool success = ca_boot_receive_update(my_mac, timeout);

Parameters conf:1.00 **Q:** What is the purpose of the wait_ms parameter and what value should I use to wait indefinitely?
A: The wait_ms parameter defines the timeout in milliseconds for the TFTP transfer to complete. You should use the constant CA_WAIT_FOREVER to block indefinitely.

Return conf:1.00 **Q:** What does a return value of false indicate?
A: A return value of false indicates that the update failed. This can occur if the device is in a trial state, the TFTP transfer failed, the image header is invalid, or the boot request could not be initiated.

Error/Edge case conf:1.00 **Q:** What are common mistakes that cause ca_boot_receive_update to fail?
A: Common mistakes include calling the function while the system is in an unconfirmed trial state, having insufficient free flash space, or calling it before the network stack is initialized.

Behavior conf:1.00 **Q:** Is ca_boot_receive_update thread-safe or safe to call from an ISR?
A: No, it is not thread-safe and must never be called from an ISR. It is a blocking call that must be executed from a task context.

ca_boot_request_update

Header: caos/inc/boot_image.h:83
Source: caos/src/boot_image.c:75:82
GUARD: EN_BOOT_IMAGE

```
bool ca_boot_request_update(char slot)
```

Requests a system reboot into the bootloader to perform a firmware update on a specific flash slot.

Parametri:

Nome	Tipo	Descrizione
slot	char	The target flash slot for the update. Must be either 'A' or 'B'. Any other character will cause the function to return false.

Ritorna:
Returns false if the slot is invalid, if the system is currently in an unconfirmed trial state, or if the backup register write fails. If successful, the function triggers a system reset and does not return.

Note:

- This function is a high-level control routine that triggers a system reset; it is not thread-safe in the sense that it alters global system state (backup registers) and halts execution. It must not be called from an ISR because it performs a system reset, which is destructive to the current execution context. A common beginner mistake is calling this function without verifying the integrity of the received update or ignoring the return value, which could lead to a boot loop if the backup register write fails. Ensure that the system is not in a 'trial' state that requires confirmation before attempting an update, as the function will block the request to prevent bricking an unverified installation.

Uso:

- This function is typically used at the end of a firmware download process (e.g., via TFTP or UART). The typical sequence is: 1) Receive the update data, 2) Verify the data integrity, 3) Call ca_boot_request_update to signal the bootloader to perform the swap/install upon the next reset. It is often paired with ca_os_sleep to ensure communication buffers are flushed before the reset occurs.

Esempio:

```
/* Example: Triggering an update after receiving a valid image */
char target_slot = 'B';

/* Ensure we are not in a critical state before requesting update */
if (ca_boot_is_trial() == false) {
    /* Wait briefly to allow communication buffers to clear */
    ca_os_delay_ms(100);

    /* Request the update; if this returns, the request failed */
    if (ca_boot_request_update(target_slot) == false) {
        ca_printf("Failed to initiate update request for slot %c\n", target_slot
    );
    }
} else {
    /* Handle case where trial must be confirmed first */
```

```
    ca_printf("Cannot update: current trial not confirmed.\n");
}
```

Q&A — fine-tuning review *4/4 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** When is the appropriate time to call ca_boot_request_update in my firmware update routine?
A: It should be called at the end of a firmware download process, specifically after receiving the update data and verifying its integrity. It is recommended to pair it with ca_os_sleep to ensure communication buffers are flushed before the system reset occurs.

Code example conf:0.90 **Q:** How do I implement a call to ca_boot_request_update in C using caOS types?
A: You should verify the return value to ensure the request was accepted before the system resets. Example: bool status = ca_boot_request_update('A'); if (!status) { /* Handle error */ }

Parameters conf:1.00 **Q:** What are the valid values for the 'slot' parameter in ca_boot_request_update?
A: The 'slot' parameter must be either 'A' or 'B'. Providing any other character will cause the function to return false and the update request will not be processed.

Return conf:1.00 **Q:** Why might ca_boot_request_update return false instead of triggering a reset?
A: The function returns false if the provided slot is invalid, if the system is currently in an unconfirmed trial state, or if the backup register write fails. If successful, the function triggers a system reset and does not return.

`ca_bswap16`

Header: `caos/inc/endian.h:63`
GUARD: `EN_ENDIAN`

```
static inline u16 ca_bswap16(u16 value)
```

Swaps the byte order of a 16-bit unsigned integer to convert between little-endian and big-endian formats.

Parametri:

Nome	Tipo	Descrizione
`value`	`u16`	The 16-bit value to be byte-swapped. Any valid u16 value is accepted.

Ritorna:
The byte-swapped 16-bit value (e.g., 0x1234 becomes 0x3412).

Note:

- This function is a highly efficient, non-blocking operation that typically maps to a single CPU instruction (REV16) on ARM Cortex-M processors. It is thread-safe and can be safely called from an ISR because it performs no memory access or OS-level blocking. The most common mistake is using this function on data that is already in the correct host endianness, which will corrupt the data; always verify the source format (e.g., network packets are usually big-endian) before applying the swap.

Uso:

- This function is essential when parsing binary protocols or reading hardware registers that do not match the CPU's native endianness. It is typically used in the data-link or application layer when processing raw buffers received from peripherals like SPI, I2C,

or Ethernet. You will often see it paired with manual buffer indexing or memory copy operations to ensure that multi-byte fields are correctly interpreted by the application logic.

Esempio:

```
/* Example: Reading a 16-bit big-endian value from a buffer */
#include "caos.h"

u16 process_network_data(u8 *buffer) {
    /* Combine two bytes into a 16-bit value (little-endian construction) */
    u16 raw_val = (u16)(((u16)buffer[1] << 8) | (u16)buffer[0]);

    /* If the network protocol is big-endian, swap the bytes to host order */
    u16 host_val = ca_bswap16(raw_val);

    return host_val;
}
```

Q&A — fine-tuning review *4/4 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** When should I use ca_bswap16 in my caOS application?
A: You should use ca_bswap16 when parsing binary protocols or reading hardware registers that do not match the CPU's native endianness. It is essential for converting between little-endian and big-endian formats, such as when processing raw buffers received from peripherals like SPI, I2C, or Ethernet.

Code example conf:1.00 **Q:** How do I implement a byte swap for a 16-bit value using caOS types?
A: You can use the function directly as shown: u16 raw_val = 0xAA55; u16 swapped = ca_bswap16(raw_val); // swapped becomes 0x55AA.

Parameters conf:1.00 **Q:** What are the constraints on the 'value' parameter for ca_bswap16?
A: The parameter 'value' is a u16 type representing the 16-bit value to be byte-swapped. Any valid u16 value is accepted as an input.

Return conf:1.00 **Q:** What does the return value of ca_bswap16 represent, and can it fail?
A: The function returns the byte-swapped 16-bit value (e.g., 0x1234 becomes 0x3412). The function cannot fail as it is a non-blocking, thread-safe operation that maps to a single CPU instruction; however, the result will be logically incorrect if the input data was already in the correct host endianness.

`ca_bswap16_signed`

Header: `caos/inc/endian.h:134`
GUARD: `EN_ENDIAN`

```
static inline i16 ca_bswap16_signed(i16 value)
```

Swaps the byte order of a 16-bit signed integer to convert between Little-Endian and Big-Endian formats.

Parametri:

Nome	Tipo	Descrizione
`value`	`i16`	The 16-bit signed integer to be byte-swapped. Any valid i16 value is accepted.

Ritorna:
The input value with its two bytes swapped. The return type is i16, preserving the signed representation.

Note:

- This function is a static inline helper that performs a byte-swap operation. It is thread-safe and can be safely called from an ISR because it performs a simple register-level manipulation without blocking or accessing shared resources. It is primarily used when communicating with external hardware or network protocols that use a different endianness than the STM32 (which is natively Little-Endian). A common mistake is assuming this function performs a mathematical sign inversion; it only swaps the memory layout of the bytes, not the value's sign.

Uso:

- Use this function when receiving 16-bit data from external sensors, network packets, or storage devices that transmit data in Big-Endian format. It is typically used in the data processing stage after receiving raw bytes from a communication peripheral like SPI or UART. It is often paired with ca_bswap32_signed or ca_bswap64_signed when handling larger data structures, and is essential for ensuring data integrity when parsing protocol headers or sensor registers.

Esempio:

```c
/* Example: Processing a 16-bit signed temperature value received from a sensor */
#include "caos.h"

void process_sensor_data(void) {
    u16 raw_data = 0x0A00; // Example: 0x0A00 received from a Big-Endian sensor

    /* Convert Big-Endian raw data to local Little-Endian format */
    i16 temperature = ca_bswap16_signed((i16)raw_data);

    /* Log the result using caOS logging facilities */
    ca_printf("Processed temperature: %d\n", temperature);
}
```

Q&A — fine-tuning review *4/4 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** When should I use ca_bswap16_signed in my caOS project?
A: You should use this function when communicating with external hardware, network protocols, or storage devices that transmit 16-bit data in Big-Endian format, as the STM32 is natively Little-Endian. It is typically used after receiving raw bytes from peripherals like SPI or UART.

Code example conf:1.00 **Q:** How do I implement a byte swap for a signed 16-bit sensor reading?
A: You can use the function as follows: i16 raw_data = 0x1234; i16 swapped_data = ca_bswap16_signed(raw_data);

Parameters conf:1.00 **Q:** Are there any restrictions on the i16 value passed to ca_bswap16_signed?
A: No, any valid i16 value is accepted. The parameter represents the 16-bit signed integer whose byte order you wish to swap.

Return conf:1.00 **Q:** Does the return value of ca_bswap16_signed indicate an error if the sign bit changes?
A: No, the function does not perform mathematical sign inversion or error checking. It returns the input value with its two bytes swapped, preserving the signed representation. There are no failure states as it performs simple register-level manipulation.

`ca_bswap32`

Header: `caos/inc/endian.h:85`
GUARD: `EN_ENDIAN`

```
static inline u32 ca_bswap32(u32 value)
```

Swaps the byte order of a 32-bit unsigned integer (Endianness conversion).

Parametri:

Nome	Tipo	Descrizione
value	u32	The 32-bit integer to be byte-swapped. Any 32-bit value is valid.

Ritorna:
The byte-swapped 32-bit integer (e.g., 0x11223344 becomes 0x44332211).

Note:

- This function is a high-performance utility that typically maps to the hardware 'REV' instruction on ARM Cortex-M processors. It is non-blocking, thread-safe, and can be safely called from an ISR because it performs a simple register-level operation without accessing shared resources or OS primitives. The most common mistake is using this on data that is already in the correct host endianness, which will corrupt the value; always verify if your data source is Big-Endian or Little-Endian before calling this.

Uso:

- This function is essential when parsing network protocols or reading binary files from external storage where data is stored in Big-Endian format, but your STM32 is running in Little-Endian mode. It is typically used in a sequence where you read raw bytes from a buffer, assemble them into a u32, and then pass the result through ca_bswap32 to ensure the CPU interprets the bytes correctly. It is often paired with ca_bswap16 or ca_bswap64 depending on the data width being processed, and is frequently used alongside memory management functions like ca_memory_allocate to prepare data structures for network transmission.

Esempio:

```c
#include "caos.h"

// Example: Reading a 32-bit Big-Endian value from a buffer
void process_network_data(u8 *buffer) {
    u32 raw_val;
    u32 host_val;

    // Assemble 4 bytes from buffer into a 32-bit integer (Big-Endian order)
    raw_val = ((u32)buffer[0] << 24) | ((u32)buffer[1] << 16) |
              ((u32)buffer[2] << 8)  | ((u32)buffer[3]);

    // Convert from Big-Endian (network) to Little-Endian (host)
    host_val = ca_bswap32(raw_val);

    // Log the result using caOS logging
    ca_printf("Converted value: %u\n", host_val);
}
```

Q&A — fine-tuning review *4/4 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** When should I use ca_bswap32 in my caOS project?
A: You should use ca_bswap32 when parsing network protocols or reading binary data from external storage like SD cards or Flash. It is necessary when the data source is in Big-Endian format and your STM32 is operating in Little-Endian mode, ensuring the CPU interprets the bytes correctly.

Code example conf:1.00 **Q:** How do I implement a simple byte swap for a 32-bit value using caOS types?
A: You can use the function directly as follows: u32 raw_data = 0x11223344; u32 swapped = ca_bswap32(raw_data); // swapped becomes 0x44332211.

Parameters conf:1.00 **Q:** What are the constraints on the 'value' parameter for ca_bswap32?
A: The 'value' parameter is a u32 type representing the 32-bit integer to be byte-swapped. Any 32-bit value is valid for this function.

Return conf:1.00 **Q:** What does the return value of ca_bswap32 represent, and can it fail?
A: The function returns the byte-swapped 32-bit integer. It cannot fail because it is a non-blocking, high-performance utility that maps to the hardware 'REV' instruction on ARM Cortex-M processors; it does not access shared resources or OS primitives.

`ca_bswap32_signed`

Header: `caos/inc/endian.h:143`
GUARD: `EN_ENDIAN`

```
static inline i32 ca_bswap32_signed(i32 value)
```

Swaps the byte order of a 32-bit signed integer to convert between Little-Endian and Big-Endian formats.

Parametri:

Nome	Tipo	Descrizione
`value`	`i32`	The 32-bit signed integer value to be byte-swapped. Any 32-bit value is valid.

Ritorna:
The input value with its bytes reversed (e.g., 0x12345678 becomes 0x78563412).

Note:

- This function is a static inline helper that performs a byte-swap on the underlying bit representation of a signed integer. It is thread-safe and non-blocking because it performs a simple CPU register manipulation without accessing shared resources or OS primitives. It is safe to call from an ISR (Interrupt Service Routine) because it does not trigger context switches or wait for locks. The most common mistake is assuming this function performs a mathematical sign inversion; it only affects the memory layout of the bytes, not the numerical sign of the value.

Uso:

- This function is typically used when communicating with external hardware or network protocols that use a different endianness than the STM32 (which is Little-Endian). You will often use it when preparing data to be sent via ca_uart_dma_send or ca_net_send, or when parsing incoming data from a buffer received via ca_queue_static_receive. It is essential for ensuring that multi-byte integers are interpreted correctly by both the sender and the receiver.

Esempio:

```
/* Example: Preparing a signed 32-bit value for a Big-Endian network protocol */

void send_signed_data(i32 raw_value) {
    /* Convert from local Little-Endian to Big-Endian for network transmission
    */
    i32 network_value = ca_bswap32_signed(raw_value);

```

```
    /* Send the swapped value over a network interface */
    /* ca_net_send(interface_handle, &network_value, sizeof(network_value)); */

    ca_printf("Original: %d, Swapped: %d\n", raw_value, network_value);
}
```

Q&A — fine-tuning review *4/4 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** When should I use ca_bswap32_signed in my caOS project?
A: You should use this function when communicating with external hardware or network protocols that use a different endianness than the STM32's native Little-Endian format. It is typically used when preparing data for transmission via ca_uart_dma_send or ca_net_send, or when parsing data received from ca_queue_static_receive.

Code example conf:1.00 **Q:** How do I implement a byte swap for a signed 32-bit integer in caOS?
A: You can use the function directly as shown here: i32 raw_data = 0x12345678; i32 swapped_data = ca_bswap32_signed(raw_data);

Parameters conf:1.00 **Q:** Are there any restrictions on the i32 value passed to ca_bswap32_signed?
A: No, any 32-bit signed integer value is valid. The function operates on the underlying bit representation of the integer, so there are no restricted or invalid input ranges.

Return conf:1.00 **Q:** What does the return value of ca_bswap32_signed represent, and can it fail?
A: The return value is the input integer with its bytes reversed (e.g., 0x12345678 becomes 0x78563412). The function cannot fail as it performs a simple CPU register manipulation; it is thread-safe, non-blocking, and safe to call from an ISR.

`ca_bswap64`

Header: `caos/inc/endian.h:110`
GUARD: `EN_ENDIAN`

```
static inline u64 ca_bswap64(u64 value)
```

Swaps the byte order of a 64-bit unsigned integer to convert between little-endian and big-endian formats.

Parametri:

Nome	Tipo	Descrizione
`value`	`u64`	The 64-bit integer value to be byte-swapped. Any 64-bit value is valid.

Ritorna:
The byte-swapped 64-bit integer. There are no error conditions as this is a pure mathematical transformation.

Note:

- This function is a non-blocking, thread-safe, and CPU-cycle-efficient operation that performs a direct register manipulation. It is safe to call from an ISR because it does not interact with the OS scheduler, memory, or peripherals. The most common mistake is using this function when the data is already in the correct host endianness, which will result in corrupted data values. Always verify the endianness of your data source (e.g., network packets or external sensors) before applying this swap.

Uso:

- This function is typically used when parsing binary protocols or reading raw data from external hardware that uses a different endianness than the STM32 (which is little-endian).

It is often paired with memory access functions like ca_memcpy or when reading from communication buffers. You use it to normalize incoming data into the host's native format so that subsequent arithmetic or logic operations work correctly. It is a fundamental building block for network stacks and file system drivers.

Esempio:

```c
/* Example: Converting a 64-bit timestamp received from a network buffer */
#include "caos.h"

u64 process_network_timestamp(u8 *buffer) {
    u64 raw_val;
    /* Copy raw bytes from buffer into a 64-bit variable */
    ca_memcpy(&raw_val, buffer, sizeof(u64));

    /*
     * Assuming the network protocol is Big-Endian,
     * we must swap bytes to match the STM32 Little-Endian format.
     */
    u64 host_val = ca_bswap64(raw_val);

    return host_val;
}
```

Q&A — fine-tuning review *4/4 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** When should I use ca_bswap64 in my caOS project?
A: You should use ca_bswap64 when parsing binary protocols or reading raw data from external hardware that uses a different endianness than the STM32's native little-endian format. It is used to normalize incoming data into the host's native format so that subsequent arithmetic or logic operations function correctly.

Code example conf:1.00 **Q:** Can you provide a minimal example of how to use ca_bswap64?
A: u64 raw_data = 0x0102030405060708ULL; u64 host_data = ca_bswap64(raw_data);

Parameters conf:1.00 **Q:** What are the constraints on the 'value' parameter for ca_bswap64?
A: The 'value' parameter is a u64 type representing the 64-bit integer to be byte-swapped. Any 64-bit value is valid, as there are no restricted ranges for this mathematical transformation.

Return conf:1.00 **Q:** What error codes does ca_bswap64 return if the operation fails?
A: There are no error conditions for this function. It is a pure mathematical transformation that always returns the byte-swapped 64-bit integer.

`ca_bswap64_signed`

Header: `caos/inc/endian.h:152`
GUARD: `EN_ENDIAN`

```c
static inline i64 ca_bswap64_signed(i64 value)
```

Converts a 64-bit signed integer between host and network byte order (endianness swap).

Parametri:

Nome	Tipo	Descrizione
`value`	`i64`	The 64-bit signed integer to be byte-swapped. Any valid 64-bit signed value is accepted.

Ritorna:
The byte-swapped 64-bit signed integer. There are no error conditions as this is a pure mathematical transformation.

Note:

- This function is a simple wrapper around ca_bswap64 that casts the result back to a signed type. It is a non-blocking, thread-safe, and pure function, meaning it performs no I/O and does not rely on RTOS state; therefore, it is perfectly safe to call from an ISR or any task context. The most common mistake is assuming this function handles network-to-host conversion automatically based on the CPU architecture; it always performs the swap, so only use it when you know the data is in the opposite endianness of your current system.

Uso:

- This function is typically used when processing raw binary data received from external hardware or network protocols that use Big-Endian format (e.g., network packets or specific sensor registers) on a Little-Endian STM32 processor. It is often paired with memory access functions like ca_memcpy or when parsing buffers received via ca_queue_static_receive. You use it to normalize data before performing arithmetic operations or storing it in your application's internal structures.

Esempio:

```c
/* Example: Processing a 64-bit timestamp received from a network buffer */
#include "caos.h"

i64 process_network_timestamp(void *buffer) {
    i64 raw_data;

    /* Copy raw bytes from the buffer into our local variable */
    ca_memcpy(&raw_data, buffer, sizeof(i64));

    /*
     * The network sends data in Big-Endian, but our STM32 is Little-Endian.
     * We must swap the bytes to get the correct signed integer value.
     */
    i64 host_timestamp = ca_bswap64_signed(raw_data);

    return host_timestamp;
}
```

Q&A — fine-tuning review *4/4 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** When should I use ca_bswap64_signed in my caOS application?
A: You should use this function when processing raw binary data from external hardware or network protocols that use Big-Endian format, such as data received from a sensor or network packet, to normalize it for your Little-Endian STM32 processor before performing arithmetic or storage.

Code example conf:1.00 **Q:** How do I implement a simple byte swap for a 64-bit signed integer in caOS?
A: i64 raw_data = 0x0102030405060708; i64 normalized_data = ca_bswap64_signed(raw_data);

Parameters conf:1.00 **Q:** Are there any restrictions on the i64 value parameter for ca_bswap64_signed?
A: No, there are no restrictions. Any valid 64-bit signed integer is accepted as the input parameter.

Return conf:1.00 **Q:** What error codes does ca_bswap64_signed return if the operation fails?
A: There are no error conditions for this function. It is a pure mathematical transformation that always returns the byte-swapped 64-bit signed integer.

ca_bus_error_init

Header: caos/inc/bus.h:31
Source: caos/src/bus.c:24:27
GUARD: EN_BUS

```
void ca_bus_error_init(void)
```

Enables the BusFault exception handler in the ARM Cortex-M processor to catch memory access errors.

Ritorna:
void

Note:

- This function is non-blocking and executes almost instantaneously as it only performs a single register write to the System Control Block (SCB). It is thread-safe because it modifies a system-level configuration register that is typically only accessed during the boot sequence. It is not intended to be called from an ISR, as system configuration should be finalized during the initialization phase before the scheduler starts. The most common mistake is calling this function before the system clock or basic hardware abstraction layers are ready, though in this specific case, it is safe to call early in main(). If you fail to call this, the processor might treat bus errors as generic HardFaults, making it significantly harder to debug exactly which memory address caused the crash.

Uso:

- This function is used exclusively during the system startup sequence, typically inside the main() function before the RTOS scheduler is started. It is usually paired with other hardware protection initializations like ca_mpu_init() and ca_mpu_protect_canary_msp(), which set up memory boundaries and stack overflow protection. By enabling BusFaults, you ensure that if the code attempts to access an invalid memory address or a peripheral that is not responding, the CPU triggers a specific exception handler rather than silently failing or hanging. It is a mandatory step for building robust embedded systems where memory safety and fault detection are critical for long-term stability.

Esempio:

```
int main(void) {
    /* Initialize memory protection unit and stack protection */
    ca_mpu_init();
    ca_mpu_protect_canary_msp((u32)&_msp_stack_base);

    /* Enable BusFault exception to catch invalid memory access */
    ca_bus_error_init();

    /* Initialize heap and scheduler after hardware protection is active */
    ca_memory_init(&_heap_start, &_heap_end);
    if (ca_scheduler_init(1) == false) {
        /* Handle initialization failure */
        while(1);
    }

    /* Start the RTOS scheduler */
    // ca_os_run();
    return 0;
}
```

Q&A — fine-tuning review *2/2 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I call ca_bus_error_init() in my caOS project, and why is it important?
A: You should call ca_bus_error_init() early in your caOS project initialization, before initializing the MPU and the scheduler. This function enables BusFault exception handling to detect invalid memory access errors. It's important because it helps catch memory access violations that could lead to system instability or unpredictable behavior. The function must be called before MPU and scheduler initialization, otherwise it may not work correctly or cause unexpected results.

Code example conf:0.90 **Q:** Can you show me a minimal C example using ca_bus_error_init() with caOS types?
A: void example_usage(void) { // Initialize bus error handling before MPU and scheduler ca_bus_error_init(); // Continue with other initialization // ... rest of initialization code }

`ca_can_deinit`

Header: `caos/drivers/inc/can.h:42`
Source: `caos/drivers/src/can.c:147:151`
GUARD: `EN_CAN`

```
bool ca_can_deinit(u8 num)
```

Disables and resets the specified CAN peripheral hardware controller.

Parametri:

Nome	Tipo	Descrizione
`num`	`u8`	The index of the CAN peripheral to deinitialize. Must correspond to a valid hardware instance (e.g., 0 for CAN1, 1 for CAN2) defined in the system configuration.

Ritorna:
Always returns true. This indicates that the deinitialization command has been issued to the hardware abstraction layer.

Note:

- This function is non-blocking and performs a direct hardware reset of the CAN controller. It is not thread-safe by itself, so ensure no other tasks are attempting to transmit or receive data on the same peripheral instance while this is called. It is generally safe to call from an ISR, but doing so is discouraged as it abruptly terminates communication. The most common beginner mistake is calling this function while the CAN bus is still active, which can lead to bus errors or 'stuck' states on the physical CAN network because the controller stops acknowledging frames mid-transmission.

Uso:

- This function is used during system shutdown, power-saving transitions, or when reconfiguring the CAN peripheral with different baud rates or filters. It is typically paired with an initialization function (e.g., ca_can_init) at the start of the application lifecycle. In a typical sequence, you would stop all application-level CAN processing, call ca_can_deinit to release the hardware resources, and then potentially call the init function again if a hardware reset or reconfiguration is required.

Esempio:

```c
/* Example: Shutting down CAN1 before entering a low-power mode */
#define CAN_PORT_1 0

void system_shutdown_can(void) {
    /* Ensure no further processing is done */
    if (ca_can_deinit(CAN_PORT_1)) {
        /* Hardware is now disabled, safe to power down or reconfigure */
    } else {
        /* This branch is theoretically unreachable based on current
    implementation */
    }
}
```

Q&A — fine-tuning review *4/4 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I call ca_can_deinit() and what is its purpose in a caOS application?
A: You should call ca_can_deinit() when you want to disable and release the hardware resources of a specific CAN channel. This function is typically used during system shutdown, resource cleanup, or when dynamically managing CAN channels. It ensures that the CAN peripheral is properly disabled and its associated memory or registers are freed for other uses.

Code example conf:0.90 **Q:** Can you show a minimal C code example using ca_can_deinit() with caOS types?
A: u8 result = ca_can_deinit(1); if (result) { /* CAN channel 1 successfully deinitialized */ } else { /* Invalid channel number or internal error */ }

Parameters conf:0.95 **Q:** What does the 'num' parameter in ca_can_deinit() represent, and what are valid values?
A: The 'num' parameter specifies the CAN channel number to be deinitialized. Valid values are 0, 1, 2, and 3, corresponding to the four CAN channels available on the STM32 microcontroller. Any other value, such as 4 or 5, is considered invalid and will cause the function to return false.

Return conf:0.90 **Q:** What do the return values of ca_can_deinit() indicate, and what causes it to return false?
A: The function returns true if the CAN channel was successfully deinitialized and its resources were released. It returns false if the channel number is invalid (not 0-3) or if an internal error occurs during the deinitialization process. Calling the function with an invalid parameter or after already deinitializing the same channel may also result in false.

`ca_can_hw_deinit`

Header: `caos/drivers/inc/ca_glue_hw.h:72`
GUARD: `EN_CA_GLUE_HW`

```c
extern void ca_can_hw_deinit(u8 num); /* disabilita e resetta il
    periferico CAN */
```

Disables and resets the specified CAN peripheral hardware and its associated clock.

Parametri:

Nome	Tipo	Descrizione
`num`	`u8`	The index of the CAN peripheral to deinitialize (e.g., 1 for CAN1, 2 for CAN2). Passing an invalid index will result in the function returning early without performing any action.

Ritorna:
void

Note:

- This function is non-blocking and performs direct register manipulation to put the CAN peripheral into a reset state and disable its clock. It is not thread-safe; if multiple tasks attempt to deinitialize or initialize the CAN hardware simultaneously, it can lead to race conditions or system instability. It is generally safe to call from an ISR, but you must ensure that no other part of the application is actively using the CAN peripheral, as this will immediately stop all communication and reset the hardware registers. A common beginner mistake is calling this function while a transmission is still in progress, which will cause the hardware to abort the operation abruptly without completing the frame. Furthermore, on some architectures, the clock is only disabled if both CAN instances are inactive, so calling this on one instance may not immediately cut the power to the entire peripheral block if the other instance is still running.

Uso:

- This function is used during the teardown phase of the application lifecycle, such as when shutting down a communication module or reconfiguring the system to save power. It is typically paired with an initialization function (like ca_can_init) to form a complete lifecycle. In the caOS driver architecture, it is called by the higher-level ca_can_deinit function to ensure that the hardware is safely powered down and the clock gate is disabled, preventing unnecessary power consumption when the CAN bus is not in use. Always ensure that any pending messages are handled or discarded before calling this, as the hardware reset will clear all internal buffers and configuration registers.

Esempio:

```c
/* Example: Shutting down CAN1 safely */
#include "caos.h"

void shutdown_can_module(void) {
    /* Ensure the peripheral is not currently transmitting before deinit */
    /* Check if the CAN queue is empty or wait for transmission completion */

    /* Perform hardware-level deinitialization */
    ca_can_hw_deinit(1);

    /* Log the event or update system state */
    ca_printf("CAN1 hardware disabled\n");
}
```

Q&A — fine-tuning review *4/4 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I call ca_can_hw_deinit() and what is its purpose?
A: You should call ca_can_hw_deinit() to disable and reset a CAN peripheral, typically before reinitializing or shutting down the CAN channel. It is a low-level function that directly manipulates hardware registers to reset the CAN controller and disable its clock. It must not be called from an ISR or when other threads or ISRs are using the CAN channel.

Code example conf:0.90 **Q:** Can you show a minimal C example using ca_can_hw_deinit() with caOS types?
A: u8 can_num = 1; ca_can_hw_deinit(can_num);

Parameters conf:0.90 **Q:** What does the 'num' parameter in ca_can_hw_deinit() represent and what values are valid?
A: The 'num' parameter specifies which CAN channel to disable. For F1xx devices, only 1 is valid. For F4xx, F7xx, H5xx, and H7xx, both 1 and 2 are supported. Values other

than 1 or 2 are ignored and the function returns without performing any action.

HW differences conf:0.85 **Q:** How does ca_can_hw_deinit() differ between F1xx and H7xx families in terms of hardware implementation?
A: For F1xx, ca_can_hw_deinit() uses bxCAN (CAN1) and directly resets the CAN1 peripheral and disables its clock via RCC_APB1ENR_CAN1EN. For H7xx, it uses FDCAN (FDCAN1/FDCAN2) and sets the CCCR_INIT bit to enter initialization mode. Clock disabling for FDCAN is conditional and only occurs when both instances are inactive, using RCC_APB1HENR_FDCANEN.

`ca_can_hw_init`

Header: `caos/drivers/inc/ca_glue_hw.h:69`
GUARD: `EN_CA_GLUE_HW`

```
extern bool ca_can_hw_init (const ca_can_cfg_t *cfg); /* inizializza il
    periferico CAN con baudrate e filtri */
```

Initializes the CAN/FDCAN hardware peripheral with specified baudrate and operating modes.

Parametri:

Nome	Tipo	Descrizione
`cfg`	`const ca_can_cfg_t *`	Pointer to a configuration structure containing the CAN instance number (1 or 2), desired baudrate, and flags for loopback or silent mode. Must not be NULL.

Ritorna:
Returns true if the hardware successfully entered and exited initialization mode with the new settings. Returns false if the configuration is invalid, the hardware fails to respond to initialization requests, or the baudrate calculation fails.

Note:

- This function is blocking because it waits for the hardware to acknowledge the transition into and out of initialization mode using a software timeout loop. It is not thread-safe and should not be called from an ISR, as it performs hardware-level register configuration that expects a stable system state. A common beginner mistake is calling this function multiple times without checking the return value or failing to ensure the system clock (HSE/SystemCoreClock) is correctly configured before initialization, which leads to incorrect baudrate timing.

Uso:

- This function is the primary hardware abstraction layer (HAL) entry point for CAN setup. It is typically called during the system boot sequence or when a specific communication interface needs to be brought online. It is always paired with a higher-level driver function (like ca_can_init) that manages the internal state tracking of active CAN peripherals. You should use this to prepare the peripheral before attempting to send or receive any CAN frames.

Esempio:

```
ca_can_cfg_t my_can_cfg = { .can_num = 1, .baudrate = 500000, .loopback = false,
    .silent = false };

/* Initialize the CAN hardware */
```

```
if (!ca_can_hw_init(&my_can_cfg)) {
    /* Handle error: hardware failed to initialize */
    while(1);
}

/* Proceed to use other caOS functions to send/receive data */
/* ca_can_send(1, &my_frame); */
```

Q&A — fine-tuning review *7/7 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I call ca_can_hw_init() in my caOS application?
A: You should call ca_can_hw_init() during system initialization, typically right after enabling the CAN peripheral clock and before starting any CAN communication tasks. It's used to configure the CAN controller with a specific baudrate and filter settings, preparing the hardware for message transmission and reception.

Code example conf:0.95 **Q:** Can you show a minimal C example using ca_can_hw_init() with caOS types?
A:

```
ca_can_cfg_t cfg = {
    .can_num = 1,
    .baudrate = 125000,
    .loopback = false,
    .silent = false
};
bool success = ca_can_hw_init(&cfg);
if (!success) {
    // Handle initialization failure
}
```

Parameters conf:0.90 **Q:** What does the 'can_num' parameter in ca_can_hw_init() represent and what are valid values?
A: The 'can_num' parameter specifies which CAN controller instance to initialize. For bxCAN-based MCUs (like H5xx), it must be 1 or 2. For FDCAN-based MCUs (like H7xx), it also supports 1 or 2, but the underlying hardware registers differ. Invalid values like 0 or 3 will cause the function to return false.

Return conf:0.95 **Q:** What does a return value of false from ca_can_hw_init() indicate?
A: A return value of false indicates that the initialization failed, typically due to timeout during entry into init mode, invalid baudrate calculation, or invalid parameter values such as an unsupported can_num. The function does not return true unless all steps complete successfully.

Error/Edge case conf:0.90 **Q:** What are common mistakes when calling ca_can_hw_init()?
A: Common mistakes include passing a null pointer for the config structure, using an unsupported can_num (e.g., 0 or 3), specifying an invalid baudrate that cannot be calculated, or calling the function before enabling the required peripheral clocks. Also, not checking the return value can lead to assuming initialization succeeded when it did not.

Behavior conf:0.90 **Q:** Is ca_can_hw_init() blocking or non-blocking, and is it safe to call from an ISR?
A: ca_can_hw_init() is a blocking function that waits for the CAN controller to enter init mode and complete configuration. It is not safe to call from an ISR because it may block and could interfere with real-time behavior. It is thread-safe as long as no other threads are modifying the same CAN controller registers.

HW differences conf:0.85 **Q:** How does ca_can_hw_init() differ between bxCAN and FDCAN-based MCUs?
A: On bxCAN-based MCUs (H5xx, H7xx), ca_can_hw_init() configures registers like NBTP, CCCR, and RXGFC for FDCAN-compatible settings. On FDCAN-based MCUs (H7xx), it uses FDCAN-specific registers like SIDFC, XIDFC, GFC, RXF0C, and TXBC. The FDCAN implementations also support more advanced features like dedicated FIFOs

and message RAM layouts, while bxCAN uses simpler register sets.

---

ca_can_hw_recv

Header: caos/drivers/inc/ca_glue_hw.h:71
GUARD: EN_CA_GLUE_HW

```
extern bool ca_can_hw_recv (u8 num, ca_can_frame_t *frame); /* legge un
    frame dal FIFO di ricezione; false se vuoto */
```

Reads a single CAN frame from the hardware receive FIFO buffer.

Parametri:

Nome	Tipo	Descrizione
num	u8	The index of the CAN peripheral to read from (e.g., 0, 1). Must correspond to a valid, initialized hardware instance.
frame	ca_can_frame_t *	Pointer to a structure where the received frame data (ID, DLC, data bytes, etc.) will be stored. Must not be NULL.

Ritorna:
Returns true if a frame was successfully read from the FIFO. Returns false if the FIFO is empty or if the peripheral index is invalid.

Note:

- This function is non-blocking; it checks the hardware status register immediately and returns false if no data is available, making it ideal for polling loops. It is generally thread-safe regarding the hardware registers, but you must ensure that the same CAN peripheral is not being accessed simultaneously by multiple tasks or an ISR. A common beginner mistake is calling this function without checking the return value, which leads to processing uninitialized or stale data in the 'frame' structure. Always ensure the CAN peripheral has been properly initialized before calling this function, otherwise, the hardware access may trigger a hard fault.

Uso:

- This function is typically used in a polling loop or inside a CAN receive interrupt service routine (ISR) to drain the hardware FIFO. It is usually paired with a check for pending messages to avoid unnecessary processing. In a typical application, you would call this function repeatedly until it returns false to ensure all queued messages are cleared from the hardware buffer, preventing FIFO overflow conditions.

Esempio:

```
ca_can_frame_t rx_frame;
// Poll the CAN peripheral 0 for incoming messages
if (ca_can_hw_recv(0, &rx_frame)) {
    // Successfully received a frame, process the data
    if (rx_frame.id == 0x123) {
        // Handle specific message ID
    }
} else {
    // No frames available in the hardware FIFO
}
```

Q&A — fine-tuning review *7/7 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I call ca_can_hw_recv in my CAN application?
A: You should call ca_can_hw_recv to read incoming CAN frames from the hardware FIFO buffer. It's typically used in a loop or interrupt handler to process received messages. Since it's non-blocking, you can call it periodically to check for new frames without waiting.

Code example conf:0.95 **Q:** Can you show a minimal example of how to use ca_can_hw_recv?
A: ca_can_frame_t frame; bool result = ca_can_hw_recv(1, &frame); if (result) { // Process the received frame // frame.id, frame.dlc, frame.data contain the frame data }

Parameters conf:0.95 **Q:** What does the 'num' parameter represent and what values are valid?
A: The 'num' parameter specifies the CAN channel number. For f1xx, f4xx, and f7xx families, only 1 is supported. For h5xx and h7xx families, both 1 and 2 are supported. Any other value returns false immediately.

Return conf:0.95 **Q:** What do the return values of ca_can_hw_recv mean?
A: Returns true if a frame was successfully read from the FIFO buffer. Returns false if the FIFO is empty or if the channel number 'num' is invalid.

Error/Edge case conf:0.90 **Q:** What are common mistakes when using ca_can_hw_recv?
A: Common mistakes include passing a NULL pointer for the frame parameter (causes crash), using an unsupported channel number (returns false), and calling the function without first initializing the CAN peripheral and configuring the FIFO buffer.

Behavior conf:0.95 **Q:** Is ca_can_hw_recv blocking or thread-safe?
A: ca_can_hw_recv is non-blocking and does not wait for frames. It returns immediately. It is also not thread-safe, so concurrent calls from multiple threads may cause data corruption. It can be safely called from ISRs, but care must be taken to avoid interference with other CAN operations.

HW differences conf:0.90 **Q:** How does ca_can_hw_recv differ between bxCAN and FDCAN implementations?
A: For bxCAN (f1xx, f4xx, f7xx), the function reads from CAN_TypeDef->sFIFOMailBox[0] and uses CAN_RF0R register to check FIFO status and release frames. For FDCAN (h5xx, h7xx), it reads from FDCAN_GlobalTypeDef->RXF0S and uses FDCAN_RXF0A to acknowledge frames, with different register offsets and memory layout.

`ca_can_hw_send`

Header: `caos/drivers/inc/ca_glue_hw.h:70`
GUARD: `EN_CA_GLUE_HW`

```
1 extern bool ca_can_hw_send (u8 num, const ca_can_frame_t *frame); /*
     trasmette un frame CAN; false se mailbox piena */
```

Transmits a CAN frame over the specified hardware interface and waits for completion.

Parametri:

Nome	Tipo	Descrizione
`num`	`u8`	The index of the CAN peripheral to use (e.g., 0, 1). Must correspond to a valid, initialized hardware controller.
`frame`	`const ca_can_frame_t *`	Pointer to the structure containing the CAN ID, DLC, data bytes, and flags (IDE/RTR). Must not be NULL.

Ritorna:
Returns true if the frame was successfully transmitted (or acknowledged by the hardware). Returns false if the mailbox is full, the peripheral index is invalid, or the transmission timed

out.

Note:

- This function is blocking; it enters a busy-wait loop until the hardware confirms the transmission or a timeout occurs. It is NOT thread-safe if multiple threads access the same CAN peripheral simultaneously without external synchronization (like a mutex). Do not call this function from an Interrupt Service Routine (ISR) because the blocking loop will stall the system and potentially cause a watchdog reset. The most common beginner mistake is assuming this function is non-blocking or calling it from an ISR, which leads to system hangs or missed interrupts.

Uso:

- This function is typically used in the application layer or CLI commands to send data packets over the CAN bus. It is usually preceded by the initialization of the CAN peripheral and the population of a ca_can_frame_t structure. It is often paired with logic that checks the return value to handle bus congestion or hardware errors, ensuring the system can recover if the CAN bus is saturated or disconnected.

Esempio:

```
ca_can_frame_t my_frame = {0}; my_frame.id = 0x123; my_frame.dlc = 2; my_frame.data[0] = 0xAA; my_frame.data[1] = 0xBB; if (!ca_can_hw_send(0, &my_frame)) { /* Handle error: bus might be busy or disconnected */ } else { /* Transmission successful */ }
```

Q&A — fine-tuning review *7/7 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I use ca_can_hw_send() in my caOS application?
A: You should use ca_can_hw_send() when you need to transmit a CAN frame from your application. It is typically called from a thread context when you have a valid CAN frame to send. The function is designed for blocking transmission, so it's suitable for applications where you want to ensure the frame is sent before proceeding.

Code example conf:0.95 **Q:** Can you show a minimal example of how to use ca_can_hw_send()?
A:

```
ca_can_frame_t frame;
frame.id = 0x123;
frame.ide = false;
frame.rtr = false;
frame.dlc = 8;
for (int i = 0; i < 8; i++) frame.data[i] = i;
bool success = ca_can_hw_send(1, &frame);
if (!success) {
    // Handle transmission failure
}
```

Parameters conf:0.95 **Q:** What does the 'num' parameter in ca_can_hw_send() represent and what values are valid?
A: The 'num' parameter represents the CAN channel number. Only value 1 is supported; passing any other value will cause the function to return false immediately. This is because caOS currently only supports one CAN channel per device.

Return conf:0.95 **Q:** What do the return values of ca_can_hw_send() indicate?
A: The function returns true if the frame was successfully transmitted via a free mailbox. It returns false if the mailbox is full, the timeout expired, or if the CAN channel is invalid (num != 1). The function blocks until transmission completes or timeout occurs.

Error/Edge case conf:0.90 **Q:** What are common mistakes when calling ca_can_hw_send()?
A: Common mistakes include calling with num != 1, passing a NULL frame pointer, calling from an ISR (which can cause indefinite blocking), or not ensuring the CAN channel is properly initialized before calling. Also, calling from multiple threads without synchronization can lead to race conditions.

Behavior conf:0.95 **Q:** Is ca_can_hw_send() thread-safe and ISR-safe?
A: No, ca_can_hw_send() is neither thread-safe nor ISR-safe. It is a blocking function that can cause indefinite blocking if called from an ISR, and concurrent calls from multiple threads can lead to race conditions due to shared mailbox access.

HW differences conf:0.85 **Q:** How does ca_can_hw_send() differ between bxCAN and FDCAN implementations?
A: For bxCAN (H7/H7xx), it uses mailbox registers like TXBAR and TXBTO with 32-bit mailbox indices. For FDCAN (H7/H7xx, H7xx), it uses TXFQS for FIFO status and TXBAR for transmission requests, with different memory layout in SRAMCAN for frame elements. FDCAN also has a TX FIFO full check using TFQF_Msk.

`ca_can_init`

Header: `caos/drivers/inc/can.h:39`
Source: `caos/drivers/src/can.c:106:122`
GUARD: `EN_CAN`

```
bool ca_can_init (const ca_can_cfg_t *cfg)
```

Initializes the CAN peripheral hardware and registers the driver configuration within the caOS framework.

Parametri:

Nome	Tipo	Descrizione
`cfg`	`const ca_can_cfg_t *`	Pointer to a configuration structure containing parameters like CAN instance number, baud rate, and pin mapping. Must not be NULL.

Ritorna:
Returns true if the hardware initialization succeeded and the configuration was stored; returns false if the pointer is NULL, hardware initialization fails, or the CAN instance index is out of bounds.

Note:

- This function is non-blocking and performs low-level hardware setup. It is not thread-safe and should be called during the system initialization phase before any tasks or interrupts attempt to use the CAN bus. It must not be called from an ISR. A common beginner mistake is passing an uninitialized or NULL configuration pointer, which will immediately return false and prevent the CAN peripheral from functioning. Ensure the hardware clocks and GPIOs are configured correctly by the underlying ca_can_hw_init before calling this, as this function relies on that hardware-specific setup.

Uso:

- This function is typically called once during the system startup sequence, usually within the main initialization routine or a dedicated hardware setup task. It acts as the gateway to the CAN subsystem, pairing with later functions like ca_can_send or ca_can_receive to perform actual data transmission. If the CLI is enabled, it also registers a command-line interface node, allowing developers to debug CAN status via a terminal. Always check the return value; if it returns false, the CAN peripheral is not ready, and attempting to use it will lead to undefined behavior or system crashes.

Esempio:

```
ca_can_cfg_t my_can_cfg = { .can_num = 1, .baudrate = 500000 }; // Define config

```

```
if (ca_can_init(&my_can_cfg)) {
    // Initialization successful, safe to use CAN functions
} else {
    // Handle error: log failure or enter safe state
    while(1);
}
```

Q&A — fine-tuning review *6/6 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I call ca_can_init() in a caOS application?
A: You should call ca_can_init() once during system initialization, typically at startup, to configure a CAN interface on an STM32 microcontroller. It is meant to be called only once per CAN channel to avoid concurrency issues and ensure proper hardware setup.

Code example conf:0.90 **Q:** Can you show a minimal example of how to use ca_can_init() with caOS types?
A: ca_can_cfg_t cfg = { .can_num = 1, .baudrate = 1000000 }; bool success = ca_can_init(&cfg);

Parameters conf:0.90 **Q:** What does the cfg parameter in ca_can_init() represent and what are valid values?
A: The cfg parameter is a pointer to a ca_can_cfg_t structure that holds configuration details for the CAN interface. It must be a valid, non-NULL pointer. The can_num field must be either 1 or 2, indicating which CAN peripheral to initialize (e.g., CAN1 or CAN2).

Return conf:0.95 **Q:** What do the return values of ca_can_init() indicate?
A: The function returns true if initialization was successful, meaning the CAN channel was properly configured. It returns false if initialization failed, which can be due to a NULL cfg pointer or an error in hardware initialization (ca_can_hw_init).

Error/Edge case conf:0.85 **Q:** What are common mistakes or edge cases when calling ca_can_init()?
A: Common mistakes include passing a NULL pointer to cfg, calling ca_can_init() multiple times for the same CAN channel, or failing to properly initialize the hardware (e.g., due to incorrect register settings in ca_can_hw_init).

Behavior conf:0.90 **Q:** Is ca_can_init() thread-safe, ISR-safe, and blocking?
A: ca_can_init() is not thread-safe and should not be called from an ISR. It may be blocking if ca_can_hw_init() is blocking, as it typically involves hardware register configuration on peripherals like bxCAN (CAN1/CAN2 on STM32). It is intended to be called once during system startup.

`ca_can_recv`

Header: `caos/drivers/inc/can.h:41`
Source: `caos/drivers/src/can.c:141:145`
GUARD: `EN_CAN`

```
bool ca_can_recv (u8 num, ca_can_frame_t *frame)
```

Attempts to retrieve a single CAN frame from the hardware receive buffer for a specific CAN peripheral.

Parametri:

Nome	Tipo	Descrizione
num	u8	The index of the CAN peripheral to read from (e.g., 0 for CAN1, 1 for CAN2). Must correspond to a valid, initialized hardware peripheral.
frame	ca_can_frame_t *	A pointer to a structure where the received CAN data (ID, DLC, payload) will be stored. Must not be NULL.

Ritorna:
Returns true if a frame was successfully retrieved from the hardware buffer. Returns false if no frame is available, if the pointer is NULL, or if a hardware error occurred.

Note:

- This function is non-blocking; it checks the hardware status immediately and returns false if the receive buffer is empty, rather than waiting for a message to arrive. It is generally not thread-safe if multiple tasks access the same CAN peripheral simultaneously without external synchronization (like a mutex). Beginners often mistake this for a blocking function that waits for data; if you need to wait for a message, you must implement a polling loop or use an interrupt-driven approach. Ensure the CAN peripheral has been properly initialized via the driver's init function before calling this, otherwise, the hardware access may cause a system fault.

Uso:

- This function is typically used inside a periodic task or a dedicated CAN processing thread to poll for incoming messages. It is usually paired with a check for the peripheral's status or called within a loop that processes all pending frames until the buffer is empty. In a standard lifecycle, you initialize the CAN peripheral, enter a loop where you call this function to check for data, process the frame if true, and finally deinitialize the peripheral when the application shuts down.

Esempio:

```
ca_can_frame_t rx_frame;
// Poll the CAN1 peripheral for incoming messages
if (ca_can_recv(0, &rx_frame)) {
    // Successfully received a frame, process the data
    // rx_frame.id contains the message ID
    // rx_frame.data contains the payload
} else {
    // No frame available in the hardware buffer at this moment
}
```

Q&A — fine-tuning review *4/4 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I use ca_can_recv to receive CAN frames in a caOS application?
A: You should use ca_can_recv when you need to receive a CAN frame from a specific CAN interface in a blocking manner. It is suitable for applications where you want to wait until a frame is received, such as in a task that processes incoming CAN messages sequentially. The function is not suitable for use in ISRs because it is blocking and may cause scheduling issues.

Code example conf:0.90 **Q:** Can you provide a minimal C code example showing how to use ca_can_recv with caOS types?
A: ca_can_frame_t frame; bool result = ca_can_recv(0, &frame); if (result) { // Process the received frame } else { // Handle error }

Parameters conf:0.85 **Q:** What are the valid values for the 'num' parameter in ca_can_recv, and what happens if an invalid value is passed?

A: The 'num' parameter must be a valid CAN interface number, ranging from 0 up to the maximum number of CAN interfaces available in the system. If an invalid value is passed (e.g., greater than the maximum supported interface), the function will return false and will not attempt to read from any interface. The parameter must be within the range supported by the hardware (e.g., bxCAN supports up to 2 interfaces on STM32F4 series).

Return conf:0.90 **Q:** What does it mean when ca_can_recv returns false, and what are the possible causes?
A: ca_can_recv returns false when it fails to receive a frame. This can happen if the frame parameter is NULL, the CAN interface number is invalid, or if the hardware fails to deliver a frame (e.g., timeout or hardware error). It also returns false if the function is called from an ISR, as it is not designed to be called from interrupt context.

`ca_can_retune`

Header: `caos/drivers/inc/can.h:49`
Source: `caos/drivers/src/can.c:124:133`
GUARD: `EN_CAN`

```
void ca_can_retune(void)
```

Reinitializes CAN hardware peripherals to match new system clock settings.

Ritorna:
void

Note:

- This function is non-blocking and performs a hardware-level reset of the CAN controllers. It is not thread-safe and must not be called from an ISR, as it performs hardware initialization sequences that may take significant time. The primary precondition is that the CAN hardware must have been previously initialized via the standard driver startup sequence. A common beginner mistake is calling this function while CAN messages are actively being transmitted or received; since it re-initializes the hardware registers, any ongoing communication will be abruptly terminated, potentially leading to bus errors or lost frames.

Uso:

- This function is used exclusively during power management transitions, specifically when the system clock frequency is scaled up or down to save power. Because the CAN bit timing registers are derived from the peripheral clock (PCLK1), changing the system frequency invalidates the existing baud rate settings. It is typically called in a sequence alongside other 'retune' functions like ca_os_tick_retune and ca_uart_retune immediately after the system clock frequency has been modified by the power management module.

Esempio:

```
/* Example: Scaling system frequency down for power saving */
void adjust_system_power(void) {
    /* 1. Reduce system clock frequency */
    ca_os_clock_reduce_freq(SCALE_LOW);

    /* 2. Update time-dependent peripherals to match new clock */
    ca_os_tick_retune();
    ca_uart_retune();

    /* 3. Re-initialize CAN hardware to maintain correct baud rate */
```

```
    ca_can_retune();

    /* System is now running at lower frequency with synchronized peripherals */
}
```

Q&A — fine-tuning review *2/2 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** When should I call ca_can_retune and what is the primary reason for doing so?
A: You should call ca_can_retune during power management transitions, specifically after the system clock frequency has been modified. This is necessary because the CAN bit timing registers are derived from the peripheral clock (PCLK1), and changing the system frequency invalidates the existing baud rate settings.

Code example conf:0.95 **Q:** How do I correctly integrate ca_can_retune into a system clock frequency change sequence?
A: You must ensure no CAN messages are being transmitted or received before calling the function. A typical sequence looks like this:
void update_system_clock(u32 new_freq) { /* 1. Modify system clock frequency */ apply_clock_settings(new_freq);
/* 2. Retune peripherals */ ca_os_tick_retune(); ca_uart_retune(); ca_can_retune();
}

`ca_can_send`

Header: `caos/drivers/inc/can.h:40`
Source: `caos/drivers/src/can.c:135:139`
GUARD: `EN_CAN`

```
bool ca_can_send (u8 num, const ca_can_frame_t *frame)
```

Transmits a CAN frame through the specified hardware peripheral interface.

Parametri:

Nome	Tipo	Descrizione
`num`	`u8`	The index of the CAN peripheral to use. Must correspond to a valid, initialized hardware controller index.
`frame`	`const ca_can_frame_t *`	Pointer to the structure containing the CAN message data (ID, DLC, payload). Must not be NULL.

Ritorna:
Returns true if the frame was successfully queued for transmission, false if the pointer is NULL or the hardware failed to accept the frame.

Note:

- This function is a wrapper for the hardware-specific transmission routine. It is generally non-blocking, meaning it attempts to place the frame into the hardware transmit mailbox and returns immediately. It is not inherently thread-safe if multiple tasks access the same CAN peripheral simultaneously, so you should use a mutex or semaphore if your application architecture allows concurrent access. A common beginner mistake is passing a pointer to a local stack variable that goes out of scope before the hardware finishes sending, or failing to initialize the CAN peripheral via ca_can_hw_init before calling this function.

Uso:

- This function is used in the application layer to send CAN messages to external devices or other microcontrollers on the bus. It is typically used after the system has successfully initialized the CAN hardware using ca_can_hw_init. In a standard workflow, you prepare a ca_can_frame_t structure, populate its fields, and pass it to this function. It is often paired with ca_can_recv to implement full-duplex communication protocols.

Esempio:

```
ca_can_frame_t msg;
msg.id = 0x123;
msg.dlc = 8;
for(int i = 0; i < 8; i++) msg.data[i] = i;

// Attempt to send the frame on CAN peripheral 0
if (ca_can_send(0, &msg)) {
    // Frame successfully queued
} else {
    // Handle error: hardware busy or invalid parameters
}
```

Q&A — fine-tuning review *4/4 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I use ca_can_send and why is it important to check its return value?
A: You should use ca_can_send to transmit a CAN frame on a specific CAN interface (0 or 1). It is important to check the return value because a false return indicates either a NULL frame pointer or a failure to send the frame, which could be due to hardware issues like a full buffer or an uninitialized interface. This helps in debugging and ensuring reliable communication.

Code example conf:0.90 **Q:** Can you provide a minimal C code example using ca_can_send with caOS types?
A: ca_can_frame_t frame; frame.id = 0x123; frame.len = 8; frame.data[0] = 0xAA; frame.data[1] = 0xBB; // ... fill data bool success = ca_can_send(0, &frame); if (!success) { // Handle send failure }

Parameters conf:0.90 **Q:** What are the valid values for the 'num' parameter in ca_can_send and what happens if an invalid value is passed?
A: The 'num' parameter must be either 0 or 1, representing the CAN interface number. If any other value is passed, the behavior is undefined. The function assumes that only valid interface numbers are used, and passing an invalid value may lead to incorrect hardware access or system instability.

Return conf:0.95 **Q:** What does it mean when ca_can_send returns false and what are the possible causes?
A: ca_can_send returns false if the frame pointer is NULL or if the hardware send operation fails. Possible causes include a NULL frame pointer, an uninitialized or disabled CAN interface, a full hardware transmit buffer, or other hardware-level issues. The function does not block, so the failure may be due to resource unavailability at the time of call.

`ca_caos_config_hash`

Header: `caos/inc/caos_info.h:351`
Source: `caos/src/caos.c:437:445`
GUARD: `EN_CAOS_INFO`

```
void ca_caos_config_hash(u8 *digest)
```

Calculates a SHA-256 hash of the caOS configuration, excluding the volatile build version field.

Parametri:

Nome	Tipo	Descrizione
`digest`	`u8 *`	Pointer to a buffer of at least 32 bytes where the resulting 32-byte SHA-256 hash will be stored. Must not be NULL.

Ritorna:
This function does not return a value (void). The hash is written directly into the provided 'digest' buffer.

Note:

- This function is non-blocking and thread-safe, as it performs a read-only operation on a static configuration structure. It is safe to call from an ISR because it performs no I/O or synchronization primitives. The function specifically skips the 'build_ver' field at the start of the configuration struct to ensure the hash remains deterministic across different builds. The most common mistake is providing a buffer smaller than 32 bytes, which will lead to memory corruption, or passing a NULL pointer, which will trigger a hard fault.

Uso:

- This function is used to generate a unique fingerprint of the system configuration for integrity checks or version tracking. It is typically called when the system needs to verify that the current configuration matches a known state, such as during a boot-time self-test or when requested by a diagnostic CLI command. It is often paired with hex-encoding logic to display the hash to the user via serial output or stored in non-volatile memory for later comparison.

Esempio:

```
void display_config_integrity(void) {
    /* SHA-256 produces 32 bytes */
    u8 dg[32];

    /* Calculate the hash of the current system configuration */
    ca_caos_config_hash(dg);

    /* Print the hash to the console using the standard hexdump utility */
    ca_printf("Config Hash: ");
    ca_hexdump(dg, 32);
    ca_printf("\n");
}
```

Q&A — fine-tuning review *3/3 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** When should I use ca_caos_config_hash in my application?
A: You should use this function for system integrity checks. It is ideal for verifying if the current configuration matches a known state, generating a unique fingerprint for device settings, or detecting unauthorized modifications to the configuration structure.

Code example conf:1.00 **Q:** How do I implement a call to ca_caos_config_hash in C?
A: Ensure you provide a buffer of at least 32 bytes. Example: u8 hash_buffer[32]; ca_caos_config_hash(hash_buffer);

Parameters conf:1.00 **Q:** What are the requirements for the 'digest' parameter in ca_caos_config_hash?
A: The 'digest' parameter must be a pointer to a buffer of at least 32 bytes (CA_CONFIG_HASH_LEN). Providing a buffer smaller than 32 bytes is invalid and will cause a memory corruption (buffer overflow) when the function writes the SHA-256 hash.

ca_caos_get_config

Header: caos/inc/caos_info.h:327
Source: caos/src/caos.c:432:434
GUARD: EN_CAOS_INFO

```
ca_caos_config_status *ca_caos_get_config(void)
```

Retrieves a pointer to the global system configuration structure.

Ritorna:
A pointer to a ca_caos_config_status structure. This pointer is always valid as it points to a static global configuration object defined within the OS core.

Note:

- This function is thread-safe and non-blocking because it simply returns the address of a pre-allocated static structure. It is safe to call from both tasks and ISRs. The configuration is typically populated during the system boot sequence before the scheduler starts. A common mistake is attempting to modify the configuration values at runtime without verifying if the specific fields are intended to be read-only or dynamic; always check the structure definition to ensure you are not violating system constraints.

Uso:

- This function is used when a task or driver needs to access system-wide parameters, such as network buffer sizes or default port numbers, to initialize local resources. It is typically called during the initialization phase of a module, often paired with memory allocation functions like ca_memory_allocate to size buffers based on the retrieved configuration. By using this function, you ensure that your module remains synchronized with the global system settings defined in the main configuration.

Esempio:

```
void init_network_module(void) {
    // Retrieve the global configuration to check buffer requirements
    ca_caos_config_status *cfg = ca_caos_get_config();

    // Use the retrieved configuration to allocate a buffer for network tasks
    void *net_buffer = ca_memory_allocate(cfg->http_req_buf_size);

    if (net_buffer != NULL) {
        // Proceed with module initialization using the allocated memory
        // ...
    } else {
        // Handle allocation failure
        ca_printf("Failed to allocate network buffer of size %d\n", cfg->
    http_req_buf_size);
    }

    // Example of using the config hash for integrity verification
    u8 hash[32];
    ca_caos_config_hash(hash);
    ca_printf("Config hash computed successfully\n");
}
```

Q&A — fine-tuning review *3/3 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** When should I call ca_caos_get_config and what is its primary purpose?
A: You should call this function when a task or driver needs to access system-wide parameters, such as network buffer sizes or default port numbers, to initialize local resources. It

is typically used during the initialization phase of a module to ensure that local resources remain synchronized with the global system settings defined in the main configuration.

Code example conf:0.90 **Q:** How do I access the system configuration to determine a buffer size?
A: You can retrieve the configuration pointer and access its members directly. Example: ca_caos_config_status *cfg = ca_caos_get_config(); u32 buffer_size = cfg->network_buffer_size; void *ptr = ca_memory_allocate(buffer_size);

Return conf:1.00 **Q:** What does the return value of ca_caos_get_config represent, and can it return NULL?
A: The function returns a pointer to a ca_caos_config_status structure. This pointer is always valid as it points to a static global configuration object defined within the OS core; therefore, it cannot return NULL or fail.

`ca_ccm_get_free`

Header: `caos/inc/scheduler.h:70`
Source: `caos/src/scheduler.c:292:294`
GUARD: `EN_SCHEDULER`

```
u32 ca_ccm_get_free(void)
```

Returns the amount of free stack space available for the current task in bytes.

Ritorna:
A u32 value representing the number of bytes remaining in the current task's stack before it hits the limit. If the stack is exhausted or corrupted, this value may be zero or misleading.

Note:

- This function is non-blocking and thread-safe as it reads internal task control block (TCB) variables. It is safe to call from an ISR, though it only provides information about the currently executing task context. The most common beginner mistake is assuming this value is static; stack usage changes dynamically as functions are called and local variables are allocated. Always ensure the system is initialized before calling this, as it relies on the internal CCM (Core Coupled Memory) management structures being active.

Uso:

- This function is typically used for system monitoring, debugging, or implementing stack overflow protection mechanisms. It is often paired with ca_ccm_get_used to calculate the total stack footprint of a task. Developers use these functions during the development phase to tune stack sizes for specific tasks, ensuring that the allocated memory is sufficient for the worst-case call stack depth without wasting precious RAM.

Esempio:

```
/* Monitor stack usage for the current task */
#include "caos.h"

void task_monitor_stack(void) {
    u32 free_bytes = ca_ccm_get_free();
    u32 used_bytes = ca_ccm_get_used();

    /* Log the stack status to the console */
    ca_printf("Stack Status: Used %u bytes, Free %u bytes\n", used_bytes,
    free_bytes);

    /* Check if we are dangerously close to a stack overflow */
    if (free_bytes < 128) {
```

```
        /* Trigger a system warning or take corrective action */
        ca_printf("Warning: Low stack space!\n");
    }
}
```

Q&A — fine-tuning review *3/3 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** When should I use ca_ccm_get_free and what is the primary purpose of this function?
A: You should use ca_ccm_get_free during the development phase for system monitoring, debugging, or implementing stack overflow protection. It is used to tune task stack sizes to ensure allocated memory is sufficient for worst-case call stack depth without wasting RAM. It is often paired with ca_ccm_get_used to calculate the total stack footprint.

Code example conf:0.95 **Q:** How do I implement a simple check for the current task's remaining stack space using caOS types?
A: You can call the function directly within your task logic. Example: { u32 free_space = ca_ccm_get_free(); if (free_space < 128) { /* Handle low stack warning */ } }

Return conf:1.00 **Q:** What does the u32 return value represent, and are there scenarios where the returned value might be unreliable?
A: The return value is a u32 representing the number of bytes remaining in the current task's stack. If the stack is exhausted or corrupted, the value may be zero or misleading. Additionally, the value is dynamic and changes as functions are called and local variables are allocated, so it should not be treated as a static value.

`ca_ccm_get_used`

Header: `caos/inc/scheduler.h:75`
Source: `caos/src/scheduler.c:296:298`
GUARD: `EN_SCHEDULER`

```
u32 ca_ccm_get_used(void)
```

Returns the number of bytes currently used in the CCM (Core Coupled Memory) stack.

Ritorna:
Returns a u32 representing the total number of bytes currently occupied by the stack within the CCM memory region.

Note:

- This function is non-blocking and thread-safe as it performs a simple arithmetic subtraction on internal memory management structures. It is safe to call from an ISR, as it does not involve any OS primitives, mutexes, or complex logic. The function assumes that the CCM memory management system has been correctly initialized by the system startup code. A common mistake is assuming this value represents the 'peak' usage; it only reflects the current stack pointer position relative to the base address, not the maximum depth reached during execution.

Uso:

- This function is primarily used for system diagnostics, debugging, and monitoring stack health. It is often paired with ca_ccm_get_free to calculate the total stack size or to verify if a task is approaching a stack overflow condition. Developers typically use this during the development phase to tune stack sizes for specific tasks, ensuring that the allocated memory is sufficient without being excessively wasteful. It is also used in logging routines to report memory pressure to a CLI or remote monitoring interface.

Esempio:

```c
/* Check if the current CCM stack usage is within safe limits */
u32 used_bytes = ca_ccm_get_used();
u32 free_bytes = ca_ccm_get_free();

/* Log the memory status to the system console */
ca_printf("CCM Stack Status: Used %lu bytes, Free %lu bytes\r\n", used_bytes,
    free_bytes);

/* Simple safety check: if free memory is critically low, trigger a warning */
if (free_bytes < 128) {
    /* Perform emergency action or log a critical error */
    ca_printf("CRITICAL: CCM stack is nearly exhausted!\r\n");
}
```

Q&A — fine-tuning review *3/3 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** When should I use ca_ccm_get_used in my application?
A: You should use this function during development for system diagnostics, debugging, and monitoring stack health. It is particularly useful for tuning task stack sizes to ensure they are sufficient without being wasteful, or for logging memory pressure to a CLI or remote monitoring interface to detect potential stack overflow conditions.

Code example conf:1.00 **Q:** How can I check the current CCM stack usage in my code?
A: You can call the function directly as shown here: u32 used_bytes = ca_ccm_get_used();

Return conf:1.00 **Q:** What does the u32 return value represent, and can this function fail?
A: The return value is a u32 representing the total number of bytes currently occupied by the stack within the CCM memory region. It does not represent the peak usage, only the current stack pointer position relative to the base address. The function is non-blocking, thread-safe, and safe to call from an ISR; it does not fail, provided the CCM memory management system was correctly initialized at startup.

`ca_cli_callto_init`

Header: `caos/inc/callto.h:40`
Source: `caos/src/callto.c:246:251`
GUARD: `EN_CALLTO`

```c
void ca_cli_callto_init(void)
```

Registers the 'callto' command handler into the system CLI interface.

Ritorna:
This function returns nothing (void).

Note:

- This function is non-blocking and thread-safe because it uses an internal static flag to ensure the registration happens exactly once. It is not intended to be called from an ISR, as it performs memory registration operations that should occur during system initialization. The most common mistake is calling this function before the CLI system itself has been initialized via ca_cli_init, which will result in the registration failing or causing a system fault. Always ensure the CLI subsystem is ready before attempting to register specific command nodes.

Uso:

- This function is used to extend the Command Line Interface (CLI) functionality by adding the 'callto' command. It is typically called during the system startup sequence, often

wrapped in a macro like EVAL_CLI_CALLTO to ensure it only executes if the feature is enabled in the project configuration. It pairs with ca_cli_init, which must be called first to prepare the CLI infrastructure, and is followed by ca_cli_create_thread to start the CLI processing task.

Esempio:

```
/* Initialize the core CLI system first */
ca_cli_init();

/* Register the callto command handler if enabled in configuration */
ca_cli_callto_init();

/* Create the CLI thread to start processing user input */
ca_cli_create_thread();

/* Now the CLI is ready to accept commands, including 'callto' */
```

Q&A — fine-tuning review *2/2 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** When should I call ca_cli_callto_init and what are the prerequisites?
A: You should call ca_cli_callto_init during the system startup sequence to register the 'callto' command. It is critical that you call ca_cli_init first to prepare the CLI infrastructure; calling it before the CLI system is initialized will cause the registration to fail or trigger a system fault. It is not intended for use within an ISR.

Code example conf:0.90 **Q:** How do I correctly initialize the CLI and register the 'callto' command in my main startup routine?
A: You must initialize the CLI subsystem before registering the command. Example: void system_init(void) { ca_cli_init(); EVAL_CLI_CALLTO; ca_cli_create_thread(); }

`ca_cli_char_class`

Header: `caos/inc/cli.h:137`
Source: `caos/src/cli.c:1316:1319`
GUARD: `EN_CLI`

```
u8 ca_cli_char_class(u8 byte)
```

Classifies a single byte into a command-line category (e.g., command, typo, escape, erase) based on the internal CLI character table.

Parametri:

Nome	Tipo	Descrizione
`byte`	`u8`	The raw ASCII or byte value to classify. Valid range is 0-255, though only 0-127 are mapped to specific classes.

Ritorna:
Returns a u8 representing the character class (e.g., CH_CMD, CH_TYPO, CH_ERASE, CH_ESC). Returns CH_NONE if the byte is >= 128.

Note:

- This function is a non-blocking, thread-safe lookup table access. It is safe to call from an ISR because it performs no I/O, locking, or complex logic. The primary precondition is that the caOS CLI system must be initialized, though the table itself is static and always available. A common mistake is assuming this function validates input; it only classifies it, so you must still handle unexpected characters or non-printable bytes in your application

logic. Because it is a simple array lookup, it is extremely fast and deterministic, making it ideal for high-frequency character processing.

Uso:

- This function is used to build robust command-line interfaces or network transport parsers that need to distinguish between valid command characters, control sequences, and typos. It is typically used inside a character processing loop where you receive a byte via ca_cli_rx_byte or a UART handler, classify it to determine if it should be buffered or trigger an action (like an escape sequence), and then potentially update the CLI state machine. It ensures that different parts of the system, such as a local console and an SSH transport, share the exact same rules for what constitutes a valid command, preventing inconsistent behavior between different input sources.

Esempio:

```c
/* Example: Processing an incoming byte from a CLI stream */
void process_cli_input(u8 c) {
    u8 class = ca_cli_char_class(c);

    if (class == CH_ERASE) {
        /* Logic to remove last character from buffer */
        /* Use ca_put to send backspace sequence to terminal */
        ca_put("\b \b", 3);
    } else if (class == CH_ESC) {
        /* Transition CLI state machine to escape mode */
    } else if (class == CH_CMD) {
        /* Add character to command buffer */
        ca_cli_hist_add(c);
    } else if (class == CH_TYPO) {
        /* Increment internal typo counter */
        /* Use ca_cli_typo_count to track statistics */
    } else {
        /* Ignore or handle CH_NONE */
    }
}
```

Q&A — fine-tuning review *4/4 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** When should I use ca_cli_char_class in my application?
A: You should use it when building command-line interfaces or network transport parsers to distinguish between valid command characters, control sequences, and typos. It is typically used within a character processing loop to decide whether a received byte should be buffered or trigger a specific action, such as an escape sequence.

Code example conf:0.90 **Q:** How do I implement a basic character classification check using caOS types?
A: u8 input = 0x0D; u8 class = ca_cli_char_class(input); if (class == CH_CMD) { /* handle command */ }

Parameters conf:1.00 **Q:** What are the constraints for the byte parameter in ca_cli_char_class?
A: The parameter is a u8 representing the raw ASCII or byte value. While the valid range is 0-255, only values from 0-127 are mapped to specific classes; values >= 128 will result in a CH_NONE return.

Return conf:1.00 **Q:** What do the return values of ca_cli_char_class represent and when does it return CH_NONE?
A: The function returns a u8 representing the character class, such as CH_CMD, CH_TYPO, CH_ERASE, or CH_ESC. It returns CH_NONE if the input byte is 128 or greater, as these values are outside the mapped range.

ca_cli_create_thread

Header: caos/inc/cli.h:82
Source: caos/src/cli.c:1185:1201
GUARD: EN_CLI

```
u32 ca_cli_create_thread(void)
```

Initializes and spawns the Command Line Interface (CLI) background task within the RTOS.

Ritorna:
Returns a u32 task index (handle) representing the created thread, or 0xFFFFFFFF if the CLI module is disabled or the thread creation fails.

Note:

- This function is non-blocking as it merely requests the RTOS scheduler to allocate resources and start the task. It is not thread-safe to call this from an ISR, and it must only be called after the CLI module has been initialized via ca_cli_init. A common beginner mistake is calling this function before initializing the CLI buffers or setting the output sender, which leads to undefined behavior or immediate task crashes. Ensure that the system has enough stack memory available, as the task is created with STACK_MEDIUM size.

Uso:

- This function is typically used during the system startup phase, usually within the main initialization sequence or a dedicated system configuration task. It is always paired with ca_cli_init to prepare the environment and ca_cli_set_sender to define where the CLI output should be directed. Once called, the CLI thread runs in the background at a low priority (CA_TH_LEVEL3), allowing the system to process user commands asynchronously without blocking critical real-time tasks.

Esempio:

```
/* Initialize the CLI environment before spawning the thread */
ca_cli_init(4096);

/* Define the output destination for the CLI */
ca_cli_set_sender(STDOUT);

/* Spawn the background thread to handle user input */
u32 cli_handle = ca_cli_create_thread();

if (cli_handle == 0xFFFFFFFF) {
    /* Handle error: CLI could not be started */
    while(1);
}

/* Register the CLI command node after the thread is created */
ca_cli_register(&s_cli_node);
```

Q&A — fine-tuning review *5/5 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I call ca_cli_create_thread() in my caOS application?
A: You should call ca_cli_create_thread() after initializing the CLI subsystem. It creates a low-priority thread to handle command-line interface tasks. The function is meant to be called once during application initialization, not repeatedly.

Code example conf:0.90 **Q:** Can you show a minimal example of how to use ca_cli_create_thread() in a caOS application?

A: u32 thread_id = ca_cli_create_thread(); if (thread_id != 0xFFFFFFFF) { // Thread created successfully } else { // Error occurred, CLI not enabled or thread creation failed }

Return conf:0.95 **Q:** What does it mean when ca_cli_create_thread() returns 0xFFFFFFFF?
A: A return value of 0xFFFFFFFF indicates an error occurred during thread creation. Common causes include the CLI not being enabled (g_enabled is false) or a failure in the thread creation process itself.

Error/Edge case conf:0.85 **Q:** What are the most common mistakes when using ca_cli_create_thread()?
A: Common mistakes include calling the function before CLI initialization, calling it from an ISR (since it's not ISR-safe), or calling it multiple times which may lead to undefined behavior. Also, calling it in a preemption-critical section can cause issues.

Behavior conf:0.90 **Q:** Is ca_cli_create_thread() blocking or non-blocking, and is it safe to call from an ISR?
A: ca_cli_create_thread() is a blocking function and must not be called from an ISR. It is also not thread-safe or preemption-safe, so it should not be invoked in critical sections or during interrupt handling. The function is designed to be called during normal application initialization.

`ca_cli_data_from_isr`

Header: `caos/inc/cli.h:198`
Source: `caos/src/cli.c:1037:1059`
GUARD: `EN_CLI`

```
1 void ca_cli_data_from_isr(const u8 *data, u32 len)
```

Safely passes incoming data from an Interrupt Service Routine (ISR) to the CLI processing queue.

Parametri:

Nome	Tipo	Descrizione
`data`	`const u8 *`	Pointer to the raw byte array received (e.g., from UART). Must not be NULL.
`len`	`u32`	Number of bytes to copy. If greater than the internal buffer size (125 bytes), it will be truncated.

Ritorna:
void. This function does not return a status code; if the queue is full, it increments an internal drop counter.

Note:

- This function is specifically designed to be called from within an ISR, such as a UART RX interrupt handler. It is non-blocking, meaning it will not pause the CPU if the queue is full, ensuring the interrupt remains fast and responsive. It is thread-safe regarding the queue interaction, but it uses a shared static buffer (g_isr_buffer), so it cannot be called from multiple different ISRs simultaneously without risking data corruption. The most common mistake is passing a pointer to a local stack variable that goes out of scope or failing to ensure the CLI system is initialized before the interrupt is enabled.

Uso:

- This function is the bridge between hardware peripherals and the CLI task. It is typically called inside the UART RX interrupt callback after receiving a character or a packet. It

pairs with the CLI task's main loop, which uses a function like 'ca_queue_static_receive' to pull the data out of the queue for processing. You should initialize the CLI system using 'ca_cli_init' first, then enable the UART interrupt, and finally call this function inside the ISR to feed the CLI engine.

Esempio:

```
void UART_RX_ISR_Handler(void) {
    /* Assume we read a byte from the hardware register */
    u8 rx_byte = 0; /* Read from hardware register here */

    /* Pass the byte to the CLI system safely from the ISR */
    ca_cli_data_from_isr(&rx_byte, 1);

    /* If the queue was full, the internal drop counter is incremented
    automatically */
}
```

Q&A — fine-tuning review *5/5 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I use ca_cli_data_from_isr() in my embedded application?
A: You should call ca_cli_data_from_isr() from an ISR when you need to pass data from the interrupt context to the CLI task for processing. This function allows you to avoid blocking the ISR while ensuring that the CLI task can handle the data asynchronously.

Code example conf:0.90 **Q:** Can you show a minimal example of how to use ca_cli_data_from_isr() in an ISR?
A: u8 buffer[10]; // Assume buffer is filled with data in ISR ca_cli_data_from_isr(buffer, 10);

Parameters conf:0.95 **Q:** What are the valid values for the 'data' and 'len' parameters in ca_cli_data_from_isr()?
A: The 'data' parameter must be a valid pointer to data (not NULL). The 'len' parameter must be greater than 0. If either condition is not met, the function returns without doing anything.

Error/Edge case conf:0.85 **Q:** What happens if I call ca_cli_data_from_isr() with invalid parameters or in the wrong context?
A: If the 'data' parameter is NULL or 'len' is 0, the function returns without performing any action. If called from a task instead of an ISR, the behavior is undefined. If the internal queue is full, new data is dropped and g_dropped is incremented.

Behavior conf:0.90 **Q:** Is ca_cli_data_from_isr() blocking or non-blocking, and is it safe to call from a task?
A: The function is non-blocking and must only be called from an ISR. It is not thread-safe and should not be used by normal tasks. It is designed to be ISR-safe, but calling it from a task may lead to undefined behavior.

`ca_cli_exec_capture`

Header: `caos/inc/cli.h:234`
Source: `caos/src/cli.c:1062:1119`
GUARD: `EN_CLI`

```
bool ca_cli_exec_capture(const char *cmd, char *out_buf, u16 buf_size,
    u32 timeout_ms)
```

Executes a CLI command and captures its output into a provided buffer instead of the standard console.

Parametri:

Nome	Tipo	Descrizione
`cmd`	`const char *`	The CLI command string to execute. Must be a null-terminated string.
`out_buf`	`char *`	Pointer to the memory buffer where the command output will be stored. Must be at least 2 bytes.
`buf_size`	`u16`	Size of the output buffer in bytes. If the command output exceeds this, it will be truncated.
`timeout_ms`	`u32`	Maximum time in milliseconds to wait for the command to complete before returning failure.

Ritorna:
Returns true if the command executed and output was captured successfully within the timeout. Returns false if parameters are invalid, the CLI system is disabled, or the command timed out.

Note:

- This function is blocking; it suspends the calling thread until the command finishes or the timeout expires. It is NOT safe to call from an ISR because it uses semaphores and thread-level delays. The function internally manages the redirection of stdout, so it is not re-entrant; you cannot call this from two different threads simultaneously. A common mistake is providing a buffer that is too small for the expected output, leading to silent truncation, or setting a timeout that is too short for commands that perform heavy processing or I/O. Ensure the CLI system is initialized via ca_cli_init before calling this.

Uso:

- Use this function when you need to programmatically retrieve the result of a CLI command, such as displaying system status on a web page or logging diagnostic data to a file. It is typically used in a request-response cycle: you call it to trigger a command, wait for the result, and then process the captured string. It pairs with the CLI system's internal state management, automatically restoring the original stdout sender once the capture is complete, ensuring the system returns to its normal state even if the command fails.

Esempio:

```
char buffer[256];
/* Ensure CLI is initialized before use */
if (ca_cli_is_enabled()) {
    /* Execute 'status' command and wait up to 500ms for the result */
    if (ca_cli_exec_capture("status", buffer, sizeof(buffer), 500U)) {
        /* Successfully captured output, now process the buffer */
        ca_http_resp_puts(resp, buffer);
    } else {
        /* Handle error: command failed or timed out */
        ca_http_resp_puts(resp, "Error: CLI capture failed");
    }
}
```

Q&A — fine-tuning review *6/6 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I use ca_cli_exec_capture to execute CLI commands?
A: You should use ca_cli_exec_capture when you need to execute a CLI command and capture its output in a buffer for further processing. It is useful for obtaining textual responses from CLI commands in a controlled and predictable way.

Code example conf:0.90 **Q:** Can you show a minimal example of how to use ca_cli_exec_capture with caOS types?
A: char buffer[128]; bool success = ca_cli_exec_capture("help", buffer, 128, 1000); if (success) { // Use buffer content }

Parameters conf:0.90 **Q:** What are the valid and invalid values for the buf_size parameter?
A: The buf_size must be at least 2 bytes to accommodate the null terminator. If buf_size is less than 2, the function will fail. Valid values are any u16 greater than or equal to 2.

Return conf:0.85 **Q:** What does it mean when ca_cli_exec_capture returns false?
A: A return value of false indicates that the command either failed due to invalid parameters or timed out before completion. It could also mean that the CLI system was not enabled or the semaphore was not initialized.

Error/Edge case conf:0.80 **Q:** What are common mistakes when using ca_cli_exec_capture?
A: Common mistakes include passing a NULL pointer for cmd or out_buf, using a buf_size less than 2, calling the function from an ISR, or not ensuring that the CLI system is enabled and the semaphore is initialized. Also, improper handling of timeout values can lead to indefinite blocking.

Behavior conf:0.90 **Q:** Is ca_cli_exec_capture thread-safe and ISR-safe?
A: No, ca_cli_exec_capture is not thread-safe and not ISR-safe. It uses global variables such as g_exec_done, g_cap, and g_sender, which can cause race conditions in a multi-threaded environment or lead to undefined behavior if called from an ISR.

`ca_cli_exec_capture_stream`

Header: `caos/inc/cli.h:249`
Source: `caos/src/cli.c:1121:1177`
GUARD: `EN_CLI`

```
bool ca_cli_exec_capture_stream(const char *cmd, sender out_sender, u32
    timeout_ms)
```

Executes a CLI command and redirects its output stream to a specific sender until completion or timeout.

Parametri:

Nome	Tipo	Descrizione
`cmd`	`const char *`	The CLI command string to execute. Must not be NULL.
`out_sender`	`sender`	The destination sender (e.g., a network socket or UART) where the command output will be streamed. Must not be NULL.
`timeout_ms`	`u32`	Maximum time in milliseconds to wait for the command to finish and the output stream to drain.

Ritorna:
Returns true if the command executed and the output stream finished within the timeout period; returns false if the command failed, the timeout expired, or the CLI system is disabled.

Note:

- This function is blocking and must be called from a task context, never from an ISR. It is thread-safe regarding the CLI state, but users must ensure that the 'out_sender' remains valid for the duration of the call. A common mistake is failing to account for the output drain time; even if the command finishes, the function waits for the stdout queue to empty, so the timeout must be generous enough to cover both execution and transmission latency. It internally manages the CLI output redirection, so it is critical that no other task attempts to modify the CLI sender while this function is active. If the timeout expires, the function still attempts to clean up the redirection, but the caller must handle the potential partial output state.

Uso:

- This function is typically used to bridge CLI output to external interfaces like SSH or HTTP responses. The standard sequence involves: 1) Initializing a mutex to protect the session/response object, 2) Locking the mutex to assign the session, 3) Calling this function to stream the command output, and 4) Locking the mutex again after the function returns to safely clear the session pointer. This ensures that the 'drain' phase of the function completes before the session object is destroyed or reused, preventing dangling pointers and ensuring that the background drain thread has finished accessing the session context.

Esempio:

```c
/* Example: Executing a command and streaming output to a network sender */
#include "caos.h"

/* Assume s_stream_lock is initialized elsewhere */
void run_remote_command(const char *cmd, sender net_sender) {
    /* Protect the session context during the streaming operation */
    ca_mutex_lock(&s_stream_lock);
    /* Assign session context here */
    ca_mutex_unlock(&s_stream_lock);

    /* The function blocks until the command finishes and the output queue is drained */
    bool success = ca_cli_exec_capture_stream(cmd, net_sender, 5000U);

    /* Re-acquire lock to safely clear session pointer after streaming is done */
    ca_mutex_lock(&s_stream_lock);
    /* Clear session context here */
    ca_mutex_unlock(&s_stream_lock);

    if (!success) {
        ca_printf("Command failed or timed out\n");
    }
}
```

Q&A — fine-tuning review *6/6 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** When should I use ca_cli_exec_capture_stream in my caOS application?
A: You should use this function when you need to bridge CLI command output to an external interface, such as an SSH or HTTP response. It is designed to execute a command and stream its output to a specific sender until completion or timeout.

Code example conf:0.90 **Q:** Provide a minimal C example of how to call ca_cli_exec_capture_stream.
A: void run_cmd(sender my_sender) { cstr cmd = "sys_info"; u32 timeout = 5000; bool success = ca_cli_exec_capture_stream(cmd, my_sender, timeout); }

Parameters conf:1.00 **Q:** What are the requirements for the 'out_sender' parameter?
A: The 'out_sender' must not be NULL. It represents the destination for the command output, such as a network socket or UART. You must ensure this sender remains valid for the entire duration of the function call.

Return conf:1.00 **Q:** What does a return value of false indicate for ca_cli_exec_capture_stream?
A: A return value of false indicates that the command failed, the timeout period expired, or the CLI system is currently disabled.

Error/Edge case conf:1.00 **Q:** What is a common mistake when setting the timeout_ms parameter?
A: A common mistake is failing to account for the output drain time. The function waits for the stdout queue to empty after the command finishes, so the timeout must be generous enough to cover both the command execution time and the transmission latency.

Behavior conf:1.00 **Q:** Is ca_cli_exec_capture_stream safe to call from an ISR?
A: No, this function is blocking and must be called from a task context. It is never safe to call from an ISR.

---

ca_cli_filtered_count

Header: caos/inc/cli.h:110
Source: caos/src/cli.c:1474:1474
GUARD: EN_CLI

```
u32 ca_cli_filtered_count(void)
```

Returns the total number of CLI input characters that were filtered out by the system.

Ritorna:
Returns a u32 value representing the count of characters discarded by the CLI filtering logic. This value is non-negative and increments whenever the CLI subsystem rejects an incoming byte.

Note:

- This function is non-blocking and thread-safe as it simply returns the current value of a global counter. It can be safely called from both standard tasks and Interrupt Service Routines (ISRs). The primary precondition is that the CLI subsystem must have been initialized via ca_cli_init. A common mistake is assuming this count represents valid commands; it specifically tracks 'filtered' (discarded) data, which is useful for debugging noise on the serial line or identifying malformed input streams.

Uso:

- This function is typically used in diagnostic or monitoring tasks to assess the quality of the serial communication link. It is often paired with ca_cli_stats to provide a comprehensive overview of the CLI subsystem's health. Developers use it to detect if the input buffer is being flooded with unexpected characters or if the CLI parser is rejecting data due to protocol violations.

Esempio:

```
/* Check CLI health periodically */
void monitor_task(void *pvParameters) {
    /* Ensure CLI is initialized before monitoring */
    ca_cli_init();

    while (1) {
        u32 filtered = ca_cli_filtered_count();

        if (filtered > 1000) {
            /* Log a warning if too many characters are being filtered */
            ca_printf("Warning: High CLI noise detected. Filtered count: %lu\n",
    filtered);
        }

        /* Wait for 1 second before checking again */
        ca_os_delay_ms(1000);
    }
}
```

Q&A — fine-tuning review *3/3 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** When should I use ca_cli_filtered_count in my caOS application?
A: You should use this function in diagnostic or monitoring tasks to assess the quality of your serial communication link. It is useful for identifying noise on the line, detecting if the input buffer is being flooded with unexpected characters, or determining if the CLI parser is rejecting data due to protocol violations.

Code example conf:1.00 **Q:** How do I implement a simple check for discarded CLI characters in a task?
A: You can call the function directly as shown here:
void monitor_task(void) { u32 discarded_count = ca_cli_filtered_count(); if (discarded_count > 0) { /* Handle or log the diagnostic data */ } }

Return conf:1.00 **Q:** What does the u32 return value represent, and are there any failure states?
A: The return value is a non-negative u32 representing the total count of characters discarded by the CLI filtering logic. The function does not have failure states; it is non-blocking and thread-safe. The only precondition is that ca_cli_init must have been called previously.

`ca_cli_get_hook`

Header: `caos/inc/cli.h:222`
Source: `caos/src/cli.c:966:966`
GUARD: `EN_CLI`

```
ca_cli_hook_t ca_cli_get_hook(void)
```

Retrieves the currently registered CLI hook function pointer.

Ritorna:
Returns a 'ca_cli_hook_t' function pointer. If no hook has been set via ca_cli_set_hook, it returns NULL.

Note:

- This function is non-blocking and thread-safe as it performs a simple read of a global variable. It is safe to call from an ISR, though it is rarely necessary to do so. The primary precondition is that the CLI system must be initialized, and a hook must have been previously assigned using ca_cli_set_hook; otherwise, you will receive a NULL pointer. A common mistake is failing to check if the returned pointer is NULL before attempting to call it, which will result in a hard fault or system crash.

Uso:

- This function is typically used by the internal CLI engine or custom command handlers to retrieve the current hook function that processes specific CLI events or data. It is often paired with ca_cli_set_hook during the system initialization phase to define custom behavior for the CLI. Developers use this to dynamically inspect or verify which callback is currently active in the CLI processing chain, ensuring that the system logic remains consistent with the intended CLI behavior.

Esempio:

```
/* Define a custom hook function */
void my_custom_hook(void) {
    /* Custom logic for CLI event */
}

void setup_cli_system(void) {
    /* Register the hook */
```

```
    ca_cli_set_hook(my_custom_hook);

    /* Retrieve and verify the hook */
    ca_cli_hook_t current_hook = ca_cli_get_hook();

    if (current_hook != NULL) {
        /* Hook is valid, proceed with CLI initialization */
        ca_cli_init();
    } else {
        /* Handle error: hook not set */
    }
}
```

Q&A — fine-tuning review *3/3 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** When should I use ca_cli_get_hook in my caOS application?
A: You should use this function when you need to retrieve the currently registered CLI hook function pointer, typically to inspect or verify which callback is active in the CLI processing chain. It is commonly used by custom command handlers or the internal CLI engine to dynamically manage CLI event processing.

Code example conf:1.00 **Q:** How do I safely retrieve and execute the CLI hook in C?
A: You must check the returned pointer for NULL to avoid a hard fault. Example: ca_cli_hook_t my_hook = ca_cli_get_hook(); if (my_hook != NULL) { my_hook(); }

Return conf:1.00 **Q:** What does the return value of ca_cli_get_hook represent and what causes it to return NULL?
A: The function returns a 'ca_cli_hook_t' function pointer. It returns NULL if no hook has been previously assigned using ca_cli_set_hook or if the CLI system has not been initialized. Failing to check for this NULL return before calling the pointer will result in a system crash.

`ca_cli_get_sender`

Header: `caos/inc/cli.h:44`
Source: `caos/src/cli.c:116:116`
GUARD: `EN_CLI`

```
sender ca_cli_get_sender(void)
```

Retrieves the current sender handle configured for the CLI module.

Ritorna:
Returns a 'sender' type handle, which is an identifier used by the OS to route messages or responses back to the CLI interface.

Note:

- This function is non-blocking and thread-safe as it simply returns a stored global variable. It is safe to call from both threads and ISRs, provided the CLI module has been initialized. The most common mistake is assuming the returned sender is valid before calling ca_cli_init; if the CLI is not initialized, the returned handle may be null or invalid, leading to failed message routing in subsequent calls.

Uso:

- This function is typically used when you need to send data or status updates back to the CLI console from a background task or a callback. You retrieve the sender handle using this function and then pass it to other caOS communication functions (like message queues

or logging) to ensure the output is directed to the active CLI session. It is often paired with ca_cli_set_sender if you need to redirect CLI output to a different destination, such as a remote network socket or a different UART port.

Esempio:

```c
/* Retrieve the current CLI sender to respond to a command */
sender cli_sender = ca_cli_get_sender();

/* Check if the sender is valid before attempting to send data */
if (cli_sender != NULL) {
    /* Use the retrieved sender to send a status message back to the CLI */
    /* ca_message_send(cli_sender, "Command processed successfully\n"); */
} else {
    /* Handle the error: CLI sender not initialized or unavailable */
}
```

Q&A — fine-tuning review *3/3 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** When and why should I use ca_cli_get_sender in my application?
A: You should call ca_cli_get_sender when you need to send data or status updates back to the CLI console from a background task or an ISR. It retrieves the sender handle required to route messages or responses to the active CLI session, ensuring that communication functions correctly direct output to the user interface.

Code example conf:0.95 **Q:** How do I retrieve the CLI sender handle and use it in a task?
A: You can retrieve the handle and store it in a variable of type 'sender' as shown: void my_task(void) { sender cli_handle = ca_cli_get_sender(); if (cli_handle != 0) { /* Proceed to use cli_handle for routing messages */ } }

Return conf:1.00 **Q:** What does the return value of ca_cli_get_sender represent, and what causes it to be invalid?
A: The function returns a 'sender' type handle, which acts as an identifier for the OS to route messages back to the CLI interface. If the CLI module has not been initialized via ca_cli_init, the returned handle may be null or invalid, which will cause subsequent message routing calls to fail.

`ca_cli_hist_add`

Header: `caos/inc/cli.h:173`
Source: `caos/src/cli.c:1335:1345`
GUARD: `EN_CLI`

```c
void ca_cli_hist_add(const char *line)
```

Adds a command string to the CLI history buffer for future recall.

Parametri:

Nome	Tipo	Descrizione
`line`	`const char *`	Pointer to the null-terminated string to store. Must not be NULL or an empty string.

Ritorna:
void

Note:

- This function is not thread-safe; it modifies a global history buffer and index, so it should be called from a single task context or protected by a mutex if accessed concurrently. It is non-blocking and performs a simple memory copy up to the defined CLI buffer size. It

is not safe to call from an ISR because it does not implement atomic protection for the shared history indices. A common mistake is passing a pointer to a local stack variable that goes out of scope, or passing a NULL pointer, which the function handles by silently returning.

Uso:

- This function is used to populate the command history, typically after a user successfully executes a command via the CLI or an SSH session. It is usually paired with ca_cli_hist_get to retrieve previous commands when the user presses arrow keys. It is typically called after the command has been validated but before the command execution logic completes, ensuring the command is available for immediate recall. Developers should ensure that the string passed is persistent and not a temporary buffer that might be overwritten by other tasks.

Esempio:

```
void process_user_input(const char *input_buffer) {
    /* Validate the input pointer before processing */
    if (ca_valid_pointer((void *)input_buffer)) {
        /* Add the command to the CLI history for future recall */
        ca_cli_hist_add(input_buffer);

        /* Execute the command using the system CLI capture mechanism */
        /* ca_cli_exec_capture(input_buffer, 2000U); // Execute command with timeout */
    }
}
```

Q&A — fine-tuning review *4/4 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** When should I call ca_cli_hist_add in my CLI implementation?
A: You should call it immediately after the system receives a full command line from the user, but before the command is actually executed by the CLI engine. This ensures the command is stored in the history buffer for later recall via arrow keys.

Code example conf:0.90 **Q:** How do I correctly add a command string to the history buffer using caOS types?
A: You must pass a pointer to a null-terminated string. Example: { cstr cmd = "reboot"; ca_cli_hist_add(cmd); } Ensure the string is not a local stack variable that will go out of scope.

Parameters conf:1.00 **Q:** What are the constraints for the 'line' parameter in ca_cli_hist_add?
A: The 'line' parameter must be a pointer to a null-terminated string. It cannot be NULL or an empty string. If a NULL pointer is passed, the function will safely ignore the call without reporting an error.

Error/Edge case conf:1.00 **Q:** Can I call ca_cli_hist_add from an interrupt service routine (ISR)?
A: No, you should not call it from an ISR. The function is not thread-safe and performs memory operations on a shared global buffer without locking. It must be called from the context of the CLI task or a protected execution flow.

`ca_cli_hist_count`

Header: `caos/inc/cli.h:165`
Source: `caos/src/cli.c:1333:1333`
GUARD: `EN_CLI`

```
u8 ca_cli_hist_count(void)
```

Returns the current number of commands stored in the CLI history buffer.

Ritorna:
An unsigned 8-bit integer (u8) representing the total count of command strings currently available in the history buffer. The value ranges from 0 up to the maximum configured history size.

Note:

- This function is non-blocking and thread-safe as it simply returns a cached counter value. It is safe to call from an ISR, as it performs no complex operations or resource locking. The primary precondition is that the CLI module must be initialized via ca_cli_init before calling this function. A common mistake is assuming the returned value is an index; remember that this is a count, so the valid index range for ca_cli_hist_get is 0 to (ca_cli_hist_count() - 1).

Uso:

- This function is typically used to implement command navigation features, such as 'up' and 'down' arrow keys in a terminal or SSH session. It is used to check the boundaries of the history buffer before attempting to retrieve a command with ca_cli_hist_get. Developers use it to prevent out-of-bounds access when iterating through the history stack, ensuring that the navigation pointer stays within the valid range of stored commands.

Esempio:

```
/* Example: Navigating CLI history using the count */

void navigate_history(i8 *current_nav_index, i8 direction) {
    u8 total_hist = ca_cli_hist_count();

    if (total_hist == 0) return; // Nothing to navigate

    if (direction > 0) { // Moving to older commands
        if (*current_nav_index < (i8)(total_hist - 1)) {
            (*current_nav_index)++;
            const char *cmd = ca_cli_hist_get((u8)*current_nav_index);
            if (cmd) {
                ca_printf("Recalled: %s\n", cmd);
            }
        }
    } else if (direction < 0) { // Moving to newer commands
        if (*current_nav_index > 0) {
            (*current_nav_index)--;
            const char *cmd = ca_cli_hist_get((u8)*current_nav_index);
            if (cmd) {
                ca_printf("Recalled: %s\n", cmd);
            }
        }
    }
}
```

Q&A — fine-tuning review

3/3 pairs · gemini-3.1-flash-lite

Usage conf:1.00 **Q:** When should I use ca_cli_hist_count in my CLI implementation?

A: You should use this function when implementing command navigation features, such as handling 'up' and 'down' arrow keys. It allows you to check the boundaries of the history buffer to ensure that any subsequent calls to ca_cli_hist_get remain within the valid range of stored commands, preventing out-of-bounds access.

Code example conf:0.95 **Q:** How do I safely iterate through the CLI history using ca_cli_hist_count?
A: You can use the count to define the loop bounds. Example: u8 count = ca_cli_hist_count(); for(u8 i = 0; i < count; i++) { cstr cmd = ca_cli_hist_get(i); /* process cmd */ }

Return conf:1.00 **Q:** What does the return value of ca_cli_hist_count represent, and are there any failure states?
A: The function returns a u8 representing the total number of command strings currently in the history buffer, ranging from 0 to the maximum configured size. There are no failure states mentioned; however, the function requires that ca_cli_init has been called previously. It is non-blocking and safe to call from an ISR.

`ca_cli_hist_forget`

Header: `caos/inc/cli.h:182`
Source: `caos/src/cli.c:1351:1361`
GUARD: `EN_CLI`

```
void ca_cli_hist_forget(const char *prefix)
```

Wipes sensitive command history entries and the active CLI buffer to prevent unauthorized access.

Parametri:

Nome	Tipo	Descrizione
`prefix`	`const char *`	The string prefix used to identify sensitive commands in the history. Must not be NULL or empty.

Ritorna:
None (void function).

Note:

- This function is thread-safe because it wraps its internal operations in a critical section using ca_enter_critical and ca_exit_critical. It is designed to be called from task context, but because it uses critical sections, it is safe to call even if interrupts are active. The function iterates through the entire CLI history buffer and clears any entry starting with the provided prefix. A common beginner mistake is passing a NULL or empty string, which the function safely ignores, but this may lead to sensitive data remaining in the history buffer if the developer assumes the wipe was successful. Note that it also clears the active ISR line buffer if the CLI is currently idle, ensuring no residual data remains in RAM.

Uso:

- Use this function immediately after processing a command that contains sensitive information, such as passwords or cryptographic keys. It is typically paired with command execution logic where the input buffer is no longer needed. By calling this, you ensure that if a user presses the 'Up' arrow key on their terminal, the sensitive command is not retrieved from the history buffer. It is part of the security hardening process for CLI-based applications, usually invoked after the command has been parsed and the sensitive data has been moved to a secure, non-volatile or protected memory location.

Esempio:

```
/* Example: Securely handling a password input in a CLI command */
void handle_password_command(const char *input) {
    /* Assume 'input' contains a sensitive password */
```

```
    if (ca_strncmp(input, "login ", 6) == 0) {
        /* Process the password logic here */
        // ... perform authentication ...

        /* Wipe the history to prevent password leakage via arrow keys */
        ca_cli_hist_forget("login ");

        /* Clear the local buffer if it held the secret */
        ca_memzero((void *)input, ca_strlen(input));
    }
}
```

Q&A — fine-tuning review *4/4 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** When should I call ca_cli_hist_forget and what is its primary purpose?
A: You should call it immediately after processing a command containing sensitive information like passwords or cryptographic keys. Its purpose is to wipe those entries from the CLI history and the active buffer to prevent unauthorized access via terminal navigation (e.g., the 'Up' arrow key).

Code example conf:0.90 **Q:** Provide a minimal C example of how to use ca_cli_hist_forget in a caOS application.
A: void process_secure_cmd(cstr input) { /* ... process command ... */ ca_cli_hist_forget("PASS"); }

Parameters conf:1.00 **Q:** What are the requirements for the 'prefix' parameter in ca_cli_hist_forget?
A: The 'prefix' parameter must be a cstr (const char *) used to identify sensitive commands. It must not be NULL or empty, as the function will safely ignore such inputs, potentially leaving sensitive data in the history buffer.

Error/Edge case conf:1.00 **Q:** What happens if I pass an invalid prefix to ca_cli_hist_forget, and is it safe to call from an interrupt?
A: If you pass a NULL or empty string, the function safely ignores the request, which is a common mistake that may leave sensitive data in the buffer. It is safe to call from any context, including interrupts, because it uses ca_enter_critical and ca_exit_critical to ensure thread safety.

`ca_cli_hist_get`

Header: `caos/inc/cli.h:160`
Source: `caos/src/cli.c:1331:1331`
GUARD: `EN_CLI`

```
const char *ca_cli_hist_get(u8 pos)
```

Retrieves a command string from the shared CLI history buffer by its index.

Parametri:

Nome	Tipo	Descrizione
pos	u8	The index of the history entry to retrieve. 0 represents the most recent command, 1 the second most recent, and so on. Must be less than the total number of entries available.

Ritorna:
A pointer to a null-terminated string containing the command, or NULL if the index is out of bounds or the history is empty.

Note:

- This function is non-blocking and thread-safe, as it provides read-only access to a shared global history buffer. It is safe to call from an ISR, but note that it returns a pointer to internal memory; you should copy this string immediately if you intend to modify it or if the history buffer might be updated by another task. The most common beginner mistake is assuming the returned pointer remains valid indefinitely or attempting to modify the string directly, which would corrupt the shared history for all other CLI sessions.

Uso:

- This function is typically used when implementing command-line recall features, such as pressing the 'Up' arrow key in a terminal. It is usually paired with ca_cli_hist_count() to determine the valid range of indices before calling this function. Developers use it to populate a local command buffer (like a session's current line buffer) so the user can edit or re-execute a previously typed command without re-typing it.

Esempio:

```c
/* Example: Recall the most recent command from history */
#include "caos.h"

void recall_last_command(void) {
    /* Check if there is any history available */
    if (ca_cli_hist_count() > 0) {
        /* Retrieve the most recent command (index 0) */
        const char *last_cmd = ca_cli_hist_get(0);

        if (last_cmd != NULL) {
            /* Use ca_printf to display the recalled command to the user */
            ca_printf("Recalled: %s\n", last_cmd);
        }
    } else {
        ca_printf("No history available.\n");
    }
}
```

Q&A — fine-tuning review *4/4 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** When should I use ca_cli_hist_get in my CLI implementation?
A: You should use this function when implementing command-line recall features, such as handling 'Up' arrow key inputs in a terminal. It allows you to retrieve a previous command from the shared history buffer to populate a local session buffer, enabling users to edit or re-execute commands without re-typing them.

Code example conf:1.00 **Q:** How do I retrieve the most recent command using ca_cli_hist_get?
A: You can retrieve the most recent command by passing 0 as the index. Example: cstr cmd = ca_cli_hist_get(0); if (cmd != NULL) { /* copy cmd to local buffer immediately */ }

Parameters conf:1.00 **Q:** What does the u8 pos parameter represent and what are its constraints?
A: The u8 pos parameter is the index of the history entry. 0 is the most recent command, 1 is the second most recent, and so on. The value must be less than the total number of entries available; otherwise, the function will return NULL.

Return conf:1.00 **Q:** What does the return value of ca_cli_hist_get indicate, and why might it return NULL?
A: The function returns a pointer to a null-terminated string containing the command. It returns NULL if the provided index is out of bounds or if the history buffer is empty.

ca_cli_init

Header: caos/inc/cli.h:76
Source: caos/src/cli.c:975:1006
GUARD: EN_CLI

```
void ca_cli_init(u16 buf_size)
```

Initializes the Command Line Interface (CLI) internal buffers and queue structures.

Parametri:

Nome	Tipo	Descrizione
buf_size	u16	The desired size in bytes for the CLI buffer. Values are clamped to a multiple of DEFAULT_MSG_SIZE and capped at CLI_BUFFER_MAX. Passing 0 disables the CLI.

Ritorna:
void. The function does not return a status code; it initializes internal static structures and sets the CLI state to disabled.

Note:

- This function is non-blocking and performs static memory allocation for the CLI queue. It is not thread-safe and must be called during the system initialization phase, typically before the RTOS scheduler starts. It is strictly forbidden to call this from an Interrupt Service Routine (ISR) as it performs internal queue setup that is not designed for atomic context. A common beginner mistake is to assume the CLI is ready immediately after this call; however, this function only prepares the memory structures. You must follow up with ca_cli_set_sender and ca_cli_create_thread to actually start the CLI task. Additionally, if you intend to register custom commands, ensure they are registered after this initialization, as the CLI subsystem must be fully prepared to accept new command nodes.

Uso:

- This function is the mandatory first step in the CLI lifecycle. It is typically used in the main initialization sequence of your application, often wrapped in an EVAL_CLI macro to ensure it only runs if the CLI module is enabled in the build configuration. It is always paired with ca_cli_create_thread, which spawns the actual RTOS task that processes user commands. Without calling this function first, the subsequent thread creation will fail or operate on uninitialized memory, leading to system instability. It is also the prerequisite for any command registration or hook configuration.

Esempio:

```
/* Initialize the CLI system during startup */
#define CLI_BUFFER_SIZE 2048

void ca_os_main(void) {
    /* Prepare the CLI memory and queue structures */
    ca_cli_init(CLI_BUFFER_SIZE);

    /* Configure where the CLI output should be sent */
    ca_cli_set_sender(STDOUT);

    /* Finally, spawn the RTOS thread to handle CLI commands */
    ca_cli_create_thread();

```

```
    /* Register custom commands after initialization */
    /* ca_cli_register(&s_cli_node); */
}
```

Q&A — fine-tuning review *6/6 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I call ca_cli_init() in my caOS application?
A: You should call ca_cli_init() during the initialization phase of your caOS application, typically before starting any tasks or enabling the CLI thread. It is used to set up the command line interface buffer for handling user commands. The function is non-blocking and must not be called from an ISR.

Code example conf:0.90 **Q:** Can you show a minimal example of how to use ca_cli_init() with caOS types?
A:

```
u16 buffer_size = 2048;
ca_cli_init(buffer_size);
```

Parameters conf:0.95 **Q:** What does the buf_size parameter in ca_cli_init() control and what are valid values?
A: The buf_size parameter sets the size of the CLI buffer in bytes. Valid values are from 1 to CLI_BUFFER_MAX (e.g., 8192). If buf_size is 0, the CLI is disabled and no buffer is allocated. Values smaller than DEFAULT_MSG_SIZE (e.g., 64) after alignment are set to DEFAULT_MSG_SIZE.

Return conf:0.90 **Q:** Does ca_cli_init() return any value, and what does it mean?
A: The function does not return any value. It is void. It cannot fail in a traditional sense, but it may disable the CLI if buf_size is 0, or adjust the buffer size if it's too small after alignment.

Error/Edge case conf:0.85 **Q:** What are common mistakes or edge cases when using ca_cli_init()?
A: Common mistakes include calling ca_cli_init() from an ISR, which is not allowed. Also, passing a buf_size of 0 disables the CLI, which may be unintentional. If buf_size is too small after alignment, it will be set to DEFAULT_MSG_SIZE. The function does not check for memory allocation failures, as it only initializes the buffer structure.

Behavior conf:0.90 **Q:** Is ca_cli_init() blocking or non-blocking, and is it safe to call from an ISR or in a multi-threaded context?
A: ca_cli_init() is non-blocking. It is not safe to call from an ISR, as it is explicitly stated that the function must not be called from an ISR. It is also not thread-safe, so concurrent calls from multiple threads should be avoided.

`ca_cli_is_enabled`

Header: `caos/inc/cli.h:94`
Source: `caos/src/cli.c:1017:1019`
GUARD: `EN_CLI`

```
bool ca_cli_is_enabled(void)
```

Checks if the Command Line Interface (CLI) system is currently active and ready to process commands.

Ritorna:
Returns 'true' if the CLI is enabled and ready to receive input, or 'false' if it is disabled or not yet initialized.

Note:

- This function is non-blocking and thread-safe because it performs a simple read of a global boolean flag. It is safe to call from both main-line code and Interrupt Service Routines (ISRs) because it does not involve complex synchronization primitives like mutexes or semaphores. A common mistake is assuming that 'true' means the CLI is currently idle; it only indicates that the system is enabled. You must ensure that the CLI module has been properly initialized via ca_cli_init before relying on this status, otherwise, it may return a stale or incorrect value.

Uso:

- This function is typically used as a guard clause before attempting to send data to the CLI or before performing heavy operations related to the command parser. It is often paired with initialization functions like ca_cli_init that set the global state and status reporting functions like ca_cli_stats. By checking this status, you prevent the system from attempting to process commands or log output when the CLI is intentionally disabled to save resources or during system shutdown sequences.

Esempio:

```
if (ca_cli_is_enabled()) {
    // The CLI is active, so it is safe to proceed with logging or status checks
    u32 queued, buffered, dropped;
    ca_cli_stats(&queued, &buffered, &dropped);
    // Proceed to display stats to the user
} else {
    // CLI is disabled, skip operations to avoid errors or unnecessary
   processing
}
```

Q&A — fine-tuning review *3/3 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I call ca_cli_is_enabled() in my embedded application?
A: You should call ca_cli_is_enabled() to check if the CLI (Command Line Interface) is currently enabled before attempting to send commands or interact with the CLI system. This is useful for conditional logic where you want to avoid sending commands when the CLI is disabled, or to provide feedback to users about CLI availability. It's particularly helpful in ISR contexts where you want to ensure CLI operations are safe to perform.

Code example conf:0.90 **Q:** Can you show a minimal C code example using ca_cli_is_enabled() with caOS types?
A: bool enabled = ca_cli_is_enabled(); if (enabled) { // CLI is enabled, proceed with CLI operations // Example: send a command or log status } else { // CLI is disabled, handle accordingly }

Return conf:0.90 **Q:** What does ca_cli_is_enabled() return and what causes it to return false?
A: The function returns true if the CLI is enabled, and false if it is disabled. It cannot fail or return errors because it simply reads a global variable. The return value of false indicates that the CLI subsystem has been disabled, likely through a configuration or initialization step elsewhere in the code. The variable g_enabled is managed atomically elsewhere, so this function is thread-safe and does not introduce race conditions.

`ca_cli_register`

Header: `caos/inc/cli.h:70`
Source: `caos/src/cli.c:968:971`
GUARD: `EN_CLI`

```
void ca_cli_register(ca_cli_node_t *node)
```

Adds a command-line interface (CLI) node to the global linked list of available system commands.

Parametri:

Nome	Tipo	Descrizione
node	ca_cli_node_t *	Pointer to a static or persistent CLI node structure containing command definitions. Must not be NULL.

Ritorna:
void

Note:

- This function is non-blocking and performs a simple pointer assignment to link the new node into the command chain. It is NOT thread-safe; if multiple threads attempt to register nodes simultaneously, the linked list structure could become corrupted. It is NOT safe to call from an ISR because it modifies a global linked list that the CLI parser might be traversing at the same time. The most common beginner mistake is passing a pointer to a local (stack-allocated) variable; since the CLI system stores this pointer for the lifetime of the application, the stack memory will be overwritten once the function returns, leading to a system crash or garbage commands when the CLI is accessed. Always ensure the node structure is declared as 'static' or in global scope.

Uso:

- This function is used during the initialization phase of drivers or services to expose their internal status or control functions to the system CLI. It is typically paired with a static boolean flag to ensure the node is registered exactly once, even if the initialization function is called multiple times. You should use this after the hardware or service has been successfully initialized, as the CLI commands often rely on the underlying peripheral being ready. It is the standard way to make your module 'debuggable' via the serial console without needing a debugger attached.

Esempio:

```
static ca_cli_node_t my_module_cli_node = { .name = "my_cmd", .help = "Prints
    status" };

int my_module_init(void) {
    // 1. Perform hardware initialization first
    // Call hardware setup function here

    // 2. Register the CLI node only once to prevent list corruption
    static bool s_registered = false;
    if (!s_registered) {
        ca_cli_register(&my_module_cli_node);
        s_registered = true;
    }
    return 0;
}
```

Q&A — fine-tuning review *3/3 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I call ca_cli_register() and what is its purpose in a caOS project?
A: You should call ca_cli_register() to add CLI commands for debugging and configuration purposes. It is used to register a CLI node that contains command definitions for a specific driver or module. The function is typically called during system initialization or when a driver is initialized, and it allows users to interact with the system through

a command-line interface. It is not intended for use in interrupt service routines (ISR) and must be called from a main task.

Code example conf:0.85 **Q:** Can you provide a minimal C example showing how to use ca_cli_register() with caOS types?
A: ca_cli_node_t node = { .name = "adc", .help = "ADC driver commands", .cmd = NULL, .next = NULL }; ca_cli_register(&node);

Parameters conf:0.90 **Q:** What is the significance of the node parameter in ca_cli_register(), and what happens if it is NULL?
A: The node parameter is a pointer to a CLI node structure that defines the commands available for a specific driver. If the node is NULL, the function does nothing and does not cause a crash. It is a simple registration function that adds the node to a global linked list, so the node must remain valid for the entire duration of the program execution.

`ca_cli_rx_byte`

Header: `caos/inc/cli.h:206`
Source: `caos/src/cli.c:1372:1472`
GUARD: `EN_CLI`

```
1 void ca_cli_rx_byte(u32 ch)
```

Processes a single byte of input for the CLI, handling line editing, history, and VT100 escape sequences.

Parametri:

Nome	Tipo	Descrizione
`ch`	`u32`	The raw byte received from a communication peripheral (e.g., UART or USB CDC). Only the lower 8 bits are used.

Ritorna:
This function returns void. It performs internal state updates and triggers side effects like echoing characters or submitting commands.

Note:

- This function is the core of the CLI input engine. It is NOT thread-safe and must be called from the context where the byte is received (often an ISR or a dedicated communication task). It handles complex logic like backspace, arrow keys for history, and command submission (CR/LF). A common mistake is calling this from multiple threads simultaneously without external synchronization, which will corrupt the internal line buffer. It assumes the CLI has been initialized via ca_cli_init() and is enabled; if not, the byte is silently ignored. Because it performs string manipulation and triggers callbacks, ensure the stack size of the calling task is sufficient.

Uso:

- This function is typically used as a callback passed to low-level drivers (like ca_lpuart_init or USB CDC handlers). When a byte arrives at the hardware level, the driver calls ca_cli_rx_byte() to pass the data into the CLI subsystem. It is the bridge between raw hardware input and the command parser. You should never call this manually unless you are implementing a custom input stream or a virtual terminal emulator. It is usually paired with ca_cli_init() during system startup and works in conjunction with the CLI thread created by ca_cli_create_thread().

Esempio:

```c
/* Example: Integrating a UART byte into the CLI */
void my_uart_rx_callback(u8 byte) {
    /* Pass the received byte directly to the CLI engine */
    ca_cli_rx_byte((u32)byte);
}

void setup_cli_interface(void) {
    /* Initialize the CLI system first */
    ca_cli_init();

    /* Register the CLI thread to handle command execution */
    ca_cli_create_thread();

    /* Initialize UART with the callback function */
    /* ca_lpuart_init(baud, callback, wake, gpio_alt) */
    ca_lpuart_init(115200, my_uart_rx_callback, true, false);
}
```

Q&A — fine-tuning review *5/5 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I call ca_cli_rx_byte() in my embedded application?
A: You should call ca_cli_rx_byte() whenever a byte is received from a UART interface that is used for CLI input. It is designed to be invoked from an ISR (Interrupt Service Routine) when data arrives on a UART channel, allowing the CLI to process user input including special control characters like backspace, enter, and arrow keys.

Code example conf:0.90 **Q:** Can you show a minimal example of how to use ca_cli_rx_byte() in a UART ISR?
A: void UART4_IRQHandler(void) { if (USART4->SR & USART_SR_RXNE) { u8 byte = (u8)(USART4->DR & 0xFF); ca_cli_rx_byte((u32)byte); } }

Parameters conf:0.90 **Q:** What does the 'ch' parameter in ca_cli_rx_byte() represent, and what are valid values?
A: The 'ch' parameter represents a byte received from a UART interface, typically ranging from 0 to 255. Only the lower 8 bits are considered. Values above 255 may cause unpredictable behavior. Valid inputs include regular ASCII characters, control characters like backspace (0x08), carriage return (0x0D), and escape sequences such as arrow keys.

Error/Edge case conf:0.85 **Q:** What are common mistakes when using ca_cli_rx_byte()?
A: Common mistakes include calling ca_cli_rx_byte() without initializing the CLI buffer, passing invalid values for 'ch' (e.g., values > 255), or invoking the function when CLI is disabled (g_enabled != true). Additionally, calling it from a non-ISR context or from a thread that is not designed to handle CLI input can lead to incorrect behavior.

Behavior conf:0.90 **Q:** Is ca_cli_rx_byte() blocking or non-blocking, and is it safe to call from an ISR?
A: ca_cli_rx_byte() is non-blocking in terms of thread execution, but it performs processing inline during the ISR. It is designed to be called from an ISR and is not thread-safe because it modifies global internal variables. It must be called only when CLI is enabled (g_enabled=true) and should not perform time-consuming operations like printf inside the ISR.

`ca_cli_set_hook`

Header: `caos/inc/cli.h:215`
Source: `caos/src/cli.c:962:964`
GUARD: `EN_CLI`

```
void ca_cli_set_hook(ca_cli_hook_t hook)
```

Registers a custom callback function to be executed by the Command Line Interface (CLI) system.

Parametri:

Nome	Tipo	Descrizione
hook	ca_cli_hook_t	A function pointer to the custom routine you want the CLI to trigger. Passing NULL will effectively disable the current hook.

Ritorna:
void

Note:

- This function is non-blocking and executes instantly as it simply updates a global pointer variable. It is thread-safe in the sense that it performs an atomic pointer assignment, but you must ensure that the function pointed to by 'hook' is re-entrant if it accesses shared resources. It is safe to call from an ISR, though this is rarely necessary for CLI configuration. The most common beginner mistake is passing a pointer to a local function that goes out of scope or failing to verify that the hook function handles potential NULL inputs if the CLI logic expects a valid pointer.

Uso:

- This function is typically used during the system initialization phase, right after the CLI module has been started but before the main application loop begins. It is used to inject custom logic into the CLI processing pipeline, such as logging commands to an external storage or triggering specific system states based on user input. It is often paired with 'ca_cli_get_hook' if you need to verify which hook is currently active or to chain multiple hooks together by storing the previous one before setting a new one.

Esempio:

```
/* Define the custom hook function */
void my_custom_cli_hook(void) {
    /* Custom logic to execute when the CLI triggers */
}

void app_init(void) {
    /* Initialize the CLI system first */
    ca_cli_init();

    /* Register the hook during system startup */
    ca_cli_set_hook(my_custom_cli_hook);

    /* Verify the hook was set correctly */
    if (ca_cli_get_hook() == NULL) {
        /* Handle error: hook registration failed */
    }
}
```

Q&A — fine-tuning review *3/3 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I call ca_cli_set_hook and why would I want to use a custom CLI hook?
A: You should call ca_cli_set_hook when you want to handle custom CLI commands in your caOS application. This function allows you to register a callback that will be invoked whenever a CLI command is received. It's useful for extending the default CLI functionality with application-specific commands. The hook can be set at any time, even before commands are received, but if not set, custom commands will not be processed.

Code example conf:0.90 **Q:** Can you show a minimal example of how to use ca_cli_set_hook with a custom CLI handler?
A: void my_cli_hook(cstr argv[], u32 argc) { // Handle custom CLI command } void setup(void) { ca_cli_set_hook(my_cli_hook); }

Parameters conf:0.90 **Q:** What does the ca_cli_hook_t parameter in ca_cli_set_hook do, and what happens if I pass NULL?
A: The ca_cli_hook_t parameter is a function pointer that defines the callback to be executed when a CLI command is received. If you pass NULL, the hook is disabled, meaning no custom CLI command handling will occur. Passing NULL is a valid and safe operation, and it will not cause any errors or failures in the function.

`ca_cli_set_secret_prefix`

Header: `caos/inc/cli.h:191`
Source: `caos/src/cli.c:1249:1253`
GUARD: `EN_CLI`

```
void ca_cli_set_secret_prefix(const char *prefix)
```

Sets a secret prefix string that the CLI will ignore when saving commands to history.

Parametri:

Nome	Tipo	Descrizione
`prefix`	`const char *`	The string literal or buffer to be used as a secret prefix. If NULL, the secret prefix feature is disabled.

Ritorna:
void

Note:

- This function is not thread-safe and should be called during the initialization phase of your CLI task before the CLI thread starts processing user input. It is not intended to be called from an ISR. The function stores a pointer to the provided string; therefore, you must ensure the memory containing the prefix remains valid and constant for the entire duration of the application. A common mistake is passing a pointer to a local stack variable that goes out of scope, which will cause the CLI to compare incoming commands against garbage memory.

Uso:

- Use this function when you want to prevent sensitive inputs, such as passwords or authentication tokens, from appearing in the CLI command history. It is typically called once during the system setup sequence, immediately after ca_cli_register and before the CLI thread begins execution. By setting a prefix, any command starting with that specific string will be treated as 'secret' by the internal history management logic, ensuring it is never logged to the command history buffer.

Esempio:

```
/* Define the CLI structure */
static struct ca_cli_s s_my_cli;

void app_cli_setup(void) {
    /* Initialize the CLI system */
    ca_cli_init();

```

```
    /* Register the CLI interface */
    ca_cli_register(&s_my_cli);

    /* Set a secret prefix so that commands like 'login password123'
       are not saved in the history buffer */
    ca_cli_set_secret_prefix("login ");

    /* Start the CLI thread to begin processing input */
    ca_cli_create_thread();
}
```

Q&A — fine-tuning review *3/3 pairs · gemini-3.1-flash-lite*

Usage conf:1.00 **Q:** When should I call ca_cli_set_secret_prefix and what is its primary purpose?
A: You should call this function during the initialization phase of your CLI task, specifically after ca_cli_register and before the CLI thread starts processing input. Its purpose is to prevent sensitive inputs, such as passwords or authentication tokens, from being saved to the CLI command history buffer.

Code example conf:0.95 **Q:** How do I correctly implement ca_cli_set_secret_prefix in my application?
A: You must ensure the prefix string is stored in memory that remains valid for the entire application duration, such as a global constant. Example: static const cstr secret = "SECURE:"; void app_init(void) { ca_cli_set_secret_prefix(secret); }

Parameters conf:1.00 **Q:** What happens if I pass a NULL value to the prefix parameter, and are there any restrictions on the memory I provide?
A: Passing NULL to the prefix parameter disables the secret prefix feature. You must not pass a pointer to a local stack variable, as the function stores the pointer and expects the memory to remain valid and constant for the entire duration of the application; otherwise, the CLI will compare commands against garbage memory.

`ca_cli_set_sender`

Header: `caos/inc/cli.h:88`
Source: `caos/src/cli.c:1008:1015`
GUARD: `EN_CLI`

```
void ca_cli_set_sender(sender out)
```

Configures the output destination (sender) for the Command Line Interface (CLI) system.

Parametri:

Nome	Tipo	Descrizione
`out`	`sender`	A pointer or identifier representing the output stream (e.g., STDOUT). Passing a valid pointer enables the CLI, while passing NULL disables it.

Ritorna:
This function returns void and does not provide a status code, so it assumes the provided sender is valid.

Note:

- This function is non-blocking and performs a simple assignment to global variables. It is not thread-safe in a multi-threaded environment if called while the CLI thread is actively processing, so it should be used during the initialization phase. It is not intended

to be called from an ISR. A common beginner mistake is calling this function before ca_cli_init(), which results in the configuration being ignored or causing a system fault because the internal CLI structures are not yet ready. Always ensure the underlying communication peripheral is initialized before assigning it as the sender.

Uso:

- This function is used during the system startup phase to link the CLI engine to a physical communication channel. It is typically called immediately after ca_cli_init() and before ca_cli_create_thread(). By setting the sender, you define where the CLI output (like command prompts and logs) will appear. It is standard practice to pair this with ca_cli_init() and ca_cli_create_thread() to ensure the CLI is fully operational before the scheduler starts.

Esempio:

```
/* Initialize the CLI system with a stack size of 2048 bytes */
ca_cli_init(2048);

/* Set the output destination to the standard output (STDOUT) */
ca_cli_set_sender(STDOUT);

/* Now that the sender is configured, start the CLI thread */
ca_cli_create_thread();

/* Register the CLI node to handle commands */
ca_cli_register(&s_cli);

/* To disable the CLI output later, pass NULL to the sender */
ca_cli_set_sender(NULL);
```

Q&A — fine-tuning review *3/3 pairs · qwen3-coder:latest*

Usage conf:0.95 **Q:** When should I call ca_cli_set_sender() and why would I want to disable the CLI output?
A: You should call ca_cli_set_sender() when you want to control where CLI output is sent, such as to a serial terminal or a custom logging function. If you pass NULL as the sender, you disable the CLI output, which can be useful if you want to conserve resources or if you're handling CLI commands through a different mechanism. The function is non-blocking and can be called from any context, including ISRs, but it's not thread-safe.

Code example conf:0.90 **Q:** Can you show a minimal example of how to use ca_cli_set_sender() with a custom output function?
A: void serial_output(cstr msg) { // Simulate sending message to serial port u32* uart_dr = (u32*)0x40013800; // UART1_DR register *uart_dr = (u32)msg; }
void example() { ca_cli_set_sender(serial_output); }
